If the crystal is shorted, this circuit should still oscillate. This gives an easy way of adjusting the tank; it is even better to temporarily replace the crystal with a small-value (tens of ohms) resistor to simulate its *equivalent series resistance* (ESR), and adjust  $L$  until the circuit oscillates close to the wanted frequency. Then restore the crystal and set the quiescent current. If a lot of these oscillators were built, it would sometimes be necessary to adjust the current individually due to the different equivalent series resistance of individual crystals. One variant of this circuit has the emitter connected directly to the  $C1/C2$  junction, while the crystal is a decoupler for the transistor base (the existing capacitor and ferrite bead not being used). This works, but with a greater risk of parasitic oscillation.

We commonly want to trim a crystal oscillator's frequency. While off-tuning the tank a little will pull the frequency slightly, too much detuning spoils the mode control and can stop oscillation (or worse, make the circuit unreliable). The answer to this is to add a trimmer capacitor, which will act as part of the equivalent series tuned circuit, in series with the crystal. This will shift the frequency in one way only, so the crystal frequency must be respecified to allow the frequency to be varying around the required value. It is common to specify a crystal's frequency with a standard load (30 pF is commonly specified), so that the manufacturer grinds the crystal such that the series resonance

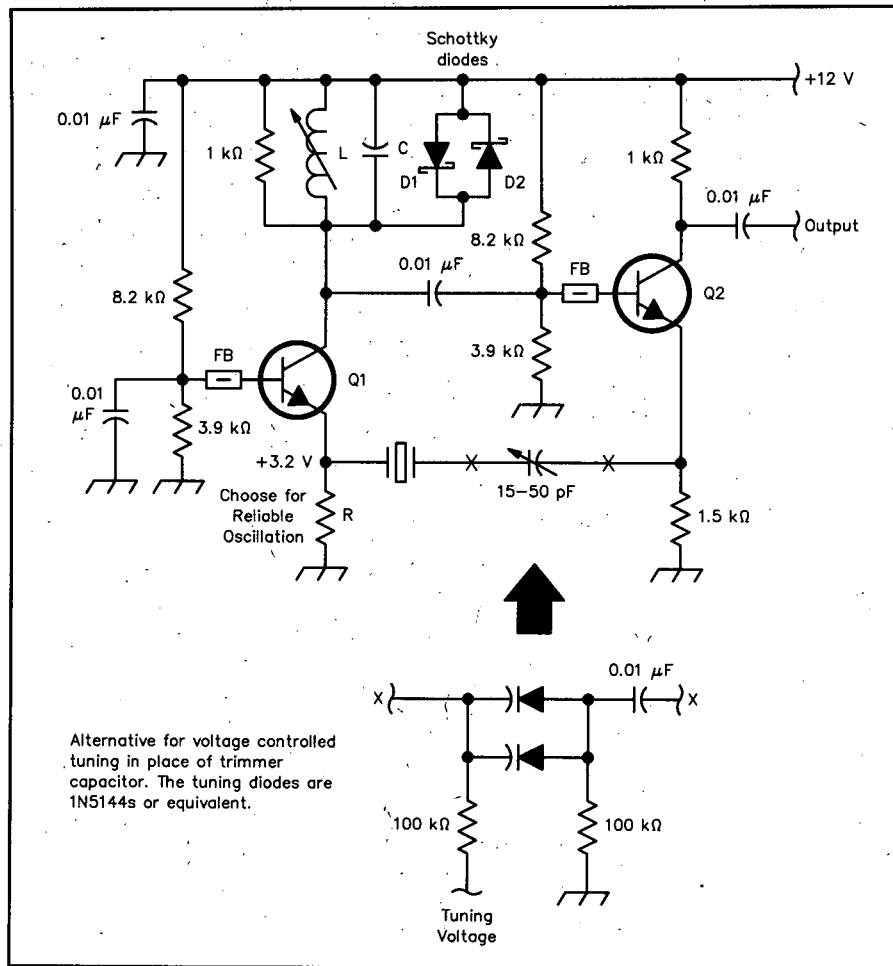

Fig 14.23 — A Butler crystal oscillator.

of the specified mode is accurate when measured with a capacitor of this value in series. A 15- to 50-pF trimmer can be used in series with the crystal to give fine frequency adjustment. Too little capacitance can stop oscillation or prevent reliable starting. The Q of crystals is so high that marginal oscillators can take several seconds to start!

This circuit can be improved by reducing the crystal's driving impedance with an emitter follower as in Fig 14.23. This is the *Butler* oscillator. Again the tank controls the mode to either force the wanted overtone or protect the fundamental mode. The tank need not be tapped because Q2 provides current gain, although the circuit is sometimes seen with  $C$  split, driving Q2 from a tap. The position between the emitters offers a good, low-impedance environment to keep the crystal's in-circuit Q high.  $R$ , in the emitter of Q1, is again selected to give reliable oscillation. The circuit has been shown with a capacitive load for the crystal, to suit a unit specified for a 30-pF load. An alternative circuit to give electrical fine tuning is also shown. The

diodes across the tank act as limiters to stabilize the operating amplitude and limit the power dissipated in the crystal by clipping the drive voltage to Q2. The tank should be adjusted to peak at the operating frequency, not used to trim the frequency. The capacitance in series with the crystal is the proper frequency trimmer.

The Butler circuit works well, and has been used in critical applications to 140 MHz (seventh-overtone crystal, 2N5179 transistor). Although the component count is high, the extra parts are cheap ones. Increasing the capacitance in series with the crystal reduces the oscillation frequency but has a progressively diminishing effect. Decreasing the capacitance pulls the frequency higher, to a point at which oscillation stops; before this point is reached, start-up will become unreliable. The possible amount of adjustment, called *pulling range*, depends on the crystal; it can range from less than ten to several hundred parts per million. Overtone crystals have much less pulling range than fundamental crystals on the same frequency; the reduction in pulling is roughly proportional to the square

of the overtone number.

### Low-Noise Crystal Oscillators

Fig 14.24A shows a crystal operating in its series mode in a series-tuned Colpitts circuit. Because it does not include an LC tank to prevent operation on unwanted modes, this circuit is intended for fundamental mode operation only and relies on that mode being the most active. If the crystal is ordered for 30-pF loading, the frequency trimming

capacitor can be adjusted to compensate for the loading of the capacitive divider of the Colpitts circuit. An unloaded crystal without a trimmer would operate slightly off the exact series resonant frequency in order to create an inductive impedance to resonate with the divider capacitors. Ulrich Rohde, KA2WEU, in Fig 4-47 of his book *Digital PLL Frequency Synthesizers — Theory and Design*, published an elegant alternative method of extracting

an output signal from this type of circuit, shown in Fig 14.24B. This taps off a signal from the current in the crystal itself. This can be thought of as using the crystal as a band-pass filter for the oscillator output. The RF choke in the emitter keeps the emitter bias resistor from loading the tank and degrading the Q. In this case (3-MHz operation), it has been chosen to resonate close to 3 MHz with the parallel capacitor (510 pF) as a means of forcing operation on the

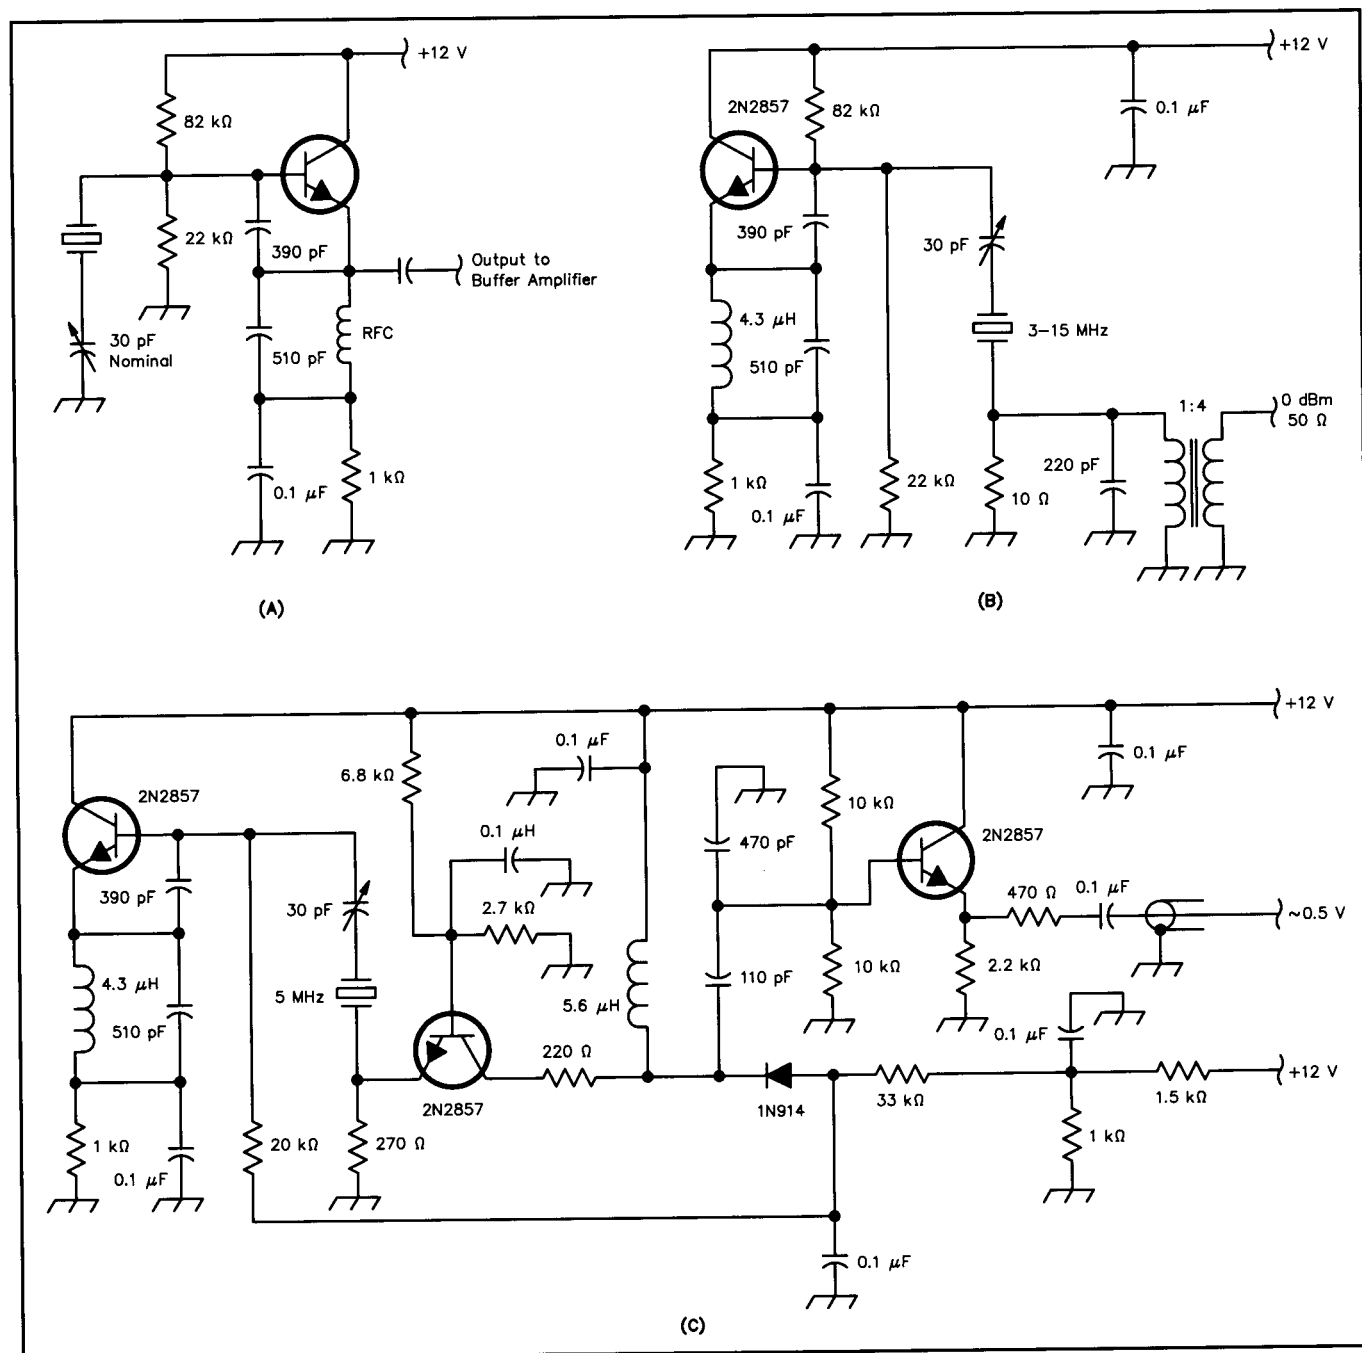

Fig 14.24 — The crystal in the series-tuned Colpitts oscillator at A operates in its series-resonant mode. B shows KA2WEU's low-noise version, which uses the crystal as a filter and features high harmonic suppression. The circuit at C builds on the B version by adding a common-base output amplifier and ALC loop.

wanted mode. The 10- $\Omega$  resistor and the transformed load impedance will reduce the in-circuit Q of the crystal, so a further development substituted a common base amplifier for the resistor and transformer. This is shown in Fig 14.24C. The common-base amplifier is run at a large quiescent current to give a very low input impedance, its collector is tuned to give an output with low harmonic content, and an emitter follower is used to buffer this from the load. This oscillator sports a simple ALC system, in which the amplified and rectified signal is used to reduce the bias voltage on the oscillator transistor's base. This circuit is described as achieving a phase noise level of 168 dBc/Hz a few kilohertz out from the carrier. This may seem far beyond what may ever be needed, but frequency multiplication to high frequencies, whether by classic multipliers or by frequency synthesizers, multiplies the deviation of any FM/PM sidebands as well as the carrier frequency. This means that phase noise worsens by 20 dB for each tenfold multiplication of frequency. A clean crystal oscillator and a multiplier chain is still the best way of generating clean microwave signals for use with narrow-band modulation schemes.

It has already been mentioned that overtone crystals are much harder to pull than fundamental ones. This is another way of saying that overtone crystals are less influenced by their surrounding circuit, which is helpful in a frequency standard oscillator like this one. Even though 5 MHz is in the main range of fundamental-mode crystals and this circuit will work well with them, an overtone crystal has been used. To further help stability, the power dissipated in the crystal is kept to about 50  $\mu$ W. The common-base stage is effectively driven from a higher impedance than its own input impedance, under which conditions it gives a very low noise figure.

## VXOs

Some crystal oscillators have frequency trimmers. If the trimmer is replaced by a variable capacitor as a front-panel control, we have a *variable crystal oscillator* (VXO): a crystal-based VFO with a narrow tuning range, but good stability and noise performance. VXOs are often used in small, simple QRP transmitters to tune a few kilohertz around common calling frequencies. Artful constructors, using optimized circuits and components, have achieved 1000-ppm tuning ranges. Poor-quality "soft" crystals are more pullable than high-Q ones. Overtone crystals are

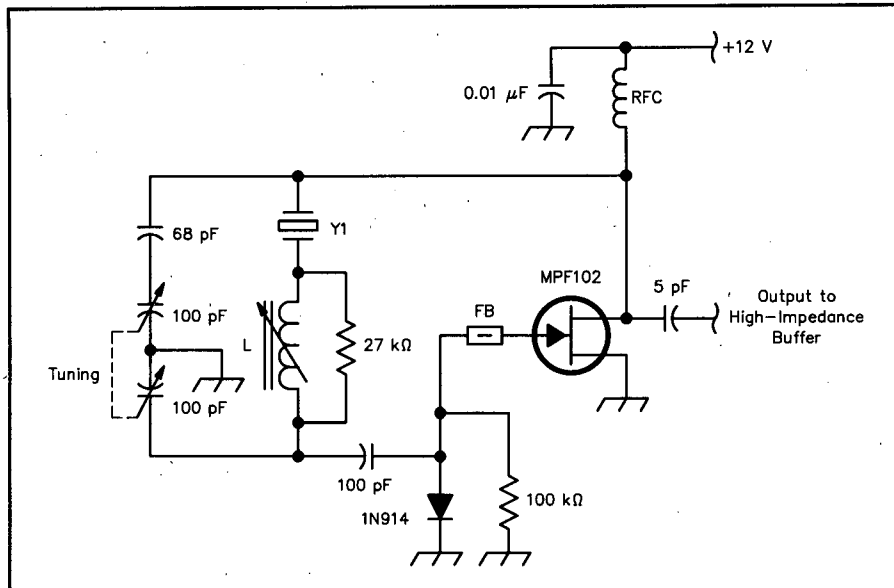

Fig 14.25 — A wide-range variable-crystal oscillator (VXO).

not suited to VXOs. For frequencies beyond the usual limit for fundamental mode crystals, use a fundamental unit and frequency multipliers.

ICOM and Mizuho made some 2 m SSB transceivers based on multiplied VXO local oscillators. This system is simple and can yield better performance than many expensive synthesized radios. SSB filters are available at 9 or 10.7 MHz, to yield sufficient image rejection with a single conversion. Choice of VXO frequency depends on whether the LO is to be above or below signal frequency and how much multiplication can be tolerated. Below 8 MHz multiplier filtering is difficult. Above 15 MHz, the tuning range per crystal narrows. A 50-200 kHz range per crystal should work with a modern front-end design feeding a good 9 MHz IF, for a constant quality 2 m SSB Receiver.

The circuit in Fig 14.25 is a JFET VXO from Wes Hayward, W7ZOI, and Doug DeMaw, W1FB, optimized for wide-range pulling. Published in *Solid State Design for the Radio Amateur*, many have been built and its ability to pull crystals as far as possible has been proven. Ulrich Rohde, KA2WEU, has shown that the diode arrangement as used here to make signal-dependent negative bias for the gate confers a phase-noise disadvantage, but oscillators like this that pull crystals as far as possible need any available means to stabilize their amplitude and aid start-up. In this case, the noise penalty is worth paying. This circuit can achieve a 2000-ppm tuning range with amenable crystals. If you have some overtone crystals in your junk box whose fundamental frequency is close to the wanted value, they are worth trying.

This sort of circuit doesn't necessarily stop pulling at the extremes of the possible tuning range, sometimes the range is set by the onset of undesirable behavior such as jumping mode or simply stopping oscillating. L was a 16- $\mu$ H slug-tuned inductor for 10-MHz operation. It is important to minimize the stray and interwinding capacitance of L as this dilutes the range of impedance that is presented to the crystal.

One trick that can be used to aid the pulling range of oscillators is to tune out the C0 of the equivalent circuit with an added inductor. Fig 14.26 shows how. L is chosen to resonate with C0 for the individual crystal, turning it into a high impedance parallel-tuned circuit. The Q of this circuit is orders of magnitude less than the Q of the true series resonance of the crystal, so its tuning is much broader. The value of C0 is usually just a few picofarads, so L has to be a fairly large value considering the frequency it is resonated at. This means that L has to have low stray capacitance or else it will self-resonate at a lower frequency. The tolerance on C0 and the variations of the stray C of the inductor means that individual adjustment is needed. This technique can also work wonders in crystal ladder filters.

## Logic-Gate Crystal Oscillators

A 180° phase-shift network and an inverting amplifier can be used to make an oscillator. A single stage RC low-pass network cannot introduce more than 90° of phase shift and only approaches that as the signal becomes infinitely attenuated. Two stages can only approach 180° and

then have immense attenuation. It takes three stages to give  $180^\circ$  and not destroy the loop gain. Fig 14.27A shows the basic form of the *phase shift* oscillator; Fig 14.27B is an example the phase-shift oscillator as commonly used in commercial Amateur Radio transceivers as an audio sidetone oscillator. The frequency-determining network of an RC oscillator has a Q of less than one, which is a massive disadvantage compared to an LC or crystal resonator. The Pierce crystal oscillator is a converted phase shift oscillator with the crystal taking the place of one series resistor, Fig 14.27C. At the exact series resonance, the crystal looks resistive, so by suitable choice of the capacitor values, the circuit can be made to oscillate. The crystal has a far steeper phase/frequency relationship than the rest of the

network, so the crystal is the dominant controller of the frequency. The Pierce circuit is rarely seen in this full form, instead, a cut-down version has become the most common circuit for crystal clock oscillators for digital systems. Fig 14.27D shows this minimalist Pierce, using a logic inverter as the amplifier.  $R_{bias}$  provides dc negative feedback to bias the gate into its linear region. At first sight it appears that this arrangement should not oscillate, but the crystal is a resonator (not a simple resistor) and oscillation occurs off-set from the series resonance, where the crystal appears inductive, which makes up the missing phase shift. This is one circuit which *cannot* oscillate exactly on the crystal's series resonance. This circuit is included

in many microprocessors and other digital ICs that need a clock, it is also the usual circuit inside the miniature clock oscillator cans. It is not a very reliable circuit, as operation is dependent on the crystal's equivalent series resistance and the output impedance of the logic gate, occasionally the logic device or the crystal needs to be changed to start oscillation, sometimes playing with the capacitor values is necessary. It is doubtful whether these circuits are ever designed, values (the two capacitors) seem to be arrived at by experiment. Once going, the circuit is reliable, but its drift and noise are moderate, not good — acceptable for a clock oscillator. The commercial packaged oscillators are the same, but the manufacturers have handled the

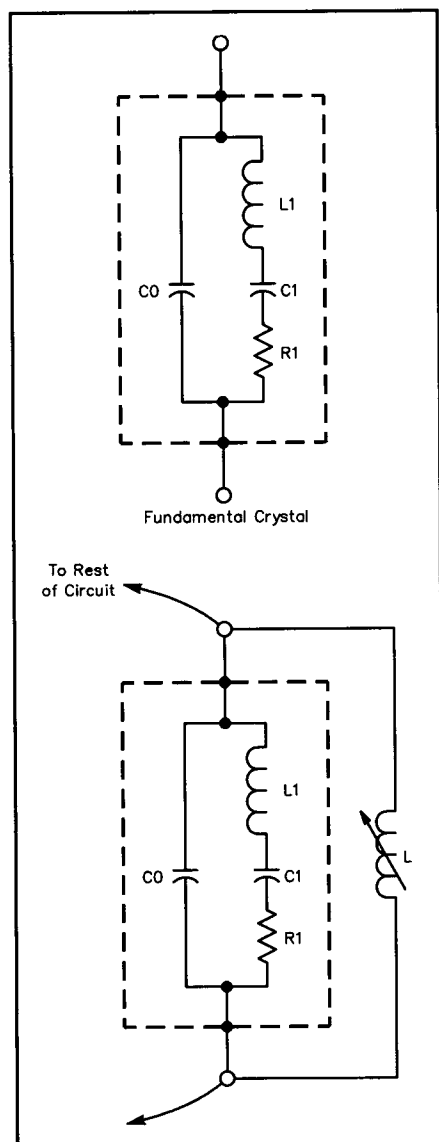

Fig 14.26 — Using an inductor to “tune out”  $C_0$  can increase a crystal oscillator’s pulling range.

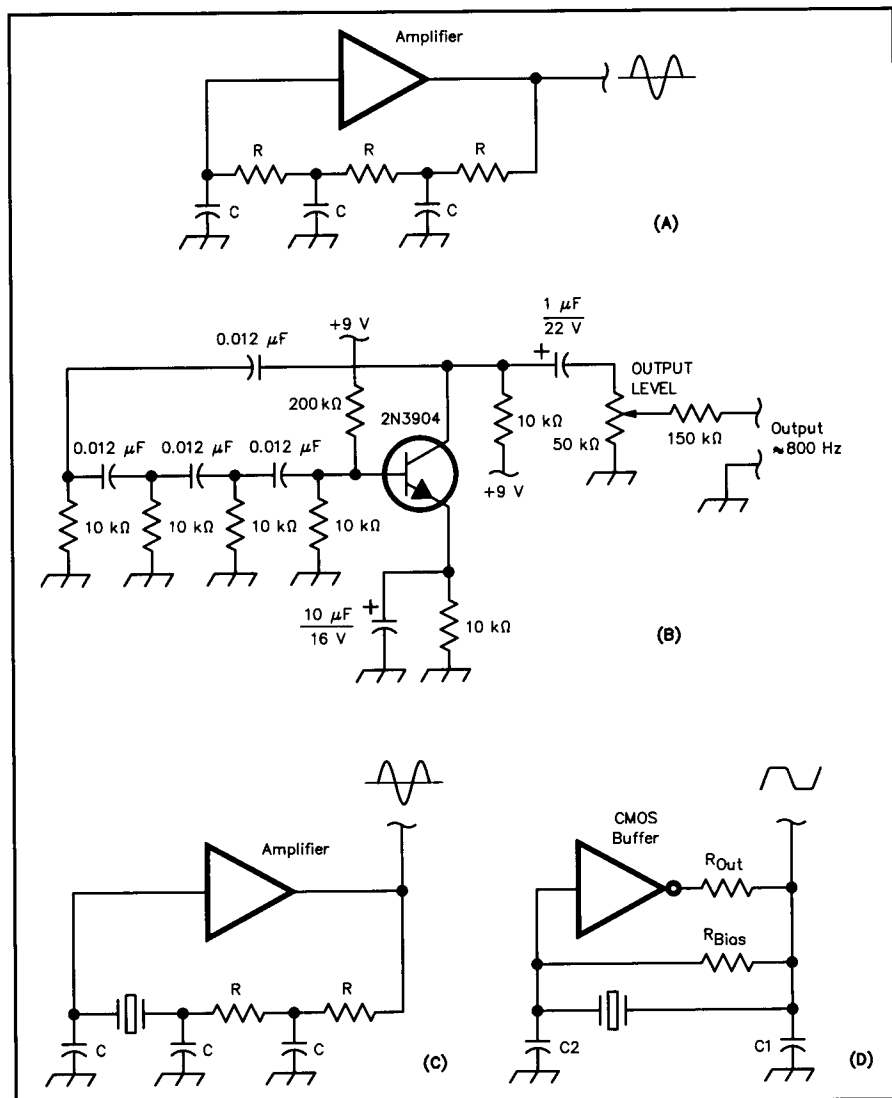

Fig 14.27 — In a phase-shift oscillator (A) based on logic gates, a chain of RC networks — three or more — provide the feedback and phase shift necessary for oscillation, at the cost of low Q and considerable loop loss. Many commercial Amateur Radio transceivers have used a phase-lead oscillator similar to that shown at B as a sidetone generator. Replacing one of the resistors in A with a crystal produces a Pierce oscillator (C), a cut-down version of which (D) has become the most common clock oscillator configuration in digital systems.

production foibles on a batch-by-batch basis.

## RC Oscillators

Plenty of RC oscillators are capable of operating to several megahertz. Some of these are really constant-current-into-capacitor circuits which are easier to make in silicon. Like the phase-shift oscillator above, the timing circuit  $Q$  is less than one, giving very poor noise performance that's unsuitable even to the least demanding radio application. One example is the oscillator section of the CD4046 phase-locked-loop IC. This oscillator has poor stability over temperature, large batch-to-batch variation and a wide variation in its voltage-to-frequency relationship. It is not recommended that this sort of oscillator is used at RF in radio systems. (The '4046 phase detector section is very useful, however, as we'll see later.) These oscillators are best suited to audio applications.

## VHF AND UHF OSCILLATORS

A traditional way to make signals at higher frequencies is to make a signal at a lower frequency (where oscillators are easier) and multiply it up to the wanted range. Multipliers are still one of the easiest ways of making a clean UHF/microwave signal. The design of a multiplier depends on whether the multiplication factor is an odd or even number. For odd multiplication, a Class-C biased amplifier can be used to create a series of harmonics; a filter selects the one wanted. For even multiplication factors, a full-wave-rectifier arrangement of distorting devices can be used to create a series of harmonics with strong even-order components, with a filter selecting the wanted component. At higher frequencies, diode-based passive circuits are commonly used. Oscillators using some of the LC circuits already described can be used in the VHF range, at UHF different approaches become necessary.

Fig 14.28 shows a pair of oscillators based on a resonant length of line. The first one is a return to basics: a resonator, an amplifier and a pair of coupling loops. The amplifier can be a single bipolar or FET device, or one of the monolithic microwave integrated circuit (MMIC) amplifiers. The second circuit is really a Hartley, and one was made as a test oscillator for the 70-cm band from a 10-cm length of wire suspended 10 mm over an unetched PC board as a ground plane, bent down and soldered at one end, a trimmer at the other end. The FET was a BF981 dual-gate device used as a source follower.

No free-running oscillator will be stable enough on these bands except for use with

wideband FM or video modulation and AFC at the receiver. Oscillators in this range are almost invariably tuned with tuning diodes controlled by phase-locked-loop synthesizers, which are themselves controlled by a crystal oscillator.

There is one UHF oscillator which is extremely common, yet rarely applied intentionally. The answer to this riddle is a configuration that is sometimes deliberately built as a useful wide-tuning oscillator covering say, 500 MHz to 1 GHz — and is also the modus operandi of a very common form of *spurious* VHF/UHF oscillation in circuitry intended to process lower-frequency signals! This oscillator has no generally accepted name. It relies on the creation of a small negative resistance in series with a series resonant LC tank.

Fig 14.29A shows the circuit in its simplest form. This circuit is well-suited to construction with printed-circuit inductors. Common FR4 glass-epoxy board is lossy at these frequencies; better performance can be achieved by using the much more expensive glass-Teflon board. If you can get surplus offcuts of this type of material, it has many uses at UHF and microwave, but it is difficult to use, as the adhesion between the copper and the substrate can be poor. A high-UHF transistor with a 5-GHz  $f_T$  like the BFR90 is suitable; the base inductor can be 30 mm of 1-mm trace folded into a hairpin shape (inductance, less than 10 nH). Analyzing this circuit using a comprehensive model of the UHF transistor reveals that the emitter presents an impedance that is small, resistive and negative to the outside world. If this is large enough to more than cancel the effective series resistance of the emitter tank, oscillation will occur. Fig 14.29B shows a very basic emitter-follower circuit with some capacitance to ground on both the input and output. If the capacitor shunting the input is a distance away from the transistor, the trace can look like an inductor — and small capacitors at audio and low RF can look like very good decouplers at hundreds of MHz. The length to the capacitor shunting the output will behave as a series resonator at a frequency where it is a  $1/4$  wavelength long. This circuit is the same as in Fig 14.29A; it, too, can oscillate. The semiconductor manufacturers have steadily improved their small-signal transistors to give better gain and bandwidth so that any transistor circuit where all three electrodes find themselves decoupled to ground at UHF may oscillate at several hundred megahertz. The upshot of this is that there is no longer any branch of electronics where RF design and layout techniques can be safely ignored. A circuit must not just be de-

Fig 14.28 — Oscillators that use transmission-line segments as resonators. Such oscillators are more common than many of us may think, as Fig 14.29 reveals.

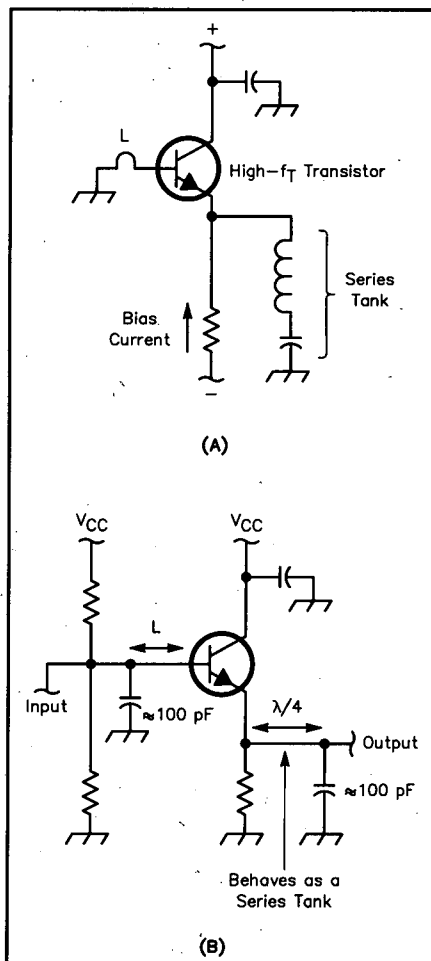

Fig 14.29 — High device gain at UHF and resonances in circuit-board traces can result in spurious oscillations even in non RF equipment.

**Fig 14.30 — Evolution of the cavity resonator.**

**Fig 14.31 — Currents and fields in a cavity.**

waveguide and now uses low-loss coaxial cable with a solid-copper shield — *semi-rigid cable* — to connect circuits made flat on ceramic or Teflon based substrates. Semiconductors are often bonded on as unpackaged chips, with their bond-wire connections made directly to the traces on the substrate. At lower microwave frequencies, they may be used in standard surface-mount packages. From an Amateur Radio viewpoint, many of the processes involved are not feasible without access to specialized furnaces and materials. Using ordinary PC-board techniques with surface-mount components allows the construction of circuits up to 4 GHz or so. Above this, structures get smaller and accuracy becomes critical; also PC-board materials quickly become very lossy.

Older than stripline techniques and far more amenable to home construction, cavity-based oscillators can give the highest possible performance. The dielectric constant of the substrate causes stripline structures to be much smaller than they would be in free air, and the lowest-loss substrates tend to have very high dielectric constants. Air is a very low-loss dielectric with a dielectric constant of 1, so it gives high Q and does not force excessive miniaturization. **Fig 14.30** shows a series of structures used by G. R. Jessup, G6JP, to illustrate the evolution of a cavity from a tank made of lumped components. All cavities have a number of different modes of resonance, the orientation of the currents and fields are shown in **Fig 14.31**. The cavity can take different shapes, but that shown has proven to well-suppress unwanted modes. The gap need not be central and is often right at the top. A screw can be fitted through the top, protruding into the gap, to adjust the frequency.

To make an oscillator out of a cavity, an amplifier is needed. Gunn and tunnel diodes have regions in their characteristics where their current *falls* with increasing bias voltage. This is negative resistance. If such a device is mounted in a loop in a cavity and bias applied, the negative resistance can more than cancel the effective loss resistance of the cavity, causing oscillation. These diodes are capable of operating at extremely high frequencies and were discovered long before transistors were developed that had any gain at microwave frequencies.

A Gunn-diode cavity oscillator is the basis of many of the Doppler-radar modules used to detect traffic or intruders. **Fig 14.32** shows a common configuration. The coupling loop and coax output connector could be replaced with a simple

**Fig 14.32 — A Gunn diode oscillator uses negative resistance and a cavity resonator to produce radio energy.**

signed to do what it *should* do, it must also be designed so that it cannot do what it *should not* do.

There are three ways of taming such a circuit; adding a small resistor, perhaps 50 to 100  $\Omega$  in the collector lead, close to the transistor, or adding a similar resistor in the base lead, or by fitting a ferrite bead

over the base lead under the transistor. The resistors can disturb dc conditions, depending on the circuit and its operating currents. Ferrite beads have the advantage that they can be easily added to existing equipment and have no effect at dc and low frequencies. Beware of some electrically conductive ferrite materials that can short transistor leads. If an HF oscillator uses beads to prevent any risk of spurs (**Fig 14.16**), the beads should be anchored with a spot of adhesive to prevent movement that can cause small frequency shifts. Ferrite beads of Fair-Rite no. 43 material are especially suitable for this purpose; they are specified in terms of impedance, not inductance. Ferrites at frequencies above their normal usable range become very lossy and can make a lead look not inductive, but like a few tens of ohms, resistive.

### Microwave Oscillators

Low-noise microwave signals are still best made by multiplying a very-low-noise HF crystal oscillator, but there are a number of oscillators that work directly at microwave frequencies. Such oscillators can be based on resonant lengths of stripline or microstrip, and are simply scaled-down versions of UHF oscillators, using microwave transistors and printed striplines on a low-loss substrate, like alumina. Techniques for printing metal traces on substrates to form filters, couplers, matching networks and so on, have been intensively developed over the past two decades. Much of the professional microwave community has moved away from

aperture to couple into waveguide or a mixer cavity. **Fig 14.33** shows a transistor cavity oscillator version using a modern microwave transistor. FET or bipolar devices can be used. The two coupling loops are completed by the capacitance of the feedthroughs.

The *dielectric-resonator oscillator (DRO)* may soon become the most common microwave oscillator of all, as it is used in the downconverter of satellite TV receivers. The dielectric resonator itself is a ceramic cylinder, like a miniature hockey puck, several millimeters in diameter. The ceramic has a very high dielectric constant, so the surface (where ceramic meets air in an abrupt mismatch) reflects electromagnetic waves and makes the ceramic body act as a resonant cavity. It is mounted on a substrate and coupled to the active device of the oscillator by a stripline which runs past it. At 10 GHz, a FET made of gallium arsenide (GaAsFET), rather than silicon, is normally used. The dielectric resonator elements are made at frequencies appropriate to mass applications like satellite TV. The set-up charge to manufacture small quantities at special frequencies is likely to be prohibitive for the foreseeable future. The challenge with these devices is to devise new ways of using oscillators on industry standard frequencies. Their chief attraction is their low cost in large quantities and compatibility with microwave stripline (microstrip) techniques. Frequency stability and Q are competitive with good cavities, but are inferior to that achievable with a crystal oscillator and chain of frequency multipliers. Satellite TV downconverters need free running oscillators with less than 1 MHz of drift at 10 GHz.

There are a number of thermionic (vacuum-tube) microwave sources, klystrons, magnetrons and *backwards wave oscillators (BWOs)*, but available devices are either very old or designed for very high power.

The *yttrium-iron garnet (YIG)* oscillator was developed for a wide tuning range as a solid-state replacement for the BWO, and many of them can be tuned over more than an octave. They are complete, packaged units that appear to be a heavy block of metal with low-frequency connections for power supplies and tuning, and an SMA connector for the RF output. The manufacturer's label usually states the tuning range and often the power supply voltages. This is very helpful because, with new units priced in the kilodollar range, it is important to be able to identify surplus units. The majority of YIGs are in the 2- to 18-GHz region, although units

down to 500 MHz and up to 40 GHz are occasionally found. In this part of the spectrum there is no octave-tunable device that can equal their cleanliness and stability. A 3-GHz unit drifting less than 1 kHz per second gives an idea of typical stability. This seems very poor — until we realize that this is 0.33 ppm per second. Nevertheless, any YIG application involving narrow-band modulation will usually require some form of frequency stabilizer.

Good quality, but elderly, RF spectrum analyzers have found their way into the workshops of a number of dedicated constructors. A 0- to 1500-MHz analyzer usually uses a 2- to 3.5-GHz YIG as its first local oscillator, and its tuning circuits are designed around it. A reasonable understanding of YIG oscillators will help in troubleshooting and repair.

YIG spheres are resonant at a frequency controlled not only by their physical dimensions, but also by any applied magnetic field. A YIG sphere is carefully oriented within a

coupling loop connected to a negative-resistance device and the whole assembly is placed between the poles of an electromagnet. Negative-resistance diodes have been used, but transistor circuits are now common. The support for the YIG sphere often contains a thermostatically controlled heater to reduce temperature sensitivity.

**Fig 14.33 — A transistor can also directly excite a cavity resonator.**

**Fig 14.34 — A yttrium-iron-garnet (YIG) sphere serves as the resonator in the sweep oscillators used in many spectrum analyzers.**

The first problem with a magnetically tuned oscillator is that magnetic fields, especially at low frequencies, are extremely difficult to shield; the tuning will be influenced by any local fields. Varying fields will cause frequency modulation. The magnetic core must be carefully designed to be all-enclosing in an attempt at self-shielding and then one or more nested mu-metal cans are fitted around everything. It is still important to site the unit away from obvious sources of magnetic noise, like power transformers.

Cooling fans are less obvious sources of fluctuating magnetic fields, yet some are 20 dB worse than a well designed 200-W 50/60-Hz transformer.

The second problem is that the oscillator's internal tuning coils need significant current from the power supply to create strong fields. This can be eased by adding a permanent magnet as a fixed "bias" field, but the bias will shift as the magnet ages. The only solution is to have a coil with many turns, but high inductance, which will require a high supply

voltage to permit rapid tuning, thus increasing the power consumption. The usual compromise is to have dual coils: One with many turns allows slow tuning over a wide range; a second with much fewer turns allows fast tuning or FM over a limited range. The main coil can have a sensitivity in the 20 MHz/mA range; and the "FM" coil, perhaps 500 kHz/mA. The frequency/current relationship can have excellent linearity. **Fig 14.34** shows the construction of a YIG oscillator.

# Frequency Synthesizers

Narrow-band modes on HF and all modes on VHF upwards, place difficult to impossible demands on VFO stability and setting accuracy. (Wideband modes, such as WBFM, ATV and higher-speed data, may not.) Some radios are only required to tune to a few channels, and an obvious solution is to use switched crystals. This means a pair of crystals for each channel, because the transmitter and receiver usually need separate LOs to create the IF offset needed even for simplex operation. This approach soon becomes unacceptably expensive and large as the number of channels is increased; also, there is labor involved in periodically checking and adjusting each channel individually. Commercial designers were desperate for any way of reducing the size of crystal bank needed. One way, once commonly used in aircraft radios, was to have a multisuperhet, with a switched group of crystals for each LO. The last LO would have crystal frequencies chosen to give steps equal to the required channel spacing, the next earlier LO would have its crystal frequencies chosen to give steps equal to the range of the last LO + 1 channel and so on.

If a step-tuned MF/HF SSB/CW radio must sound as if it tunes as continuously as an LC VFO, a 10-Hz step size is needed. For general coverage, close to a 30-MHz LO tuning range is needed, giving a total of 3 million channels. We handle this with a first LO with 3 crystals at 10-MHz incre-

ments, a second LO with 10 crystals at 1 MHz increments, a third LO with 10 crystals at 100-kHz increments and so on to a seventh LO with 10 crystals at 10-Hz increments. Sixty-three crystals are a big improvement over three million, but are still too many, and seven frequency conversions are also excessive. Using a VXO for fine tuning could eliminate the 10- and 100-Hz stages, but would still leave a total of 43 crystals.

A way was invented of having only one crystal bank and reusing it for successive stages. Additionally, the frequency-generation system was divorced from the receiver structure. Fig 14.35 shows what has become known as a *direct synthesizer*. This has been greatly oversimplified to show just the general principle. In many designs, two stages of mixing were used in place of each mixer shown.

The first divide-by-10 reduces the increment size from the first switch tenfold. After the second divider, the influence of the first switch has been reduced one hundredfold and that of the second switch, tenfold. Notice how the structure has repeated cells, although the last cell has no divider. Careful choice of frequencies makes the cells, even the filters, absolutely identical. To get finer output step size, usually called *finer resolution*, just add more cells in the chain. This was revolutionary because it allows the generation of as many steps or channels as could be wanted from 11 crystal oscillators. (It is

not necessary to use a decimal structure with 10 components; other numerical bases can be used, although reducing the number of components will require more cells for the same number of possible output channels.)

The disadvantage is that this method requires excellent shielding, for each cell operates in roughly the same frequency range, and any signal leaking between cells can reach the output as a spurious signal. Not only must shielding be used to prevent coupling by radiation, but power buses must be well-filtered as they enter each cell, and (less obviously) isolation amplifiers are necessary to prevent signals leaking between cells along the component frequency buses. These early frequency synthesizers could change frequency extremely rapidly if diode RF switches were used to select components and could be extended to microwave frequencies.

## Phase-Locked Loops

A totally different approach, based on phase-locked loops, long ago came to dominate frequency synthesis. It is still dominant today, although it is now often combined with other techniques to form hybrids.

The principle of the *phase-locked loop* (PLL) synthesizer is very simple indeed. An oscillator can be built to cover the required frequency range, so what is needed is a system to keep its tuning correct. This

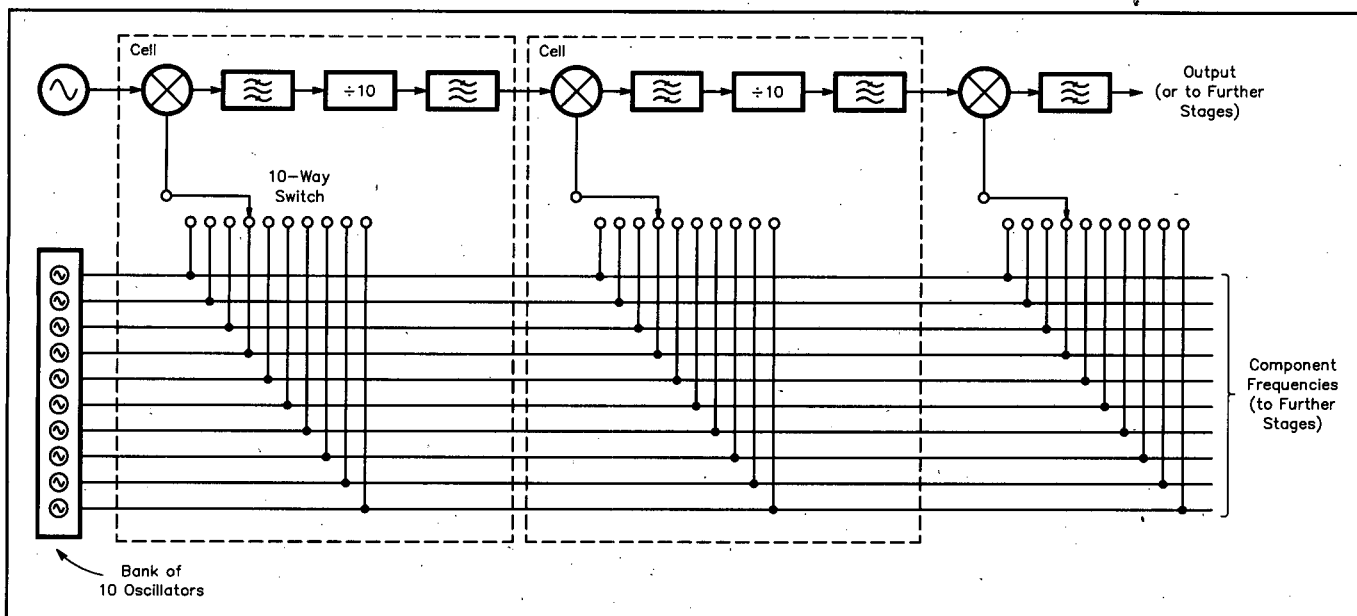

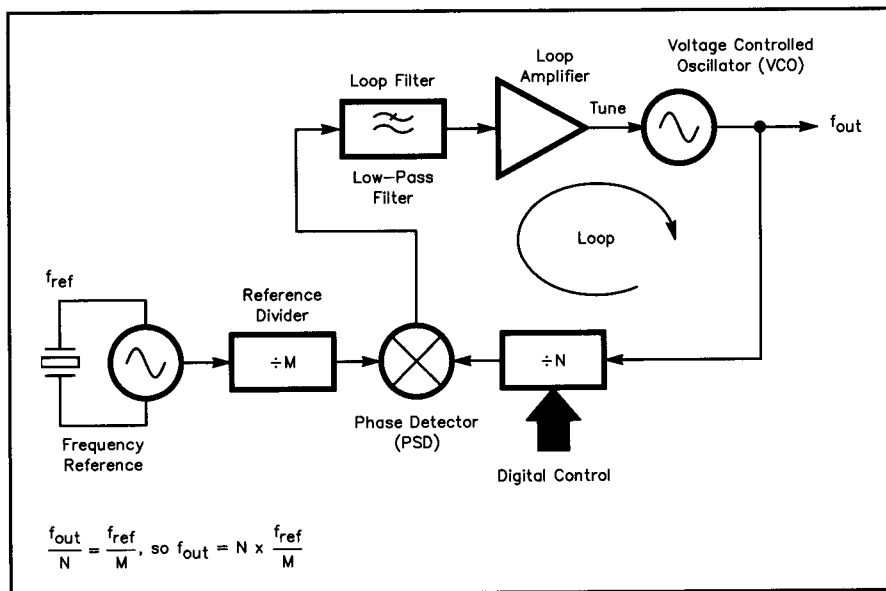

Fig 14.35 — Direct frequency synthesis involves mixing two or more signal sources together to produce sums and differences at desired output frequencies. Great elaboration (and, with it, great likelihood of spurious outputs) is necessary to achieve fine tuning steps. This direct synthesizer is simplified to emphasize the principles involved.

**Fig 14.36 — A basic phase-locked-loop (PLL) synthesizer acts to keep the divided-down signal from its voltage-controlled oscillator (VCO) phase-locked to the divided-down signal from its reference oscillator. Fine tuning steps are therefore possible without the complication of direct synthesis.**

is done by continuously comparing the phase of the oscillator to a stable reference, such as a crystal oscillator and using the result to steer the tuning. If the oscillator frequency is too high, the phase of its output will start to lead that of the reference by an increasing amount, which is detected and used to decrease the frequency of the oscillator. Too low a frequency causes an increasing phase lag, which is detected and used to increase the frequency of the oscillator. In this way, the oscillator is locked into a fixed phase relationship with the reference, which means that their frequencies are held exactly equal.

The oscillator is now under control, but is locked to a fixed frequency. **Fig 14.36** shows the next step. The phase detector does not simply compare the oscillator frequency with the reference oscillator; both signals have now been passed through frequency dividers. Advances in digital integrated circuits have made frequency dividers, up to low microwave frequencies, commonplace. The divider on the reference path has a fixed division factor, but that in the VCO path is programmable, the factor being entered digitally as a (usually) binary word. The phase detector is now operating at a lower frequency, which is a submultiple of both the reference and output frequencies.

The phase detector, via the loop amplifier, steers the oscillator to keep both its inputs equal in frequency. The reference frequency, divided by  $M$ , is equal to the output frequency divided by  $N$ . The out-

put frequency equals the reference frequency  $\times N/M$ .  $N$  is programmable (and an integer), so this synthesizer is capable of tuning in steps of  $F_{ref}/M$ .

As an example, to make a 2-m radio covering 144 to 148 MHz, having a 10.7-MHz IF, we need a local oscillator covering 154.7–158.7 MHz. If the channel spacing is 20 kHz, then  $F_{ref}/M$  is 20 kHz, so  $N$  is 7735 to 7935. There is a free choice of  $F_{ref}$  or  $M$ , but division by a round binary number is easiest. Crystals are readily available for 10.24 MHz, and one of these (divided by 512) will give 20 kHz at low cost. (ICs are readily available containing most of the circuitry necessary for the reference oscillator — less the crystal — the programmable divider and the phase detector.)

The phase detector in this example compares the relative timing of 5-V pulses (CMOS logic level) at 20 kHz. Inevitably, the phase detector output will contain strong components at 20 kHz and its harmonics in addition to the wanted “steering” signal. The loop filter must block these unwanted signals; otherwise the loop amplifier will amplify them and apply them to the VCO, generating unwanted FM. No filtering can be perfect and the VCO is very sensitive, so most synthesizers have measurable sidebands spaced at the phase detector operating frequency (and harmonics) away from the carrier. These are called *reference-frequency sidebands*. (Exactly which is the reference frequency is ambiguous: Do we mean the frequency of the reference oscillator, or

the frequency applied to the reference input of the phase detector? You must look carefully at context whenever *reference frequency* is mentioned.)

The loop filter is not usually built as a single block of circuitry, it is often made up of three areas: some components directly after the phase detector, a shaped frequency response in the loop amplifier and some more components between the loop amplifier and the VCO.

The PLL is like a feedback amplifier, although the “signal” around its loop is represented by frequency in some places, by phase in others and by voltage in others. Like any feedback amplifier, there is the risk of instability and oscillations traveling around the loop, which can be seen as massive FM on the output and a strong ac signal on the tuning line to the VCO. The loop’s filtering and gain has to be designed to prevent this. Good design makes allowance for component variation and the variation in a VCO’s sensitivity across its tuning range, as well as from unit to unit — and then leaves plenty of safety margin!

Like any feedback amplifier, the PLL has a frequency response and gain. The following example illustrates: Imagine that we shift the reference oscillator 1 Hz. The reference applied to the phase detector would shift  $1/M$  Hz, and the loop would respond by shifting the output frequency to produce a matching shift at the other phase detector port, so the output is shifted by  $N/M$  Hz. Imagine now that we apply a very small amount of FM to the reference oscillator. The amount of deviation will be amplified by  $N/M$  — but this is only true for low modulating frequencies. If the modulating frequency is increased, eventually the loop filter starts to reduce the gain around the loop, the loop ceases to track the modulation and the deviation at the output falls. This is referred to as the *closed-loop frequency response* or *closed-loop bandwidth*. Poorly designed loops can have poor closed-loop responses, for example, the gain can have large peaks above  $N/M$  at some reference modulation frequencies, indicating marginal stability and excessively amplifying any noise at those offsets from the carrier. The design of the loop filtering and the gain around the loop sets the closed-loop performance.

In a single-loop synthesizer, there is a trade-off between how fine the step size can be versus the performance of the loop. A loop with a very fine step size runs the phase detector at a very low frequency, so the loop bandwidth has to be kept very, very low to keep the reference-frequency sidebands low. Also, the reference oscillator usually has much better phase-noise

performance than the VCO, and (within the loop bandwidth) the loop acts to oppose the low-frequency components of the VCO phase-noise sidebands. This very useful cleanup activity is lost when loops have to be narrowed in bandwidth to allow narrow steps. Low-bandwidth loops are slow to respond — they exhibit overly long *settling times* — to the changes in  $N$  necessary to change channels. Absolutely everything seems to become impossible in any attempt to get fine resolution from a phase-locked loop.

Single-loop synthesizers are okay for the 2-m FM example for a number of reasons: Channel spacings in this band are not too small, FM is not as critical of phase noise as other modes, 2-m FM is rarely used for weak-signal DXing and the channelization involved does away with the desirability of simulating fast, smooth, continuous tuning. None of these excuses apply to MF/HF radios, however, and ways to circumvent the problems are needed.

A clue was given earlier, by carefully referring to *single-loop synthesizers*. It's possible to use *several* PLLs as components in a larger structure, dividing the frequency of one loop and adding it to the frequency of another that has not been divided. This represents a form of hybrid between the old direct synthesizer and the PLL. A form of PLL containing a mixer in place of the programmable divider can be used to perform the frequency addition.

### Voltage-Controlled Oscillators

Voltage-controlled oscillators are commonly merely referred to as *VCOs*. (Voltage-tuned oscillator, VTO, more accurately describes the circuitry most commonly used in VCOs, but tradition is tradition! An exception to this is the YIG oscillator, sometimes used in UHF and microwave PLLs, which is *current-tuned*.) In all the oscillators described so far, except for permeability tuning, the frequency is controlled or trimmed by a variable capacitor. These are modified for voltage tuning by using a tuning diode.

When a normal silicon diode is reverse-biased, the mobile charge carriers are stripped out of a zone either side of the junction. This is called the *depletion region* (Fig 14.37); lacking any movable charges, it is a good insulator. The two outer regions have plenty of charge carriers, so are good conductors, and are connected to the diode's leads. This insulator surrounded by conductors is the classic recipe for a capacitor. If the reverse bias voltage is increased, the depletion region widens, reducing the capacitance. The capacitance depends on the cross-sectional

Fig 14.37 — Modern VCOs use the voltage-variable characteristic of diode PN junctions for tuning.

tional area of the diode, the dielectric constant of depleted silicon and the width of the depletion region (in just the same way as for a normal capacitor). The width of the depletion region depends on the doping profile of the semiconductor and the bias voltage. All semiconductor diodes do this. Common small-signal and power diodes can be used, but their capacitance range is small, as is true of any junction of a bipolar transistor or JFET. Deliberately made tuning diodes are carefully designed to give much higher capacitance ranges. These diodes go by a wide range of names: Varactors, Varicaps, Epicaps, tuning diodes, voltage-variable capacitors.

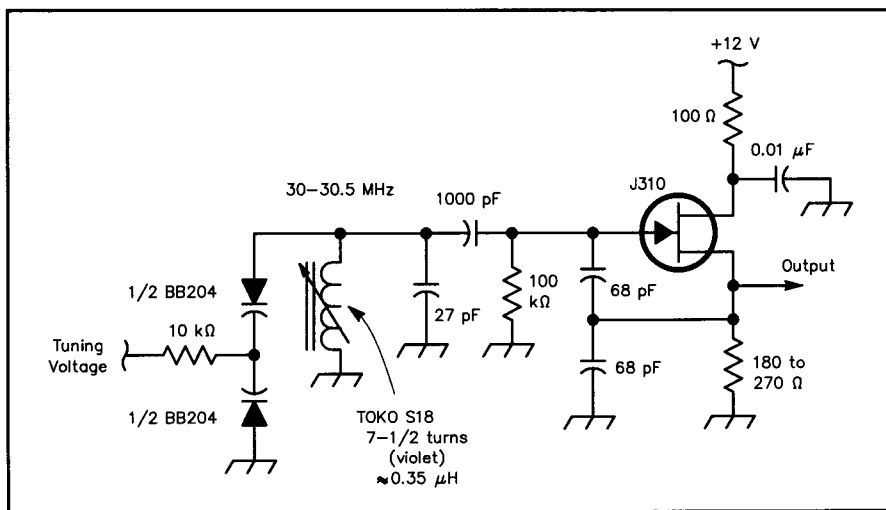

This effect is fast enough so that when a signal voltage exists across the diode, superimposed on the bias voltage, the capacitance varies following the instantaneous total voltage. This is the basis of the old tuning-diode frequency multipliers (once used to convert the output of a 2-m transmitter to a 70-cm band) and for *parametric amplifiers*. These applications are rare, however. Modulation of a diode's capacitance by the signal is usually a nuisance, distorting the signal and creating harmonics. This means that oscillators tuned by diodes can have significantly more harmonic content than those using normal capacitors, especially when run at high levels, as is often done to get best noise performance. (The collector-base junction of a transistor is a reverse-biased diode and also exhibits signal-dependent capacitance. The effect of this capacitance, including signal-dependent variation, is multiplied by the Miller effect and can cause rising distortion at increasing frequency in an amplifier.

Tuning diodes cannot rival the  $Q$  of normal fixed and variable capacitors, and their  $Q$  degrades rapidly at the low voltage/high capacitance end of their range. In

ordinary LC oscillators it is normal for the capacitors to have a  $Q$  an order of magnitude greater than the inductor, making coil losses the dominant limitation. Tuning-diode  $Q$ , however, is comparable with that of the inductor, and care is therefore needed to choose the most suitable diodes and operate them in bias regions that afford favorable  $Q$  across the capacitance range needed. The capacitance-voltage curve becomes much steeper in the low bias/high capacitance region, and the tuning characteristic of oscillators will become very nonlinear at the low-frequency end of the range. It is a good idea to avoid running tuning diodes below about 2 V of reverse bias.

When choosing a diode, read its data sheet carefully. Often, capacitance ratios over 10:1 are proclaimed, but achieving the low-capacitance end of a given such range usually requires a higher-voltage bias supply than are often available. For a high-performance synthesizer, it is worth adding a higher-voltage power supply to run varactors in their best regions, possibly using parallel connected diodes to make up for the reduction in diode capacitance at higher reverse voltages.

Fig 14.38 shows a VCO used in the PLL frequency summer later in this chapter. This is a robust circuit, rather than an attempt at the ultimate in low-noise design, but it illustrates a few useful tricks. Instead of a single tuning diode, a cathode-to-cathode pair are used. The signal voltage increases the bias on one diode while it decreases that on the other. This gives a partial cancellation of the nonlinear effects on the signal, giving lower harmonic content from the oscillator. This is a very common arrangement, and dual diodes like that used here are becoming popular. The inductor helpfully provides a dc ground path for the anode of the top

**Fig 14.38 — A practical VCO.** The tuning diodes are halves of a BB204 dual, common-cathode tuning diode (capacitance per section at 3 V, 39 pF) or equivalent. The ECG617, NTE617 and MV104 are suitable dual-diode substitutes, or use pairs of 1N5451s (39 pF at 4 V) or MV2109s (33 pF at 4 V).

diode, so only one resistor is needed to apply the tuning bias. (In high-performance, low noise synthesizers, it is normal to use an RF choke as the bias feed, to avoid modulating the oscillator with the noise generated in the high-value resistor.) The tuning range is small, 30.0 to 30.5 MHz, so the tuning diodes constitute only a part of the capacitance across the coil; the rest is in the form of high-Q fixed components. This limits the reduction of tank Q due to tuning-diode losses. When this oscillator is used in a PLL, the PLL adjusts the tuning voltage to completely cancel any drift in the oscillator (provided it does not drift further than it can be tuned) regardless of its cause, so no special care is needed to compensate a PLL VCO for temperature effects. Adjusting the inductor core will not change the frequency; the PLL will adjust the tuning voltage to hold the oscillator on frequency. This adjustment is important, though. It's set so that the tuning voltage neither gets too close to the maximum available, nor too low for acceptable Q, as the PLL is tuned across its full range.

In a high-performance, low-noise synthesizer, the VCO may be replaced by a bank of switched VCOs, each covering a section of the total range needed, each VCO having better Q and lower noise because the lossy diodes constitute only a smaller part of the total tank capacity than they would in a single, full-range oscillator. Another method uses tuning diodes for only part of the tuning range and switches in other capacitors (or inductor taps) to extend the range. The performance of wide-range VCOs can be improved by using a large

number of varactors in parallel in a high-C, low-L tank.

### Programmable Dividers

Designing your own programmable divider is now a thing of the past, as complete systems have been made as single ICs for over 10 years. The only remaining reason to do so is when an ultra-low-noise synthesizer is being designed.

It may seem strange to think of a digital counter as a source of random noise, but digital circuits have propagation delays caused by analog effects, such as the charging of stray capacitances. Digital circuits are composed of the same sorts of components as analog circuits; there are no such things as digital and analog electrons! Signals are made of voltages and currents. The prime difference between analog and digital electronics lies in the different ways meaning is assigned to the magnitude of a signal. The differences in circuit design are consequences of this, not causes.

Thermal noise in the components of a digital circuit, added to the signal voltage will slightly change the times at which thresholds are crossed. As a result, the output of a digital circuit will have picked up some timing jitter. Jitter in one or both of the signals applied to a phase detector can be viewed as low-level random phase modulation. Within the loop bandwidth, the phase detector steers the VCO so as to oppose and cancel it, so phase jitter or noise is applied to the VCO in order to cancel out the jitter added by the divider. This makes the VCO noisier. The noise performance of the high-speed CMOS logic normally used in programmable di-

viders is good. For ultra-low-noise dividers, ECL devices are sometimes used.

A programmable divider (**Fig 14.39A**) consists of a loadable counter and some control circuitry. The counter is designed to count downward. The programmed division factor is loaded into the counter, and the incoming frequency clocks the downward counting. When the count reaches zero, the counter is quickly reloaded with the division factor before the next clock edge. The maximum frequency of operation is limited by the minimum time needed to reliably perform the loading operation. One improvement is to have a circuit to recognize a state a few clock cycles before the zero count is reached, so the reload can be performed at a more leisurely pace during those cycles. This imposes a minimum division ratio, but that is rarely a problem. An output pulse is given during the loading cycle. In this way a frequency is divided by the number loaded.

The maximum input frequency that can be handled is set by the speed of available logic. The synchronous reset cycle forces the entire divider to be made of equally fast logic. Just adding a fast *prescaler* — a fixed-ratio divider ahead of the programmable one — will increase the maximum frequency that can be used, but it also scales up the loop step size. Equal division has to be added to the reference input of the phase detector to restore the step size, reducing the phase detector's operating frequency. The loop bandwidth has to be reduced to restore the filtering needed to suppress reference frequency sidebands. This makes the loop much slower to change frequency and degrades the noise performance.

### Dual-Modulus Prescalers

A plain programmable divider for VHF use would need to be built from ECL devices. It would be expensive, hot and power-hungry. The idea of a fast front end ahead of a CMOS programmable divider would be perfect if these problems could be circumvented. Consider a fast divide-by-ten prescaler ahead of a programmable divider where division by 947 is required. If the main divider is set to divide by 94, the overall division ratio is 940. The prescaler goes through its cycle 94 times and the main divider goes through its cycle once, for every output pulse. If the prescaler is changed to divide by 11 for 7 of its cycles for every cycle of the entire divider system, the overall division ratio is now  $[(7 \times 11) + (87 \times 10)] = 947$ . At the cost of a more elaborate prescaler and the addition of a slower programmable counter to control it, this prescaler does not multiply the step size and avoids all

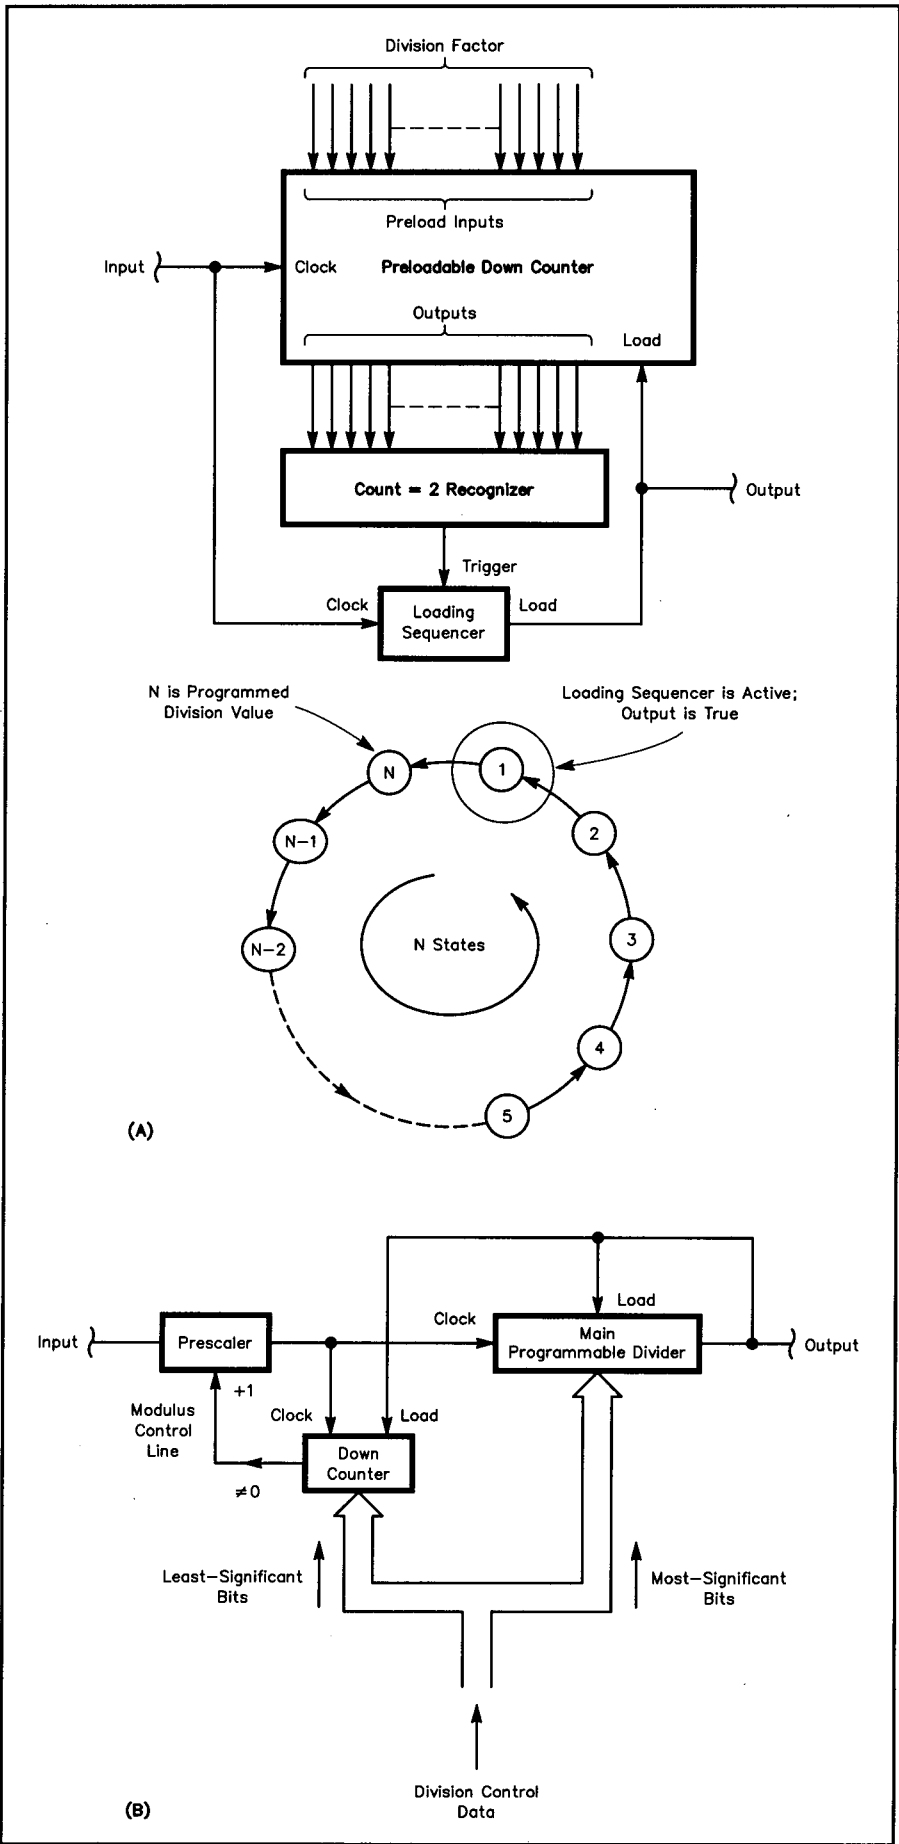

the problems of fixed prescaling. Fig 14.39B shows the general block diagram of a dual-modulus prescaled divider. The down-counter controls the modulus of the prescaler. The numerical example, just given, used decimal arithmetic, although binary is now usual. Each cycle of the system begins with the last output pulse having loaded the frequency control word, into both the main divider and the prescaler controller. If the part of the word loaded into the prescaler controller is not zero, the prescaler is set to divide by 1 greater than its normal ratio. Each cycle of the prescaler clocks the down-counter. Eventually, it reaches zero, and two things happen: The counter is designed to freeze at zero (and it will remain frozen until it is next reloaded) and the prescaler is switched back to its normal ratio, at which it will remain until the next reload. One way of visualizing this is to think of the prescaler as just being a divider of its normal ratio, but with the ability to "steal" a number of input pulses controlled by the data loaded into its companion down counter. Note that a dual-modulus prescaler system has a *minimum* division ratio, needed to ensure there are enough cycles of the prescaler to allow enough input pulses to be stolen.

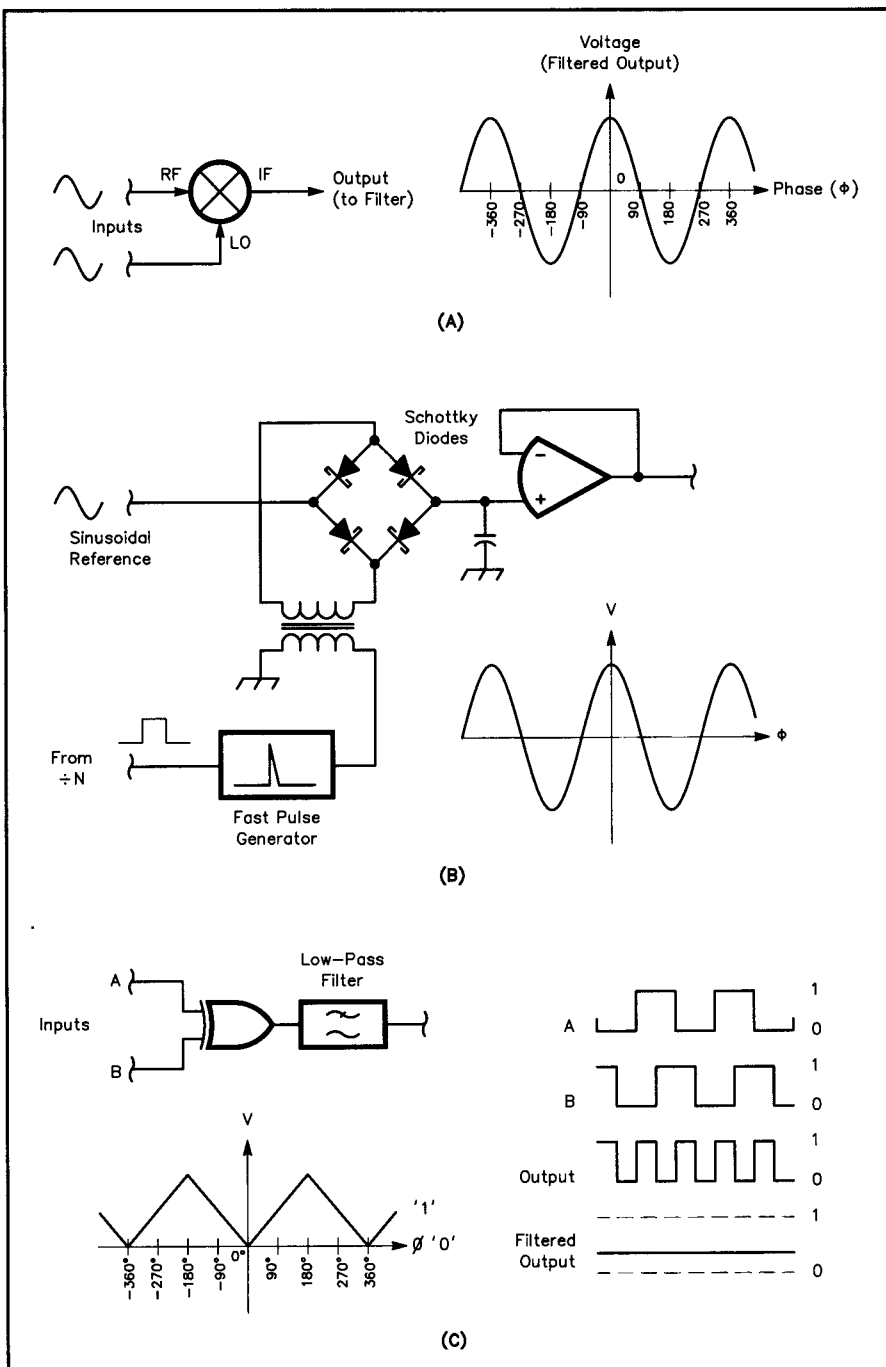

Dual-modulus prescaler ICs are widely used and widely available. Devices for use to a few hundred megahertz are cheap, and devices in the 2-GHz region are becoming available, although fixed prescaling has been more common at such frequencies. Common prescaler IC division ratio pairs are: 8-9, 10-11, 16-17, 32-33, 64-65 and so on. Many ICs containing programmable dividers are available in versions with and without built-in prescaler controllers.

### Phase Detectors

A phase detector (PSD) produces an output voltage that depends on the phase relationship between its two input signals. If two signals, *in phase on exactly the same frequency*, are mixed together in a conventional diode-ring mixer with a dc-coupled output port, one of the products is direct current (0 Hertz). If the phase relationship between the signals changes, the mixer's dc output voltage changes. With both signals in phase, the output is at its most positive; with the signals 180° out of phase, the output is at its most negative.

Fig 14.39 — Mechanism of a programmable frequency divider (A). B shows the function of a dual-modulus prescaler. The counter is reloaded with N when the count reaches 0 or 1, depending on the sequencer action.

**Fig 14.40 — Simple phase detectors: a mixer (A), a sampler (B) and an exclusive-or gate (C).**

When the phase difference is  $90^\circ$  (the signals are said to be *in quadrature*), the output is 0 V.

Applying sinusoidal signals to a phase detector causes the detector's output voltage to vary sinusoidally with phase angle, as in Fig 14.40A. This nonlinearity is not a problem, as the loop is usually arranged to run with phase differences close to  $90^\circ$ . What might seem to be a more serious complication is that the detector's phase-voltage characteristic repeats every  $180^\circ$ ,

not  $360^\circ$ . Two possible input phase differences can therefore produce a given output voltage. This turns out not to be a problem, because the two identical voltage points lie on opposing slopes on the detector's output-voltage curve. One direction of slope gives positive feedback (making the loop unstable and driving the VCO away from what otherwise would be the lock angle) over to the other slope, to the true and stable lock condition.

MD108, SBL-1 and other diode mixers

can be used as phase detectors, as can active mixers like the MC1496. Mixer manufacturers make some parts (Mini-Circuits RPD-1 and so on) that are specially optimized for phase-detector service. All these devices can make excellent, low-noise phase detectors but are not commonly used in ham equipment. A high-speed sample-and-hold circuit, based on a Schottky-diode bridge, can form a very low-noise phase detector and is sometimes used in specialized instruments. This is just a variant on the basic mixer; it produces a similar result, as shown in Fig 14.40B.

The most commonly used simple phase detector is just a single exclusive-OR (XOR) logic gate. This circuit gives a logic 1 output only when *one* of its inputs is at logic 1; if both inputs are the same, the output is a logic 0. If inputs A and B in Fig 14.40C are almost in phase, the output will be low most of the time, and its average filtered value will be close to the logic 0 level. If A and B are almost in opposite phase, the output will be high most of the time, and its average voltage will be close to logic 1. This circuit is very similar to the mixer. In fact, the internal circuit of ECL XOR gates is the same transistor tree as found in the MC1496 and similar mixers, with some added level shifting. Like the other simple phase detectors, it produces a cyclic output, but because of the square-wave input signals, produces a triangular output signal. To achieve this circuit's full output-voltage range, it's important that the reference and VCO signals applied operate at a 50% duty cycle.

### Phase-Frequency Detectors

All the simple phase detectors described so far are really specialized mixers. If the loop is out of lock and the VCO is far off frequency, such phase detectors give a high-frequency output midway between zero and maximum. This provides no information to steer the VCO towards lock, so the loop remains unlocked. Various solutions to this problem, such as crude relaxation oscillators that start up to sweep the VCO tuning until lock is acquired, or laboriously adjusted "pretune" systems in which a DAC, driven from the divider control data, is used to coarse tune the VCO to within locking range, have been used in the past. Many of these solutions have been superseded, although pretune systems are still used in synthesizers that must change frequency very rapidly.

The *phase-frequency detector* is the usual solution to lock-acquisition problems. It behaves like a simple phase detector over an extended phase range, but its characteristic is not repetitive. Because its output voltage stays high or low, de-

pending on which input is higher in frequency, this PSD can steer a loop towards lock from anywhere in its tuning range. Fig 14.41 shows the internal logic of the phase-frequency detector in the CD4046 PLL chip. (The CD4046 also contains an XOR PSD). When the phase of one input leads that of the other, one of the output MOSFETs is pulsed on with a duty cycle proportional to the phase difference. Which MOSFET receives drive depends on which input is leading. If both inputs are in phase, the output will include small pulses due to noise, but their effects on the average output voltage will cancel. If one signal is at a higher frequency than the other, its phase will lead by an increasing amount, and the detector's output will be held close to either  $V_{DD}$  or ground, depending on which input signal is higher in frequency. To get a usable voltage output, the MOSFET outputs can be terminated in a high-value resistor to  $V_{DD}/2$ , but the CD4046's output stage was really designed to drive current pulses into a capacitive load, with pulses of one polarity charging the capacitor and pulses of the other discharging it; the capacitor integrates the pulses.

Simple phase detectors are normally used to lock their inputs in quadrature, but phase-frequency detectors are used to lock their input signals in phase.

Traditional textbooks and logic-design courses give extensive coverage to avoiding *race hazards* caused by near-simultaneous signals racing through parallel paths in a structure to control a single output. Avoiding such situations is important in many circuits because the outcome is strongly dependent on slight differences in gate speed. The phase-frequency detector is the one circuit whose entire function depends on its built-in ability to *make* both its inputs race. Consequently, it's not easy to home-brew a phase-frequency detector from ordinary logic parts, but fortunately they are available in IC form, usually combined with other functions. The MC4044 is an old stand-alone TTL phase-frequency detector; the MC12040 is an ECL derivative. CMOS versions can be found in the CD4046 PLL chip and in almost all current divider-PLL synthesizer chips.

The race-hazard tendency does cause one problem in phase-frequency detectors: A device's delays and noise, rather than its input signals, control its phase-voltage characteristic in the zero-phase-difference region. This degrades the loop's noise performance and makes its phase-to-voltage coefficient uncertain and variable in a small region — unfortunately, the detector's normal operating range! It's therefore normal to bias operation slightly

Fig 14.41 — Input signals very far off frequency can confuse a simple phase-detector; a phase-frequency detector solves this problem.

away from *exact* phase equality to avoid this problem.

### PLL Synthesizer ICs

Simple PLL ICs have been available since the early 1970s, but most of these contain a crude low-Q VCO and a phase detector. They were intended for general use as tone detectors and demodulators, not as major elements in communication-quality frequency synthesizers. One device well worth noting in this group, however, is the CD4046, which contains a VCO and a pair of phase detectors. The CD4046's VCO is useless for our purposes, but its phase-frequency detector is quite good. Better yet, the CD4046 is a low-cost part and one of the cheapest ways of getting a good phase-frequency detector. Its VCO-disable pin is a definite design plus. Later CD4046 derivatives, the 74HC4046 (CMOS input levels) and 74HCT4046 (TTL compatible input levels) are usable to much higher frequencies

and seem to be more robust, but note that these versions are for +5 V supplies only, whereas the original CD4046 can be used up to 15 V.

More complex ICs specifically intended for frequency synthesizers have since appeared. They normally contain a programmable divider, a phase-frequency detector and a reference divider that usually allows a small choice of division ratios. Usually, the buffer amplifier on these parts' reference input is arranged so that it can be used as part of a simple crystal oscillator. This is adequate for modest frequency accuracy, but an independent TCXO or OCXO is better.

Outside of Japanese equipment, Motorola's range of CMOS synthesizer ICs seem by far the most widely used. The MC145151 brings all of its division-control bits out to individual pins and needs no sequencing for control. It is the best choice if only a few output frequencies are needed, because they can be programmed

via a diode matrix. The MC145151's divide-by- $N$  range is 3 to 16383, controlled by a 14-bit in binary format; the reference can be divided by 8, 128, 256, 512, 1024, 2048, 2410 and 8192. It's possible to operate the MC145151 to 30 MHz, and its phase-frequency detector is similar to that in the CD4046, lacking the MOSFET "Tri-State" output, but with the added benefit of a lock-detector output. The MC145152 is a variant that includes control circuitry for an external dual-modulus prescaler. The choice of external prescaler sets the maximum operating frequency, as well as maximum and minimum division ratios. For some unknown reason, the reference division choices differ from those of the MC145151: 8, 64, 128, 256, 512, 1024, 1160 and 2048. There is also a Tri-State phase-frequency detector output.

The MC145146 is simply an MC145152 with its control data formatted as a 4-bit bus writing to eight addresses. This reduces the number of pins required and allows more data to be input, so the reference divider is fully programmable from 3 to 4095.

## Closing the Loop

The design of a PLL's loop amplifier and loop filtering are inextricably linked. The first task is to recognize the system as a feedback loop and take action to ensure that the loop is stable. The second task is to produce a closed-loop characteristic that best suits the application.

Phase-locked loops have acquired an evil reputation with radio amateurs because some PLL designers are more careful than others. A number of commercially made radios have included poorly designed synthesizers that produced excessive noise sidebands, or wouldn't lock reliably. Some irreproducible designs have been published for home construction that could not be made to work. Many experimenters have sweated over an unstable loop desperately trying anything to get it to lock stably. So the PLL has earned its shady reputation. Because of all of this aversion therapy, very few amateurs are now prepared to attempt to build a PLL.

Note carefully that we are designing a *loop*. All oscillators are loops, and any loop will oscillate when certain conditions are met. Look at the RC phase shift oscillator from which the "Pierce" crystal oscillator is derived (Fig 14.27A). Our PLL is a loop, containing an amplifier and a number of RC sections. It has all the parts needed to make an oscillator. If a loop is unstable and oscillates, there will be an oscillatory voltage superimposed on the VCO tuning voltage. This will produce massive unwanted FM on the output of the

PLL. This is absolutely undesirable, but PLLs have become notorious for the difficulty of fixing their instability problems.

Good loops *can* be designed. Trial and error, intuitive component choice, or "re-using" a loop amplifier design from a different synthesizer, will lead to a very low probability of success. We must resort to mathematics and take a custom approach to each new loop design.

Before you turn to a less demanding chapter, consider this: It's one of Nature's jokes that easy procedures often hide behind a terror-inducing facade. The math you need to design a good PLL may look weird when you see it for the first time and seem to involve some obviously impossible concepts, but it ends in a very simple procedure that allows you to calculate the response and stability of a loop. Professional designers must handle these things daily, and because they like differential equations no more than anyone else does, they use a graphical method to generate PLL designs. (We'll leave proofs in the textbooks, where they belong! Incidentally, if you can get the math required for PLL design under control, as a free gift you will also be ready to do modern filter synthesis and design beam antennas, since the math they require is essentially the same.)

The easy solutions to PLL problems can only be performed during the design phase. We must deliberately design loops with sufficient stability safety margins so that all foreseeable variations in component tolerances, from part-to-part, over temperature and across the tuning range, cannot take the loop anywhere near the threshold of oscillation. More than this, it is important to have a large stability margin because loops with lesser margins will exhibit amplified phase-noise sidebands, and that is another notorious PLL problem that can be designed out.

Back at the beginning of the chapter, near Fig 14.4, the criterion for stability/oscillation of a loop was mentioned: Barkhausen's criterion for oscillation or Nyquist's stability criterion. This time Harry Nyquist is our hero.

A PLL is a negative feedback system, with the feedback opposing the input, this opposition or inversion around the loop amounts to a 180° phase shift. This is the frequency-independent phase shift round the loop, but there are also frequency-dependent shifts that will add in. These will inevitably give an increasing, lagging phase with increasing frequency. Eventually an extra 180° phase shift will have occurred, giving a total of 360° around the loop at some frequency. We are in trouble if the gain around the loop has not dropped

below unity (0 dB) by this frequency.

Note that we are not concerned only with the loop operating frequency. Consider a 30-MHz low-pass filter passing a 21-MHz signal. Just because there is no signal at 30 MHz, our filter is no less a 30-MHz circuit. Here we use the concept of frequency to describe "what would happen if a signal was applied at that frequency."

The next sections show how to calculate the gain and phase response around a loop. They also give a reliable recipe for a loop with sufficient stability margin to be dependable. Note that it does not matter if the phase goes very close to the limit at lower frequencies (it is the crossover point that counts) and that the recipe loop design brings the phase back to 30 to 45° of safety margin before the loop gain passes unity. Let's define some terms first:

## Poles and Zeros

We all think of frequency as stretching from zero to infinity, but let's imagine that additional numbers could be used. This is pure imagination — we can't make signals at *complex* values (with *real* and *imaginary* components) of hertz — but if we try using complex numbers for frequency, some "impossible" things happen. For example, take a simple RC low-pass network shown in Fig 14.42. The frequency response of such a network is well-known, but its phase response is *not* so well-known. The equation shown for the *transfer function*, the "gain" of this simple circuit, is pretty standard, although the  $j$  is included to make it complete and accurately describe the output in phase as well as magnitude ( $j$  is an impossible number, the square root of  $-1$ , usually called an *imaginary* number and used to represent a 90° phase shift).

Although the equation shown in Fig 14.42 was constructed to show the behavior of the circuit at real-world frequencies, there is nothing to stop us from using it to explore how the circuit would behave at impossible frequencies, just out of curiosity. At one such frequency, the circuit goes crazy. At  $f = -j2\pi RC$ , the denominator of the equation is zero, and the gain is infinite! Infinite gain is a pretty amazing thing to achieve with a passive circuit — but because this can only happen at an impossible frequency, it cannot happen in the real world. This frequency is equal to the network's  $-3$  dB frequency multiplied by  $j$ ; it is called a *pole*. Other circuits, which produce real amplitude responses that start to *rise* with frequency, act similarly, but their crazy effect is called a *zero* — an imaginary frequency at which gain goes to zero. The frequency of a circuit's zero is

again  $j$  times its 3-dB frequency (+3 dB in this case).

These things are clearly impossible, but we can map all the poles and zeros of a complex circuit and look at the patterns to determine if the circuit possesses unwanted gain and/or phase bumps across a frequency range of interest. Poles are associated with 3-dB roll-off frequencies and 45° phase lags, zeros are associated with 3-dB “roll-up” frequencies and 45° phase leads. We can plot the poles and zeros on a two-dimensional chart of real and imaginary frequency. (The names of this chart and its axes are results of its origins in *Laplace transforms*, which we don’t need to touch in this discussion.) The traditional names for the axes are used, but we can add labels with clearer meanings.

**What is a Pole?** — A pole is associated with a bend in a frequency response plot where attenuation with increasing frequency increases by 6 dB per octave (20 dB per decade; an octave is a 2:1 frequency ratio, a decade is a 10:1 frequency ratio).

There are four ways to identify the existence and frequency of a pole:

1. A downward bend in a gain vs frequency plot, the pole is at the -3 dB point for a single pole. If the bend is more than 6 dB/octave, there must be multiple poles at this frequency.

2. A 90° change in a phase vs frequency plot, where lag increases with frequency. The pole is at the point of 45° added lag. Multiple poles will add their lags, as above.

3. On a circuit diagram, a single pole looks like a simple RC low-pass filter. The pole is at the -3 dB frequency ( $1/(2\pi RC)$  Hz) Any other circuit that gives the same response will produce a pole at the same frequency.

4. In an equation for the transfer function of a circuit, a pole is a theoretical value of frequency, which would make the equation predict infinite gain. This is clearly impossible, but as the value of frequency will either be absolute zero, or will have an imaginary component, it is impossible to make a signal at a pole frequency.

**What is a Zero?** — A zero is the complement of a pole. Each zero is associated with an upward bend of 6 dB per octave in a gain vs frequency plot. The zero is at the +3 dB point. Each zero is associated with a transition on a phase-vs-frequency plot that *reduces* the lag by 90°. The zero is at the 45° point of this S-shaped transition.

In math, it is a frequency at which the transfer-function equation of a circuit predicts zero gain. This is not impossible in real life (unlike the pole), so zeros can be found at real-number frequencies as well

Fig 14.42 — A simple RC filter is a “pole.”

as complex-number frequencies.

On a circuit diagram, a pure zero would need gain that increases with frequency forevermore above the zero frequency. This implies active circuitry that would inevitably run out of gain at some frequency, which implies one or more poles up there. In real-world circuits, zeros are usually not found making gain go up, but rather in conjunction with a pole, giving a gain slope between two frequencies and flat gain beyond them. Real-world zeros are only found chaperoned by a greater or equal number of poles.

Consider a classic RC high-pass filter. The gain increases at 6 dB per octave from 0 Hz (so there must be a zero at 0 Hz) and then levels off at  $1/(2\pi RC)$  Hz. This leveling off is really a pole, it adds a 6 dB per octave roll off to cancel the roll-up of the zero.

**Poles and Zeros in the Loop Amplifier** — The loop-amplifier circuit used in the example loop has a blocking capacitor

in its feedback path. This means there is no dc feedback. At higher frequencies the reactance of this capacitor falls, increasing the feedback and so reducing the gain. This is an integrator. The gain is immense at 0 Hz (dc) and falls at 6 dB per octave. This points to a pole at 0 Hz. This is true whatever the value of the series resistance feeding the signal into the amplifier inverting input and whatever the value of the feedback capacitor. The values of these components scale the gain rather than shape it. The shape of the integrator gain is fixed at -6 dB per octave, but these components allow us to move it to achieve some wanted gain at some wanted frequency.

At high frequencies, the feedback capacitor in an ordinary integrator will have very low reactance, giving the circuit very low gain. In our loop amplifier, there is a resistor in series with the capacitor. This limits how low the gain can go, in other words the integrator’s downward (with

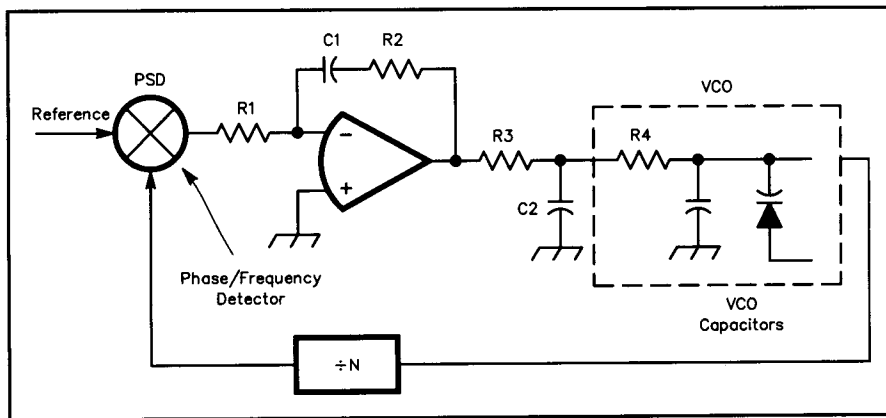

Fig 14.43 — A common loop-amplifier/filter arrangement.

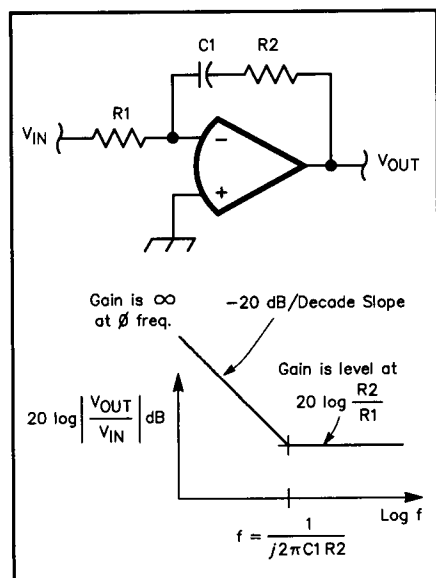

Fig 14.44 — Loop-amplifier detail.

increasing frequency) slope is leveled off. This resistor and capacitor make a zero, and its +6 dB per octave slope cancels the -6 dB per octave slope created by the pole at 0 Hz.

#### Recipe for A PLL Pole-Zero Diagram

We can choose a well-trying loop-amplifier circuit and calculate values for its components to make it suit our loop. Fig 14.43 shows a common synthesizer loop arrangement. The op amp operates as an integrator, with R2 added to level off its falling gain. An integrator converts a dc voltage at its input to a ramping voltage at its output. Greater input voltages yield faster ramps. Reversing the input polarity reverses the direction of the ramp.

The system's phase-frequency detector (connected to work in the right sense) steers the integrator to ramp in the direc-

Fig 14.45 — The loop's resulting pole-zero "constellation."

tion that tunes the VCO toward lock. As the VCO approaches lock, the phase detector reduces the drive to the integrator, and the ramping output slows and settles on the right voltage to give the exact, locked output frequency. Once lock is achieved, the phase detector outputs short pulses that "nudge" the integrator to keep the divided VCO frequency exactly locked in phase with the reference. Now we'll take a look around the entire loop and find the poles and zeros of the circuits.

The integrator produces a -20 dB per decade roll off from 0 Hz, so it has a pole at 0 Hz. It also includes R2 to cancel this slope, which is the same as adding a rising slope that exactly offsets the falling one. This implies a zero at  $f = 1/(2\pi C1R2)$  Hz, as Fig 14.44 shows. R3 and C2 make another pole at  $f = 1/(2\pi C2R3)$  Hz. A VCO usually includes a series resistor that conveys the control voltage to the tuning diode, which also is loaded by various capacitors. This creates another pole.

The VCO generates frequency, while the phase detector responds to phase. Phase is the integral of frequency, so to-

gether they act as another integrator and add another pole at 0 Hz.

**What About the Frequency Divider? —** The frequency divider is like a simple attenuator in its effect on loop response.

Imagine a signal generator that is switched between 10 and 11 MHz on alternate Tuesdays. Imagine that we divide its output by 10. The output of the divider will change between 1 and 1.1 MHz, still on alternate Tuesdays. The divider divides the deviation of the frequency (or phase) modulated signal, but it cannot affect the modulating frequency.

A possible test signal passing around the example loop is in the form of frequency modulation as it passes through the divider, so it is simply attenuated. A divide by N circuit will give  $20 \log_{10}(N)$  dB of attenuation (reduction of loop gain). This completes the loop. We can plot all this information on one *s*-plane, Fig 14.45, a plot sometimes referred to as a PLL system's *pole-zero constellation*.

#### Open-Loop Gain and Phase

Just putting together the characteristics of the blocks around the loop, without allowing for the loop itself, gives us the system's *open-loop* characteristic, which is all we really need.

**What Is Stability? —** Here "open-loop response" means the gain around the loop that would be experienced by a signal at some frequency *if* such a signal were inserted. We do not insert such signals in the actual circuit, but the concept of frequency dependent gain is still valid. We need to ensure that there is insufficient gain, at *all* frequencies, to ensure that the loop cannot create a signal and begin oscillating. More than this, we want a good safety margin to allow for component variations and because loops that are *close* to instability perform poorly.

The loop gain and phase are doing interesting things on our plots at frequencies in the AF part of the spectrum. This does not mean that there is visible operation at those frequencies. Imagine a bad, unstable loop. It will have a little too much loop gain at some frequency, and unavoidable noise will build up until a strong signal is created. The amplitude will increase until nonlinearities limit it. A 'scope view of the tuning voltage input to the VCO will show a big signal, often in the hertz to tens of kilohertz region, often large enough to drive the loop amplifier to the limits of its output swing, close to its supply voltages. As this big signal is applied to the tuning voltage input to the VCO, it will modulate the VCO frequency across a wide range. The output will look like that of a sweep generator on a spectrum analyzer. What is

wrong? How can we fix this loop? Well, the problem may be excessive loop gain, or improper loop time constants. Rather than work directly with the loop time constants, it is far easier to work with the pole and zero frequencies of the loop response. It's just a different view of the same things.

Now imagine a good, stable loop, with an adequate stability safety margin. There will be some activity around the loop: the PSD (phase detector) will demodulate the phase noise of the VCO and feed the demodulated noise through the loop amplifier in such a way as to cancel the phase noise. This is how a good PLL should give *less* phase noise than the VCO alone would suggest. In a good loop, this noise will be such a small voltage that a 'scope will not show it. In fact, connecting test equipment in an attempt to measure it can usually *add* more noise than is there.

Finally, imagine a poor loop that is only just stable. With an inadequate safety margin, the action will be like that of a Q multiplier or a regenerative receiver close to the point of oscillation: There will be an amplified noise peak at some frequency. This spoils the effect of the phase detector trying to combat the VCO phase noise and gives the opposite effect. The output spectrum will show prominent bumps of exaggerated phase noise, as the excess noise frequency modulates the VCO.

Now, let's use the pole-zero diagram as a graphic tool to find the system open-loop gain and phase. As we do so, we need to keep in mind that the frequency we have been discussing in designing a loop response is the frequency of a theoretical test signal passing around the loop. In a real PLL, the loop signal exists *in two forms*: as sinusoidal voltage between the output of the phase detector and the input of the VCO, and as a sinusoidal modulation of the VCO frequency in the remainder of the loop.

With our loop's pole-zero diagram in hand, we can pick a frequency at which we want to know the system's open-loop gain and phase. We plot this value on the graph's vertical (Real Frequency) axis and draw lines between it and each of the poles and zeros, as shown in Fig 14.46. Next, we measure the lengths of the lines and the "angles of elevation" of the lines. The loop gain is proportional to the product of the lengths of all the lines to zeros *divided by* the product of all the lengths of the lines to the poles. The phase shift around the loop (lagging phase equates to a positive phase shift) is equal to the sum of the pole angles minus the sum of the zero angles. We can repeat this calculation for a number of different frequencies and draw graphs of the loop gain and phase versus frequency.

All the lines to poles and zeros are hy-

potenuses of right triangles, so we can use Pythagoras's rule and the tangents of angles to eliminate the need for scale drawings. Much tedious calculation is involved because we need to repeat the whole business for each point on our open-loop response plots. This much tedious calculation is an ideal application for a computer.

The procedure we've followed so far gives only *proportional* changes in loop gain, so we need to calculate the loop gain's *absolute* value at some (chosen to be easy) frequency and then relate everything to this. Let's choose 1 Hz as our reference. (Note that it's usual to express angles in radians, not degrees, in these calculations and that this normally renders frequency in peculiar units of *radians per second*. We can keep frequencies in hertz if we remember to include factors of  $2\pi$  in the right places. A frequency of 1 Hz =  $2\pi$  radians/second, because  $2\pi$  radians =  $360^\circ$ .)

We must then calculate the loop's proportional gain at 1 Hz from the pole-zero diagram, so that the constant of proportion can be found. For starters, we need a reasonable estimate of the VCO's *voltage-to-frequency gain* — how much it changes frequency per unit change of tuning voltage. As we are primarily interested in stability, we can just take this number as the slope, in Hertz per volt, at the steepest part of voltage-vs-frequency tuning characteristic, which is usually at the low-frequency end of the VCO tuning range. (You can characterize a VCO's voltage-versus-frequency gain by varying the bias on its tuning diode with an adjustable power supply and measuring its tuning characteristic

with a voltmeter and frequency counter.)

The loop divide-by-N stage divides our theoretical modulation — the tuning corrections provided through the phase detector, loop amplifier and the VCO tuning diode — by its programmed ratio. The worst case for stability occurs at the divider's lowest N value, where the divider's "attenuation" is least. The divider's voltage-vs-frequency gain is therefore  $1/N$ , which, in decibels, equates to  $-20 \log(N)$ .

The change from frequency to phase has a voltage gain of one at the frequency of 1 radian/second —  $1/(2\pi)$ , which equates to  $-16$  dB, at 1 Hz. The phase detector will have a specified "gain" in volts per radian. To finish off, we then calculate the gain of the loop amplifier, including its feedback network, at 1 Hz.

There is no need even to draw the pole-zero diagram. Fig 14.47 gives the equations needed to compute the gain and phase of a system with up to four poles and one zero. They can be extended to more singularities and put into a simple computer program. Alternatively, you can type them into your favorite spreadsheet and get printed plots. The computational power needed is trivial, and a listing to run these equations on a Hewlett-Packard HP11C (or similar pocket calculator, using RPN) is available from ARRL HQ for an SASE. (Contact the Technical Department Secretary and ask for the 1995 *Handbook* PLL design program.)

Fig 14.48 shows the sort of gain- and phase-versus-frequency plots obtained from a "recipe" loop design. We want to know where the loop's phase shift equals, or becomes more negative than,  $-180^\circ$ .

Fig 14.46 — Calculating loop gain and phase characteristics from a pole-zero diagram.

$$\text{Open loop gain (dB)} = 20 \log \left[ \frac{\sqrt{P_1^2 + 1} \sqrt{P_2^2 + 1} \sqrt{P_3^2 + 1} \sqrt{P_4^2 + 1} \sqrt{Z^2 + f^2}}{\sqrt{P_1^2 + f^2} \sqrt{P_2^2 + f^2} \sqrt{P_3^2 + f^2} \sqrt{P_4^2 + f^2} \sqrt{Z^2 + 1}} \times 10^{\frac{\text{unity freq gain}}{20}} \right]$$

$$\text{Phase (lead)} = \tan^{-1}\left(\frac{f}{Z}\right) - \tan^{-1}\left(\frac{f}{P_1}\right) - \tan^{-1}\left(\frac{f}{P_2}\right) - \tan^{-1}\left(\frac{f}{P_3}\right) - \tan^{-1}\left(\frac{f}{P_4}\right)$$

$f$  is the frequency of the point to be characterized.  $P_1, P_2, P_3, P_4, Z$  are the frequencies of the poles and zero (all in same units!)

Fig 14.47 — Pole-zero frequency-response equations capable of handling up to four poles and one zero.

Fig 14.48 — An open-loop gain/phase plot.

Added to the  $-180^\circ$  shift inherent in the loop's feedback (the polarity of which must be negative to ensure that the phase detector drives the VCO toward lock instead of away from it), this will be the point at which the loop itself oscillates — if any loop gain remains at this point. The game is to position the poles and zero, and set the unit frequency gain, so that the loop gain falls to below 0 dB before the  $-180^\circ$  line is crossed.

At the low-frequency end of the Fig 14.48 plots, the two poles have had their effect, so the gain falls at 40 dB/decade, and the phase remains just infinitesimally on the safe side of  $-180^\circ$ . The next influence is the zero, which throttles the gain's fall back to 20 dB/decade and peels the phase line away from the  $-180^\circ$  line. The zero would eventually bring the phase back to  $90^\circ$  of lag, but the next pole bends it back before that and returns the gain slope back to a fall of 20 dB/decade. The last pole, that attributable to the VCO, pushes the phase over the  $-180^\circ$  line.

It's essential that there not be a pole

between the 0-Hz pair and the zero, or else the phase will cross the line early. In this example, the R3-C2 pole and the zero do all the work in setting this critical portion of the loop's response. Their frequency spacing should create a phase bump of 30 to  $45^\circ$ , and their particular frequency positions are constrained as a compromise between sufficient loop bandwidth and sufficient suppression of reference-frequency sidebands. We know the frequency of the loop amplifier zero (that contributed by R1 and C1), so all we need to do now is design the loop amplifier to exhibit a frequency response such that the open-loop gain passes through 0 dB at a frequency close to that of the phase-plot bump.

This loop-design description may have been hard to follow, but a loop amplifier can be designed in under 30 minutes with a pocket calculator and a little practice. The high output impedance of commonly used CMOS phase detectors favors loop amplifiers based on FET-input op amps and allows the use of high-impedance RC networks (large capacitors can therefore be avoided in their design). LF356 and TL071 op amps have proven successful in loop-amplifier service and have noise characteristics suited to this environment.

To sum up, the recipe gives a proven pole zero pattern (listed in order of increasing frequency):

1. Two poles at 0 Hz (one is the integrator, the other is implicit in all PLs)
2. A zero controlled by the RC series in the loop amplifier feedback path.
3. A simple RC low-pass pole
4. A second RC low-pass pole formed by the resistor driving the capacitive load of the tuning voltage inputs of the VCO

To design a loop: Design the VCO, divider, PSD and find their coefficients to get the loop gain at unit frequency (1 Hz), then, keeping the poles and zeros in the above order, move them about until you get the same  $45^\circ$  phase bump at a frequency close to your desired bandwidth. Work out how much loop-amplifier unit-

frequency gain is needed to shift the gain-vs-frequency plot so that 0-dB loop gain occurs at the center of the phase bump. Then calculate R and C values to position the poles and zero and the feedback-RC values to get the required loop amplifier gain at 1 Hz.

**To Cheat** — You can scale the example loop to other frequencies: Just take the reactance values at the zero and pole frequencies and use them to scale the components, you get the nice phase plot bump at a scaled frequency. Even so, you still must do the loop-gain design.

Don't forget to do this for your lowest division factor, as this is usually the least stable condition because there is less attenuation. Also, VCOs are usually most sensitive at the low end of their tuning range.

### Noise in Phase-Locked Loops

Differences in Q usually make the phase-noise sidebands of a loop's reference oscillator much smaller than those of the VCO. Within its loop bandwidth, a PLL acts to correct the phase-noise components of its VCO and impose those of the reference. Dividing the reference oscillator to produce the reference signal applied to the phase detector also divides the deviation of the reference oscillator's phase-noise sidebands, translating to a 20-dB reduction in phase noise per decade of division, a factor of  $20 \log(M)$  dB, where M is the reference divisor. Offsetting this, within its loop bandwidth the PLL acts as a frequency *multiplier*, and this multiplies the deviation, again by 20 dB per decade, a factor of  $20 \log(N)$  dB, where N is the loop divider's divisor. Overall, the reference sidebands are increased by  $20 \log(N/M)$  dB. Noise in the dividers is, in effect, present at the phase detector input, and so is increased by  $20 \log(N)$  dB. Similarly, op-amp noise can be calculated into an equivalent phase value at the input to the phase detector, and this can be increased by  $20 \log(N)$  to arrive at the effect it has on the output.

Phase noise can be introduced into a PLL by other means. Any amplifier stages between the VCO and the circuits that follow it (such as the loop divider) will contribute some noise as will microphonic effects in loop- and reference-filter components (such as those due to the piezoelectric properties of ceramic capacitors and the crystal filters sometimes used for reference-oscillator filtering). Noise on the power supply to the system's active components can modulate the loop. The fundamental and harmonics of the system's ac line supply can be coupled into the VCO directly or by means of ground loops.

Fig 14.49 shows the general shape of the PLL's phase noise output. The dashed curve shows the VCO's noise performance when unlocked; the solid curve shows how much locking the VCO to a cleaner reference improves its noise performance. The two noise bumps are a classic characteristic of a phase-locked loop. If the loop is poorly designed and has a low stability margin, the bumps may be exaggerated — a sign of noise amplification due to an overly peaky loop response.

Exaggerated noise bumps can also occur if the loop bandwidth is less than optimum. Increasing the loop bandwidth in such a case would widen the band over which the PLL acts, allowing it to do a better job of purifying the VCO — but this might cause other problems in a loop that's deliberately bandwidth-limited for better suppression of reference-frequency sidebands. Immense loop bandwidth is not desirable, either: Farther away from the carrier, the VCO may be so quiet on its own that widening the loop would make it worse.

### Multiloop Synthesizers

The trade-off between small step size (resolution) and all other PLL performance parameters has already been mentioned. The *multiloop synthesizer*, a direct synthesizer constructed from two or more PLL synthesizers, is one way to break away from this trade-off. Fig 14.50, the block diagram of a five-loop synthesizer, reflects the complexity found in some professional receivers. All of its synthesis loops run with a 100-kHz step size, which allows about a 10-kHz loop bandwidth. Such a system's noise performance, settling time after a frequency change and reference-sideband suppression can all be very good.

Cost concerns generally render such elaboration beyond reach for consumer-grade equipment, so various cut-down versions, all of which involve trade-offs in performance, have been used. For ex-

Fig 14.49 — A PLL's open- and closed-loop phase-noise characteristics. The noise bumps at the crossover between open- and closed-loop characteristics are typical of PLLs; the severity of the bumps reflects the quality of the system's design.

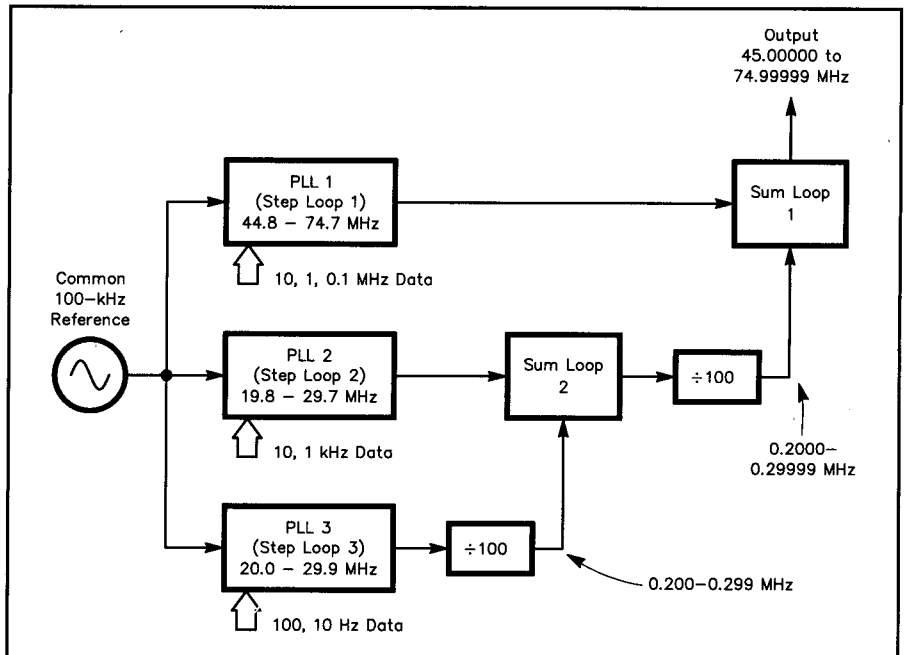

Fig 14.50 — A five-loop synthesizer.

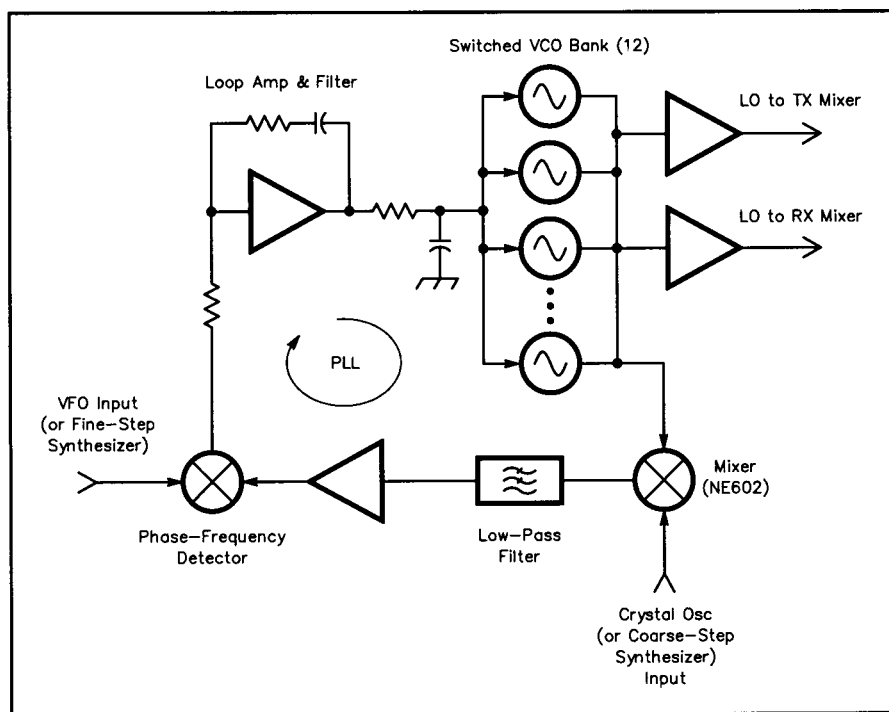

ample, a three-loop machine can be made by replacing the lower three loops with a single loop that operates with a 1-kHz step size and accepting the slower frequency stepping determined by the narrow loop bandwidth this involves.

### A Summing-Loop Synthesizer

Radio amateurs have tended to refer only to relatively modern radio gear as "synthesized," but any means of generating a frequency by adding and/or subtracting the frequencies of two or more signal

sources also qualifies as frequency synthesis. It's therefore true to say that radio amateurs have used frequency-synthesized equipment for decades, with the synthesizer — in radios such as the R. L. Drake 4-line (in which the technique was termed *premixing*) — usually taking the form of a mixer, a crystal oscillator (one crystal per band segment) and a bank of switched filters.

Hams who build their own equipment have also successfully used this form of frequency synthesis. Among them, Ian

**Fig 14.51** — In a summing-loop synthesizer, a mixer takes the place of the divider. The drawing diagrams a design by G3ROO and GM4ZNX that uses a 5- to 5.5-MHz VFO and crystal oscillators to provide LO signals appropriate for ham-band operation from 1.8 through 29.7 MHz with a 9-MHz IF.

Keyser, G3ROO, has designed and built several entire, multimode transceivers for the HF bands, of which many copies have been built. All have been based on the proven formula of a 9-MHz IF and a 5- to 5.5-MHz VFO upconverted to the proper LO frequency (desired signal + 9 MHz) by signals from a bank of switched crystal oscillators.

Misadjusting the nontrivial post-mixer filtering in such systems can cause spurious signals and out-of-band operation, and few home equipment builders have the test equipment necessary to adjust such filters easily and surely. G3ROO therefore decided to try *summing loop* synthesis, the means taken in a number of popular commercial ham transceivers from the mid- 1970s to mid-1980s, in his latest transceiver as a means of avoiding these difficulties.

A summing-loop synthesizer uses a mixer instead of a programmable divider, producing its output frequency by adding (or subtracting) the frequency of a high-stability HF VFO, which may be a VXO, VFO or PLL-synthesized, to (from) the frequency of a crystal oscillator. A circuit designed by G3ROO and GM4ZNX does this job in the latest G3ROO transceiver. **Fig 14.51** shows its block diagram

This loop can be easily aligned with just a DMM. In an attempt to counter the bad

reputation of PLLs, it has been designed to have very dependable stability. Although it does not attempt to set a record for low phase noise, it is a circuit designed to be robust, easy to set up and to build the confidence of constructors venturing into a new area. The circuit (**Fig 14.52**) was first published in the G QRP Club's journal, *SPRAT* (No. 70, Spring 1992). At least 10 successful copies, all trouble-free, were built before the Radio Society of Great Britain's *Radio Communication* carried a construction article about it in December 1993. This loop was originally used to combine a 5- to 5.5-MHz VFO with the output from one of a bank of crystal oscillators. Suitable crystal oscillators and VFOs can be found earlier in this chapter. With a coil change, the G3PDM VFO (**Fig 14.15**) can be used to cover 5 to 5.5 MHz. Ian has chosen to operate the crystal oscillators above the desired output frequency, which makes the VFO tune "backwards" — increasing VFO frequency equates to decreasing loop output frequency — because crystals are commonly used on these frequencies in many of the older transceivers (the prototype used the crystal oscillator board from a Yaesu FT-707). **Table 14.3** lists the necessary conversion-crystal frequency, VCO tuned-circuit padding capacitance and VCO-inductor winding data on a band-by-band basis.

**Fig 14.52** — The G3ROO/GM4ZNX summing-loop PLL phase-locks its VCO to the frequency difference between a crystal oscillator and 5- to 5.5-MHz VFO (these circuits are not shown; see text). **Table 14.3** lists the conversion-crystal frequency, VCO tuned-circuit padding capacitance ( $C_X$ ) and VCO inductor data required for each band. Any 5- to 5.5-MHz VFO capable of at least 2.5 mW (4 dBm) output with a 50- $\Omega$  load — 1 V P-P — can drive the circuit's VFO input.

$C_X$ ,  $C_2$ ,  $C_3$  — NP0 or C0G ceramic, 10% or tighter tolerance.

$C_{65}$ ,  $C_{66}$ ,  $C_{67}$  — NP0, C0G or general-purpose ceramic, 10% tolerance or tighter.

$D_{0A}$ ,  $D_{0B}$  — BB204 dual, common-cathode tuning diode (capacitance per section at 3 V, 39 pF) or equivalent. The ECG617, NTE617 and MV104 are suitable dual-diode substitutes, or use pairs of 1N5451s (39 pF at 4 V) or MV2109s (33 pF at 4V).

$D_1$  — BA244 switching diode. The 1N4152 is a suitable substitute.

$L_1$  — Variable inductor; see **Table 14.3** for value.

$L_{13}$ ,  $L_{14}$  — 22- $\mu$ H choke, 20% tolerance or better (Miller 70F225A1, 78F270J, 8230-52, 9250-223; Mouser 43LQ225; Toko 144LY-220J [Digi-Key TK4232] suitable).

$T_1$  — 6 bifilar turns of #28 enameled wire on an FT-37-72 ferrite toroid ( $\approx 30 \mu$ H per winding).

$U_2$  — 74HC4046 or 74HCT4046 PLL IC (CD4046 unsuitable; see text).

The summing loop's phase-frequency detector ( $U_2$ , a 74HC4046 or 74HCT4046) steers the integrator and tunes whichever VCO is selected to keep its inputs (pin 3 and 14) locked equal in frequency. The VFO, applied to pin 14, serves as a variable reference. Via  $Q_{13}$ , pin 3 of the phase detector receives the output of  $U_1$ , an NE602AN, which mixes signals from the VCO and crystal oscillator appropriate to the band in use.  $U_1$ 's output contains sum and difference frequencies, but the phase detector responds only to the *difference* ( $f_{XO} - f_{VCO}$ , where  $f_{XO}$  is the crystal oscillator frequency and  $f_{VCO}$  is the VCO frequency) because of its close proximity to its reference signal (the VFO). Consequently, the difference between the VCO and crystal oscillator frequencies must equal the VFO frequency, and the loop operates as a *subtractor*.

You can use this loop to *add* frequencies (adding the signal from a 13-MHz crystal to the 5-MHz VFO for output at 18 MHz, for instance) by changing the crystal frequency and transposing the phase detector input signals (VFO to pin

**Table 14.3****Band-Specific Component Data for the Summing Loop**

Band (MHz)	Output Range (MHz)	Crystal Frequency (MHz)	$C_x$ (pF)	VCO Coil
1.5-2.0	10.5-11.0	16.0	0	20 turns on Toko 10K-series inductor form ( $\approx 4.29 \mu\text{H}$ )
3.5-4.0	12.5-13.0	18.0	0	16 turns on Toko 10K-series inductor form ( $\approx 3.03 \mu\text{H}$ )

The Toko 10K-series forms have four-section bobbins. The VCO-coil windings for 160 through 30 m are therefore split into four equal sections (for example, 5 + 5 + 5 + 5 turns for the 160-m coil).

3, U2 output [via Q13], to pin 14). The phase detector inputs must be transposed for adding to keep the loop feedback negative; otherwise, the phase detector would drive the VCO in the wrong direction — away from lock instead of toward it. For this reason, you cannot have some crystals above and some crystals below the output frequency driving the same loop — unless you also build in means to transpose the phase detector inputs as necessary.

The loop's phase/frequency detector is a high-speed CMOS IC, the 74HC4046 or 74HCT4046. This part, which is faster, more robust and better behaved than the original CD4046, has a power-supply range of 2 to 6 V. (The CD4046 is not recommended in this circuit because its limited high-frequency response may make it unreliable.) The internal VCO in this chip is not worth using for our purposes, so we disable it by tying pin 5 high. Both inputs can be driven by ac-coupled signals, but many CMOS parts are prone to damage if their inputs exceed their supply voltage or go below ground potential, so the Fig 14.52 circuit includes clipping diodes to protect U2 against transients at turn on. Assuming a VFO input level of 1 V P-P, R84, VFO level, can be set to maximum. (You may need to turn it down for higher VFO input levels, but its setting is uncritical.)

The loop amplifier uses a JFET-input op amp (a TL072) with both inputs biased to +2.5 V. R61 and C76 give a zero in the open-loop response at 2 kHz. C76 and R60 set the integrator gain to 3.4 at 1 Hz. (This gain is much lower than the usual value for a loop with a programmable divider, because this loop does not have to make up for reduction in loop gain that occurs in division.) R62 and C78 give the next pole,

at 10 kHz. R63 is included as a result of the use of earlier-generation PC-board versions of the circuit. Its value is noncritical and can be anything from 0 to the value shown in Fig 14.52 because it merely connects the R62/C78 network to U3B, which isolates these parts from R64 and C79. They form the fourth pole, at 160 kHz. (The poles in the VCOs themselves are all much higher and can be ignored.) The overall loop design conforms exactly to the "recipe" described earlier and was designed using an HP11C pocket calculator program implementing the equations in Fig 14.47.

In normal operation, TP1 and TP2 are joined, completing the loop. For troubleshooting, TP1 can be connected to TP3 instead, breaking the loop and placing a fixed 5-V tuning voltage on all the tuning diodes. This should put the VCO frequencies somewhere within their normal operating range, so that the oscillators, amplifiers and mixer can be checked. The phase detector should drive the loop amplifier to one end of its output-voltage swing, which end depending on whether the VCO frequency is too high or too low. Tuning the VFO across its range should cause this to change, and the output voltage of the loop amplifier/filter system should change over to the other extreme.

All of the VCOs remain connected to the tuning-voltage line at all times. The VCOs are selected merely by switching +12 V to the desired one, applying power to its JFET and turning on its output switching diode, which connects its output to R49, VCO OUTPUT.

R49 allows adjustment of the TX LO and RX LO output level to suit whatever the system is driving. The TX LO and RX LO amplifiers are capable of 500 mV RMS

output, which is sufficient for driving a Plessey SL6440 mixer directly. Power amplification will be needed to drive a diode-ring mixer, however. The output amplifiers are designed to keep signals from *entering* the system and to prevent unwanted signals at either output from reaching the other output. This may sound odd, but if you use, say, the TX LO output to drive something noisy, like a frequency counter, its amplifier's reverse isolation provides valuable protection against unwanted signals reaching whatever is connected to the RX LO output — say, a receiver mixer. The output amplifiers' output impedance is roughly equal to their collector resistances (680  $\Omega$ ), but coax terminated in 50  $\Omega$  can be driven successfully.

R50, VCO LEVEL, sets the VCO signal applied to the NE602. It can be set at maximum if the VCO circuit in Fig 14.52 is used, but has been included in case anyone wants to experiment with different devices and values in the VCO circuits, which could change their output level. VCO drive to the NE602 should be roughly 200 mV P-P.

The NE602's full differential output is used to avoid the need for a gain stage between it and the phase detector. The low-pass filter (C65, C66, C67, L13 and L14) passes the VFO tuning range (5 to 5.5 MHz) while rolling off the higher-frequency VCO signals. Ordinary 20%-tolerance chokes with Qs of 30 or more will work adequately at L13 and L14.

To adjust the unit, connect TP1 to TP3. Select each band in turn and adjust the frequency of the appropriate VCO to about the middle of the output frequency range for that band. Reconnect TP1 to TP2 to close the loop. With the

loop locked, for each band in turn, tune the VFO to the center of its range (5.25 MHz) and check that the voltage on TP1 is roughly 5 V. This confirms that all ranges can lock. Now we need only check that the diode tuning voltage doesn't go too low or too high at the band edges. For each range in turn, tune the VFO from 5.5 to 5 MHz while monitoring the tuning voltage on TP1. It must not go below 3 V or above 9 V or there will not be insufficient margin for aging and temperature effects. (Ideally, the voltage should be 4 V at the low-frequency end of each band.) Adjust the cores of the VCO inductors as necessary to optimize the tuning-voltage swing.

Summing loops have a serious drawback: If the VCO is ever, even momentarily, tuned to a frequency on the opposite side of the crystal oscillator, the sense of the feedback via the phase/frequency detector changes, and positive feedback forces the VCO even further from the correct output frequency. The loop can latch-up far from lock. This design avoids that risk by using a bank of narrow-range VCOs — an approach with the added advantage that narrow-range VCOs can give better noise performance than wide-range ones. Designing a summing loop around a lower-frequency VFO than that used here would move the VCO frequencies closer to the crystal oscillator frequencies, requiring careful design to avoid latch-up.

A PLL's tuning voltage is a superb indicator of its health. A quick check with a voltmeter as the loop is tuned across its range will show if aging has brought the loop close to unlocking and when the VCOs need readjusting.

### Lock Detectors

It's a good idea, especially on a transmitter, to have some warning if a synthesizer loses lock. Many phase-detector chips have auxiliary outputs that, with a little filtering and amplification, can be used to light warning lights and inhibit transmission.

Another method is to monitor the tuning voltage, where the loop amplifier is an integrator. The rest of the loop can be thought of as a dc feedback path around the loop amplifier — and the loop amplifier has no local feedback at dc. If the loop fails, the amplifier will drift off into saturation close to either its + or – supply voltage. Window comparator circuitry can be used to continuously monitor the tuning voltage to confirm that it stays within thresholds set between the normal tuning-

voltage range and the limits of the op amp's output swing.

### DIRECT DIGITAL SYNTHESIS

Direct digital synthesis (DDS) is covered in this *Handbook's* **Digital Signal Processing** chapter, but as good consumer-affordable DDSs don't yet cover the full tuning range required for even an MF/HF transceiver, we need to consider how to exploit them in conjunction with phase-locked loops. The VFO in the summing loop just described could be replaced by a DDS covering 5 to 5.5 MHz. A single loop with a programmable divider could be used in place of the crystal-oscillator bank. The result would be very close to the approach used in the latest generation of commercial Amateur Radio gear. That manufacturers advertise them as using direct digital synthesis has given some people the impression that their synthesizers consist entirely of DDS. In fact, the DDS in modern ham transceivers replaces the lower-significance "interpolation" loops in what otherwise would be regular multiloop synthesizers.

This is not to say that the DDS in our current ham gear is not a great improvement over the size, complexity and cost of what it replaces. Its random noise sidebands are usually excellent, and it can execute fast, clean frequency changes. The latest devices do 32-bit phase arithmetic and so offer over a billion frequency steps, which translates into a frequency resolution of a few *millihertz* with the usual clock rates for our applications — so the old battle for better resolution and low cost has already been won. Direct digital synthesis is not without a few problems, but fortunately, hybrid structures using PLL and DDS can allow one technique to compensate for the weaknesses of the other.

The prime weakness of the direct digital synthesizer is its quantization noise. A DDS cannot construct a *perfect* sine wave because each sample it outputs must be the nearest available voltage level from the set its DAC can make. So a DDS's output waveform is really a series of steps that only approximate a true sine wave.

We can view a DDS's output as an ideal sine wave plus an irregular "error" waveform. The spectrum of the error waveform is the set of unwanted frequency components found on the output of the DDS. Quantization noise is not the only source of unwanted DAC outputs. DACs can also give large output spikes, called *glitches*, as they transit

from one level to another. In some DACs, glitches cause larger unwanted components than quantization. These components are scattered over the full frequency range passed by the DDS's low-pass filter, and their frequencies shift as the DDS tunes to different frequencies. At some frequencies, a number of components may coincide and form a single, larger component.

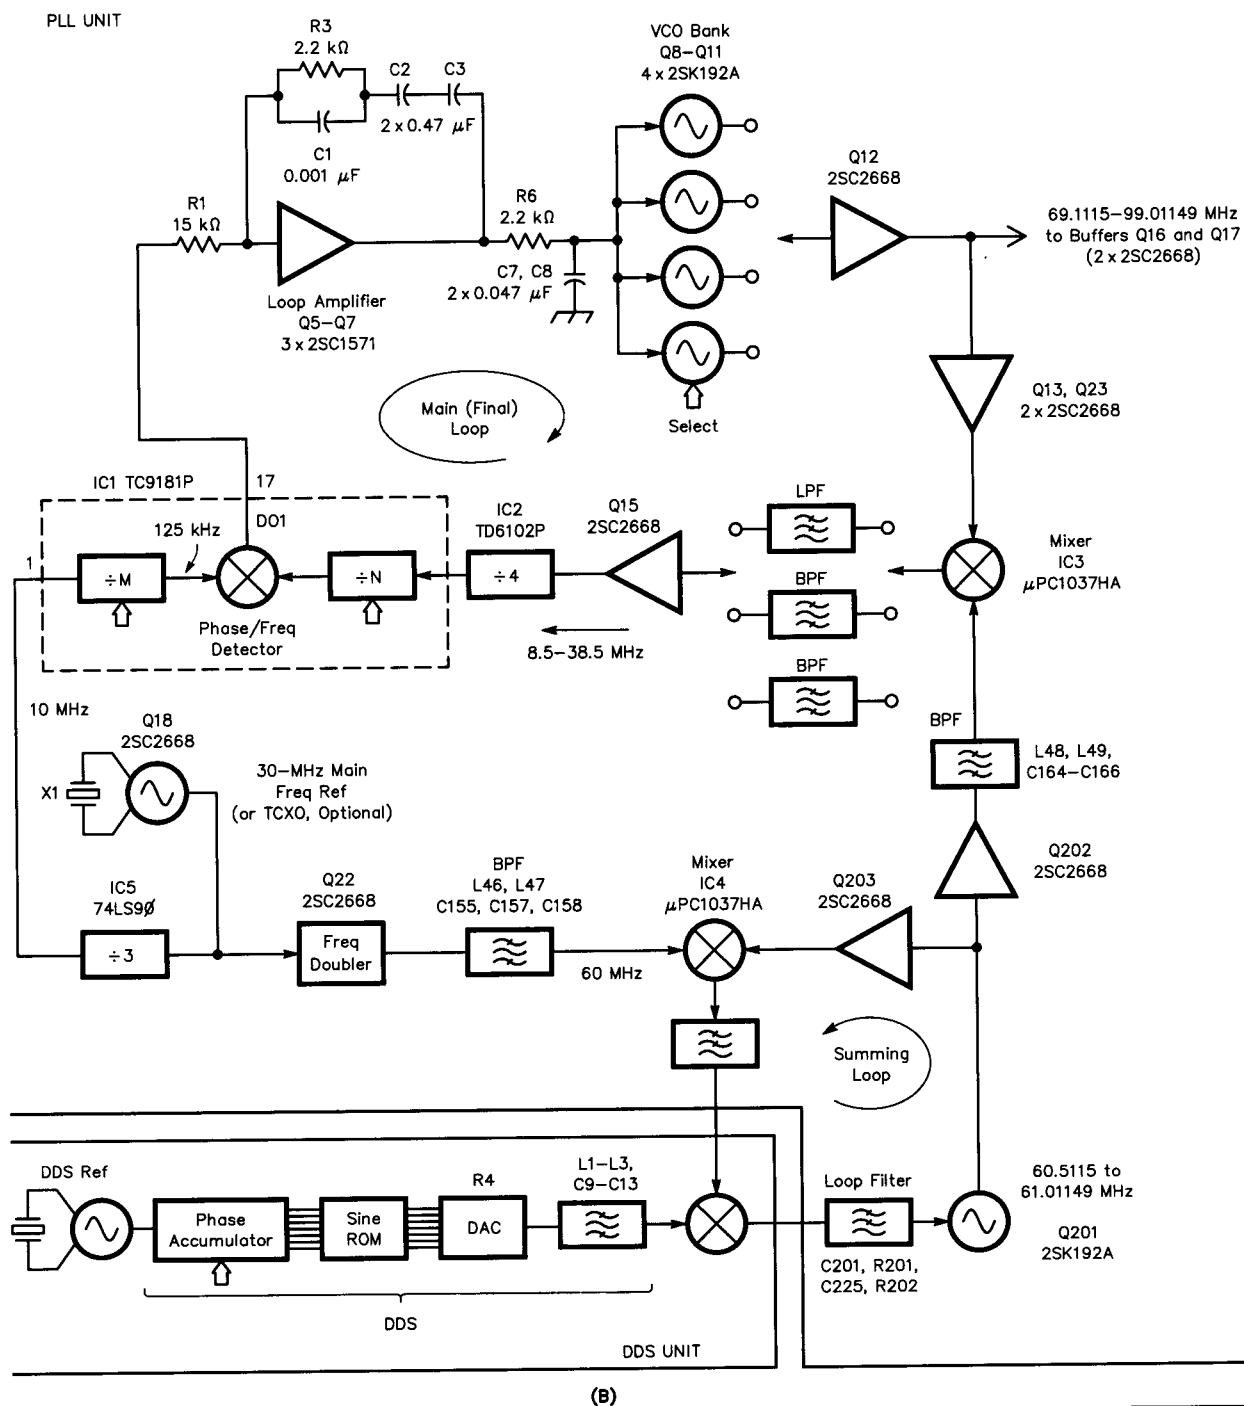

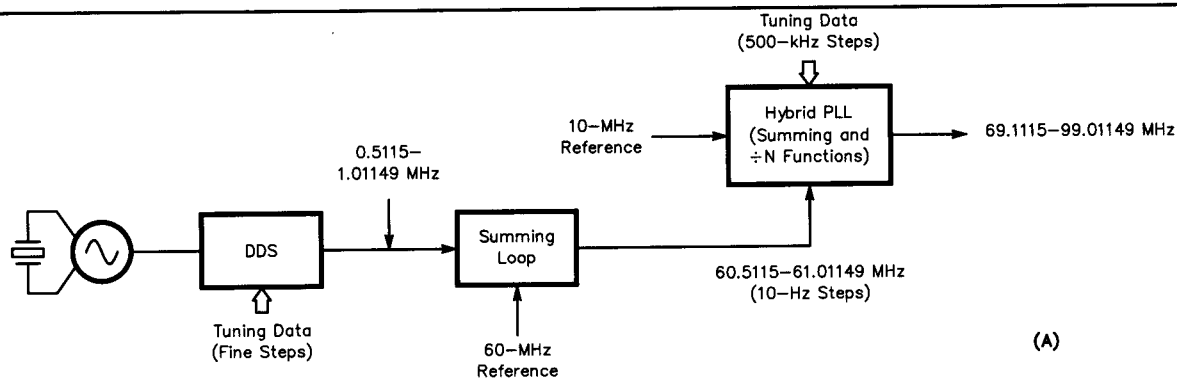

A summing loop PLL acts as a tracking filter, with a bandwidth measured in kilohertz. Acting on a DDS's output, a summing loop passes only quantization components close to the carrier. A system designer seeking to minimize the DDS's noise contribution must choose between using a loop bandwidth narrow enough to filter the DDS (thereby reducing the loop's ability to purify its VCO) or a more expensive low "glitch energy" DAC with more bits of resolution (allowing greater loop bandwidth and better VCO-noise control).

Complex ICs containing most of a DDS have been on the market for over 10 years, steadily getting cheaper, adding functions and occasionally taking onboard the functions of external parts (first the sine ROM, now the DAC as well). The Analog Devices AD7008 is an entire DDS (just add a low-pass filter . . .) on one CMOS chip. It includes a 10-bit DAC (fast enough for the whole system to clock at 50 MHz) and some digital-modulation hardware.

For the home-brewing amateur, DDS's first drawback is that these devices must receive their frequency data in binary form, loaded via a serial port, and this really forces the use of a microprocessor system in the radio. DDS's second drawback for experimenters is that surface-mount packages are becoming the norm for DDS ICs. Offsetting this, the resulting simplification of an entire synthesizer to a few ICs should cause more people to experiment with them.

### EXPLORING THE SYNTHESIZER IN A COMMERCIAL MF/HF TRANSCEIVER

Few people would contemplate building an entire synthesized transceiver, but far more will need to understand enough of a commercially built one to be able to fix it or modify it. Choosing a radio to use as an example was not too difficult. The ICOM IC-765 received high marks for its clean synthesizer in its *QST* Product Review, so it certainly has a synthesizer worth examining. We are grateful to ICOM America for their permission to reprint the IC-765's schematic in the dis-

←  
**Fig 14.53 — Simplified (A) and detailed (B) block diagrams of the ICOM IC-765 frequency synthesizer.**

cussion to follow.

**Fig 14.53A** shows a simplified block diagram of the IC-765's synthesizer. It contains one DDS and two PLLs. Notice that the DDS has its own frequency-reference oscillator. DDSs usually use binary arithmetic in their phase accumulators, so their step size is equal to their clock (reference) frequency divided by a large, round, binary number. The latest 32-bit machines give a step size of  $1/(2^{32})$  of their clock frequency, that is, a ratio of  $1/4,294,967,296$ . This means that if we want, say, a 10-Hz step size, we must have a peculiar reference frequency so that the increment of the DDS is a submultiple of 10 Hz. This is what ICOM designers chose. One alternative would be to use a convenient reference frequency (say 10 MHz) and accept a strange synthesizer step size. A 32-bit machine clocked at 10 MHz will give a step size of 0.002328... Hz. It would be simple to have the radio's microprocessor select the nearest of these very fine steps to the frequency set by the user, giving the user the appearance of a 10-Hz step size. An error of  $\pm 1.2$  millihertz is trivial compared to the accuracy of all usual reference oscillators.

Installing the IC-765's optional high-stability 30-MHz TCXO does nothing to improve the accuracy of the radio's DDS section as it uses its own reference. The effect of the stability and accuracy of the DDS reference on the overall tuned frequency, however, is smaller than that of the main reference.

The DDS runs at a comfortably low frequency (0.5115 to 1.01149 MHz) to ease the demands placed on DAC settling time. The final loop needs a signal near 60 MHz as a summing input. Just mixing the DDS with 60 MHz would require a complex filter to reject the image. The IC-765 avoids this by using a summing loop. The summing loop VCO must only tune from 60.5115 to 61.01149 MHz, plus some margin for aging and temperature, but care is needed in this circuit because, as in the home-brew summing loop described earlier, the loop may latch up if this VCO goes below 60 MHz.

The final loop is a normal PLL with a programmable divider, but instead the VCO is not fed directly into the divider — it is mixed down by the 60.5115- to 61.01149-MHz signal first. The final loop uses a bank of four switched VCOs, each

one covering a one fourth of the system's full output range of 69.1115 to 99.01149 MHz. This mix-down feeds an 8.5- to 38.5-MHz signal into the programmable divider. To remove unwanted mixer outputs over this range, three different, switched filters are needed before the signal is amplified to drive the divider.

**Fig 14.53B** shows the synthesizer in greater detail. The programmable divider/PSD chip used (IC1, a TC9181P) will not operate up to 38 MHz, so a prescaler (IC2, a TD6102P) has been added before its input. This is a fixed divide-by-four prescaler, which forces the phase detector to be run at one-fourth of the step size, at 125 kHz. (A dual-modulus prescaler would have been very desirable here because it would allow the PSD to run at 500 kHz, easing the trade-off between reference-frequency suppression and loop bandwidth. Unfortunately, the lowest division factor necessary is too low for the simple application of any of the common ICs with prescaler controllers.)

**Fig 14.54** shows the full circuit diagram of the IC-765's synthesizer. The DDS is on a small subboard, DDS unit (far right). IC1, an SC-1051, appears to be a custom IC, incorporating the summing loop's phase accumulator and phase detector. The DDS's sine ROM is split into two parts: IC2, an SC-1052; and IC3, an SC-1053. IC4 and IC5, both 74HCT374s, are high-speed-CMOS flip-flops used as latches to minimize glitches by closely synchronizing all 12 bits of data coming from the ROMs. The DAC is simply a binary-weighted resistor ladder network, R4, which relies on the CMOS latch outputs all switching exactly between the +5 V supply and ground.

Look at the output of the main loop phase detector (pin 17 of IC1 on the PLL unit), find Q5, Q6 and Q7 and look at the RC network around them. It's the recipe loop design again! R3 creates the zero, but notice C1 across it. This is a neat and economical way of creating one of the other poles. R6 and C7 create the final pole.

**Fig 14.55** shows the phase noise of an IC-765 measured on a professional phase-noise-measurement system. The areas shown in Fig 14.49 can be seen clearly. The slope above 500 Hz is the phase noise of the final VCO and exactly tracks the *Good* curve in K16WX's *QST* article on the effects of phase noise. Below the noise peak, the phase noise falls to levels 20 dB better than K16WX's *Excellent* curve. This low-noise area complements the narrow CW filter skirts and the narrow notch filter.

Many technically inclined amateurs may be wondering what could be done to

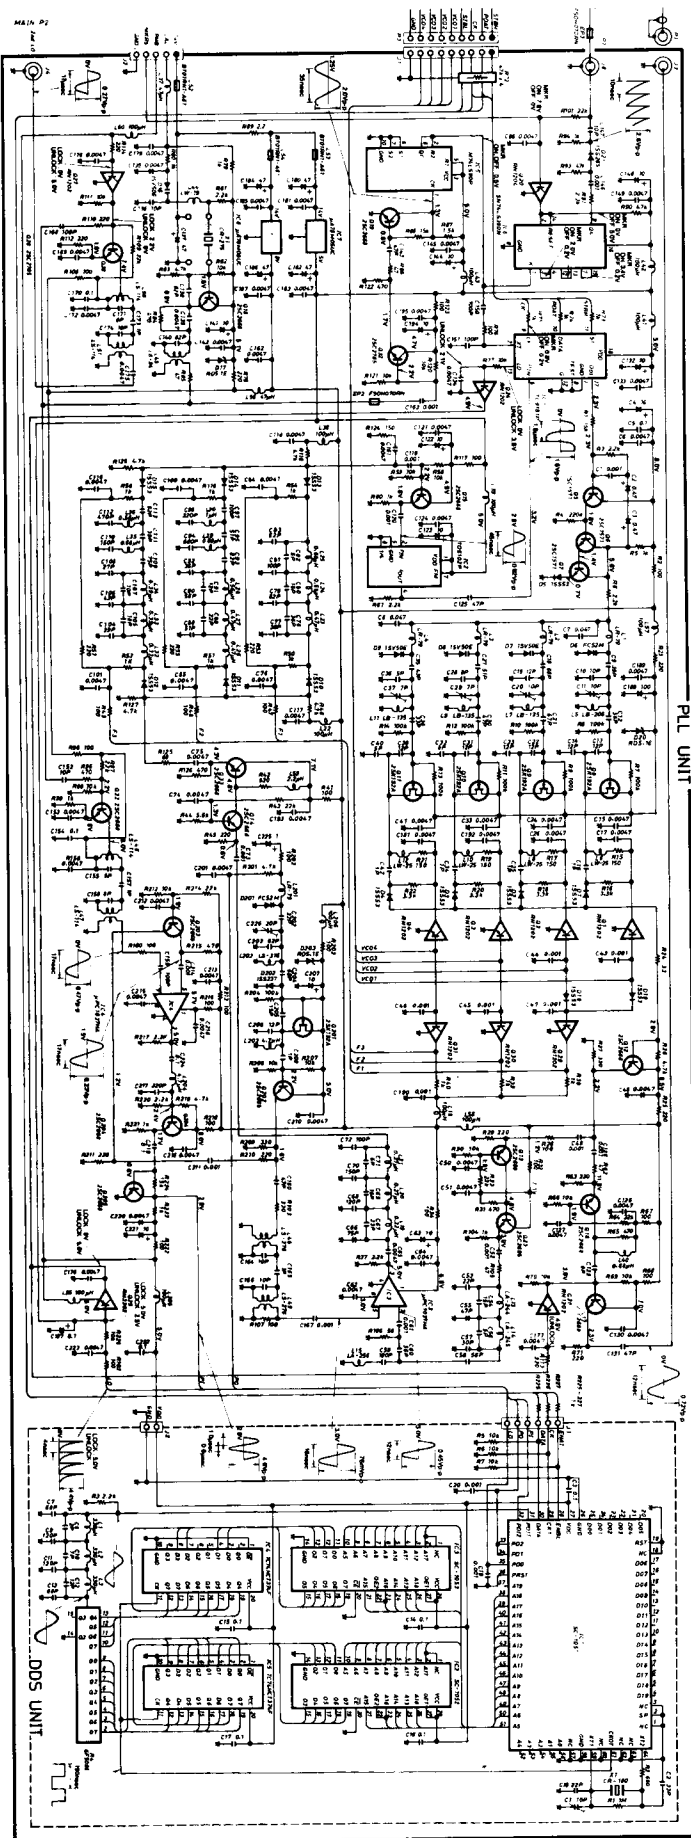

improve the IC-765's synthesizer, or to design an improved one. The peak in the IC-765's phase noise at 500 Hz is quite prominent. It does not appear to be due to a marginally unstable loop design, but rather to a mismatch between the choice of loop bandwidth and the noise performance of the oscillators involved. The DDS's resistor-based DAC is unlikely to perform as well as a purpose-designed 12-bit DAC, and it also lets power-supply noise modulate the output. The system's designers appear to have deliberately reduced the loop bandwidth to better filter DDS spurs. If we were free to increase the cost and complexity of the unit, we could buy a high-performance DAC designed for low DDS spurs and trade this improvement off against noise by increasing the loop bandwidth — redesigning the loop poles, zero and gain. To help with the loop bandwidth, and get a 12-dB improvement in any noise from the main loop's phase detector, divider and loop amplifier, we could remove the fixed prescaler (IC2, the TD6102P) and operate the PSD at 500 kHz. This would require the design of a faster programmable divider that can handle 38 MHz.

Finally, the IC-765's VCOs could be improved. Their tuned circuits could be changed to low-L, high-C, multiple-tuning-diode types. If we added a higher-voltage power supply to allow higher diode tuning voltages than the 5.6-V level at which the design now operates (only little current is needed), higher-Q tuning diodes can be used — and we can avoid using them at lower tuning voltages, where tuning-diode Q degrades. This could reduce the phase noise above the noise peak by several decibels. Changing the loop bandwidth would reduce the noise bump's height and move it farther from the carrier.

It's important to keep all of these what-ifs in perspective: The IC-765's synthesizer was one of the best available in amateur MF/HF transceivers when this chapter was written, and its complexity is about half that of old multiloop, non-DDS examples. Like any product of mass production, its design involved trade-offs between cost, performance and component availability. As better components become less expensive, we can expect excellent synthesizer designs like the IC-765's to come down in price and even better synthesizer designs to become affordable in Amateur Radio gear.

## SYNTHESIZERS: THE FUTURE

It's notoriously dangerous to predict the future in print, but there are some new developments being used in professional

←  
**Fig 14.54 — The IC-765 frequency synthesizer down to the component level. The key ICs in the radio's DDS (IC1, IC2 and IC3, right) appear to be custom components made especially for this application.**

test equipment, on sale as this chapter is being written, that can reasonably be expected to percolate through into radio equipment.

### Fractional-N Synthesis

A single loop would be capable of any step size if its programmable divider wasn't tied to integer numbers. Some designers long ago tried to use such *fractional-N* values by switching the division ratio between two integers, with a duty cycle that set the fractional part. This whole process was synchronized with the divider's operation. Averaged over many cycles, the frequency really did come out as wanted, allowing interpolation between the steps mandated by integer-N division. This approach was largely abandoned because it added huge sidebands (at the fractional frequency and its harmonics) to the loop's output. One such synthesizer design — which has been applied in a large amount of equipment and remains in use — uses a hybrid digital/analog system to compute a sawtooth voltage waveform of just the right amplitude, frequency and phase that can be added to the VCO tuning voltage to cancel the fractional-frequency FM sidebands. This system is complex, however, and like all cancellation processes, it can never provide complete cancellation. It is appreciably sensitive to changes due to tolerances, aging and alignment. Even when applied in a highly developed form using many tight-tolerance components, such a system cannot reduce its fractional frequency sidebands to a level much below -70 to -80 dBc.

A new approach, which has been described in a few articles in professional and trade journals, does not try to cancel its sidebands at all. Its basic principle is delightfully simple. A digital system switches the programmable divider of a normal single loop around a set of division values. This set of values has two properties: First, its average value is controllable in very small steps, allowing fine interpolation of the integer steps of the loop; second, the FM it applies to the loop is huge, but the resultant sideband energy is strongly concentrated in very-high-order sidebands. The loop cannot track such fast FM and so filters off this modulation!

The key to this elegant approach is that it deliberately shapes the spectrum of its loop's unwanted components such that they're small at frequencies at which the loop will pass them and large at frequencies filterable by the loop. The result is a reasonably clean output spectrum.

## BIBLIOGRAPHY AND REFERENCES

Clarke and Hess, *Communications Circuits; Analysis and Design* (Addison-Wesley, 1971; ISBN 0-201-01040-2). Wide coverage of transistor circuit design, including techniques suited to the design of integrated circuits. Its age shows, but it is especially valuable for its good mathematical treatment of oscillator circuits, covering both frequency- and amplitude-determining mechanisms. Look for a copy at a university library or initiate an interlibrary loan.

# Mixers, Modulators and Demodulators

## 15

**A**t base, radio communication involves translating information into radio form, letting it travel for a spell, and translating it back again. Translating information into radio form entails the process we call *modulation*, and *demodulation* is its reverse. One way or another, every transmitter used for radio communication, from the simplest to the most complex, includes a means of modulation; one way or another, every receiver used for radio communication, from the simplest to the most complex, includes a means of demodulation.

Modulation involves varying one or both of a radio signal's basic characteristics—amplitude and frequency (or phase)—to convey information. A circuit, stage or piece of hardware that modulates is called a *modulator*.

Demodulation involves reconstructing the transmitted information from the changing characteristic(s) of a modulated radio wave. A circuit, stage or piece of hardware that demodulates is called a *demodulator*.

Many radio transmitters, receivers and transceivers also contain *mixers*—circuits, stages or pieces of hardware that combine two or more signals to produce additional signals at sums of and differences between the original frequencies. Amateur Radio textbooks have traditionally handled mixers separately from modulators and demodulators, and modulators separately from demodulators.

This chapter, by David Newkirk, WJ1Z, and Rick Karlquist, N6RK, examines mixers, modulators and demodulators together because the job they do is essentially the same. Modulators and demodulators translate information into radio form and back again; mixers translate one frequency to others and back again. All of these translation processes can be thought of as forms of frequency translation or frequency shifting—the function traditionally ascribed to mixers. We'll therefore begin our investigation by examining what a mixer is (and isn't), and what a mixer does.

### THE MECHANISM OF MIXERS AND MIXING

#### What is a Mixer?

*Mixer* is a traditional radio term for a circuit that shifts one signal's frequency up or down by combining it with another signal. The word *mixer* is also used to refer to a device used to blend multiple audio inputs together for recording, broadcast or sound reinforcement. These two mixer types differ in one very important way: A radio mixer makes new frequencies out of the frequencies put into it, and an audio mixer does not.

#### Mixing Versus Adding

Radio mixers might be more accurately called "frequency mixers" to distinguish them from devices such as "microphone

mixers," which are really just signal *combiners*, *summers* or *adders*. In their most basic, ideal forms, both devices have two inputs and one output. The combiner simply *adds* the instantaneous voltages of the two signals together to produce the output at each point in time (**Fig 15.1**). The mixer, on the other hand, *multiplies* the instantaneous voltages of the two signals together to produce its output signal from instant to instant (**Fig 15.2**). Comparing the output spectra of the combiner and mixer, we see that the combiner's output contains only the frequencies of the two inputs, and nothing else, while the mixer's output contains *new* frequencies. Because it combines one energy with another, this process is sometimes called *heterodyning*, from the Greek words for *other* and *power*.

#### Mixing as Multiplication

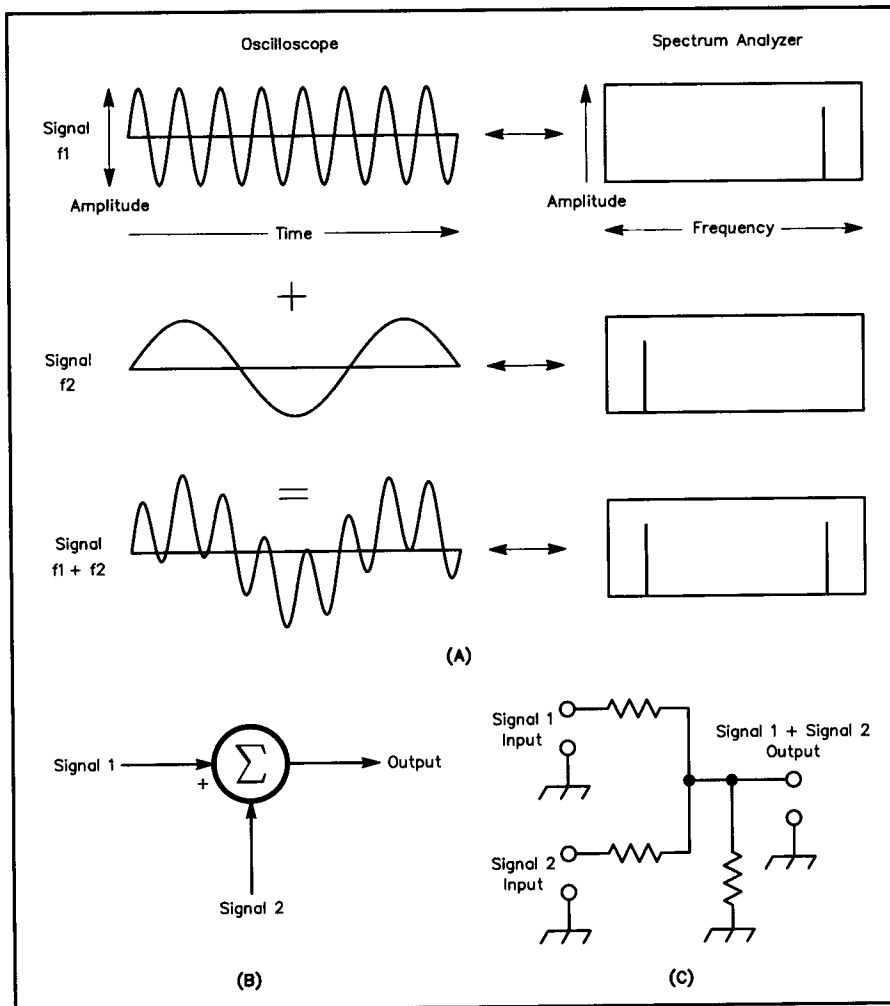

Since a mixer works by means of multiplication, a bit of math can show us how they work. To begin with, we need to represent the two signals we'll mix, A and B, mathematically. Signal A's instantaneous amplitude equals

$$A_a \sin 2\pi f_a t \quad (1)$$

in which A is peak amplitude, f is frequency, and t is time. Likewise, B's instantaneous amplitude equals

$$A_b \sin 2\pi f_b t \quad (2)$$

Since our goal is to show that multiplying two signals generates sum and difference frequencies, we can simplify these

**Fig 15.1—Adding or summing two sine waves of different frequencies ( $f_1$  and  $f_2$ ) combines their amplitudes without affecting their frequencies. Viewed with an oscilloscope (a real-time graph of amplitude versus time), adding two signals appears as a simple superimposition of one signal on the other. Viewed with a spectrum analyzer (a real-time graph of signal amplitude versus frequency), adding two signals just sums their spectra. The signals merely coexist on a single cable or wire. All frequencies that go into the adder come out of the adder, and no new signals are generated.**

Drawing B, a block diagram of a summing circuit, emphasizes the stage's mathematical operation rather than showing circuit components. Drawing C shows a simple summing circuit, such as might be used to combine signals from two microphones. In audio work, a circuit like this is often called a mixer—but it does not perform the same function as an RF mixer.

signal definitions by assuming that the peak amplitude of each is 1. The equation for Signal A then becomes

$$a(t) = A \sin(2\pi f_a t) \quad (3)$$

and the equation for Signal B becomes

$$b(t) = B \sin(2\pi f_b t) \quad (4)$$

Each of these equations represents a sine wave and includes a subscript letter to help us keep track of where the signals go.

Merely combining Signal A and Signal B by letting them travel on the same wire develops nothing new:

$$a(t) + b(t) = A \sin(2\pi f_a t) + B \sin(2\pi f_b t) \quad (5)$$

As needlessly reflexive as equation 5 may seem, we include it to highlight the fact that multiplying two signals is a quite different story. From trigonometry, we know that multiplying the sines of two variables can be expanded according to the relationship

$$\sin x \sin y = \frac{1}{2} [\cos(x - y) - \cos(x + y)] \quad (6)$$

Conveniently, Signals A and B are both sinusoidal, so we can use equation 6 to

determine what happens when we multiply Signal A by Signal B. In our case,  $x = 2\pi f_a t$  and  $y = 2\pi f_b t$ , so plugging them into equation 6 gives us

$$a(t) \cdot b(t) = \frac{AB}{2} \cos(2\pi[f_a - f_b]t) - \frac{AB}{2} \cos(2\pi[f_a + f_b]t) \quad (7)$$

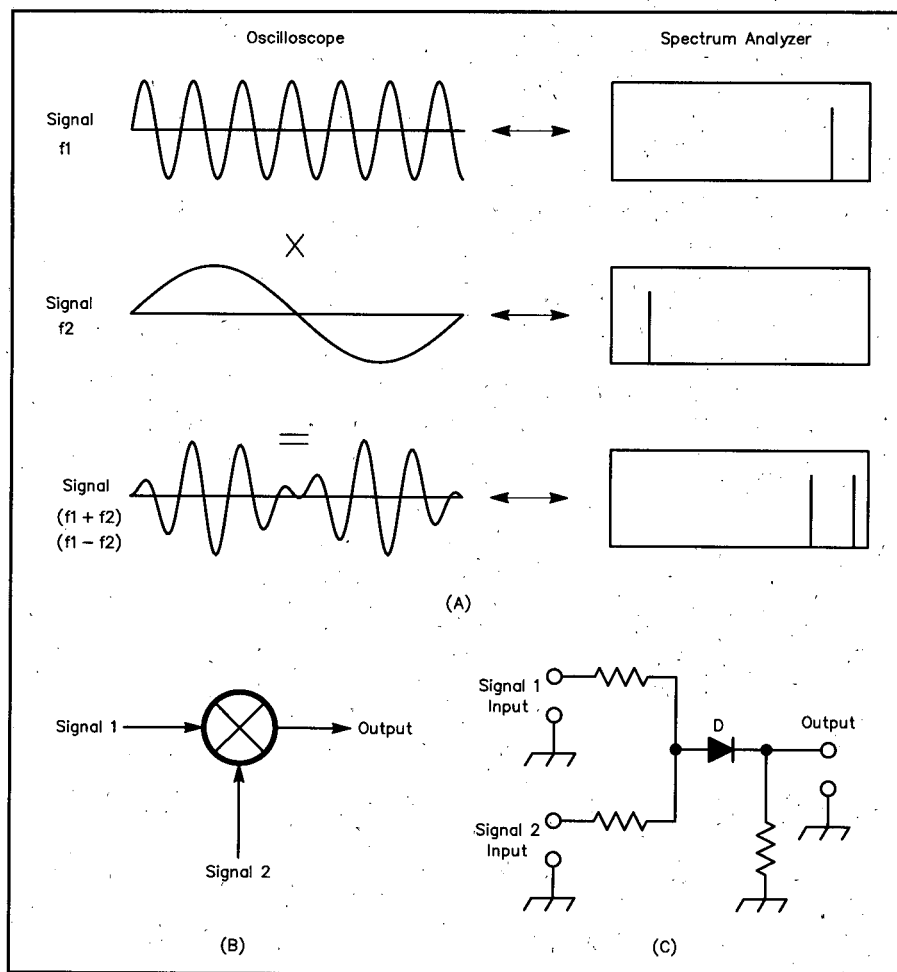

Now we see two momentous results: a sine wave at the frequency *difference* between Signal A and Signal B  $2\pi(f_a - f_b)t$ , and a sine wave at the frequency *sum* of Signal A and Signal B  $2\pi(f_a + f_b)t$ . (The products are cosine waves, but since equivalent sine and cosine waves differ only by a phase shift of  $90^\circ$ , both are called *sine waves* by convention.)

This is the basic process by which we translate information into radio form and translate it back again. If we want to transmit a 1-kHz audio tone by radio, we can feed it into one of our mixer's inputs and feed an RF signal—say, 5995 kHz—into the mixer's other input. The result is two radio signals: one at 5994 kHz ( $5995 - 1$ ) and another at 5996 kHz ( $5995 + 1$ ). We have achieved modulation.

Converting these two radio signals back to audio is just as straightforward. All we do is feed them into one input of another mixer, and feed a 5995-kHz signal into the mixer's other input. Result: a 1-kHz tone. We have achieved demodulation; we have communicated by radio.

The key principle of a radio mixer is that, in mixing multiple signal voltages together, it adds and subtracts their frequencies to produce new frequencies. (In the field of signal processing, this process, *multiplication in the time domain*, is recognized as equivalent to the process of *convolution in the frequency domain*. Those interested in this alternative approach to describing the generation of new frequencies through mixing can find more information about it in the many textbooks available on this fascinating subject.) The difference between the mixer we've been describing and any mixer, modulator or demodulator that you'll ever use is that it's ideal. We put in two signals and got just two signals out. *Real* mixers, modulators and demodulators, on the other hand, also produce *distortion* products that make their output spectra "dirtier" or "less clean," as well as putting out some energy at input-signal frequencies and their harmonics. Much of the art and science of making good use of multiplication in mixing, modulation and demodulation goes into minimizing these unwanted multiplication products (or their effects) and making multipliers do their frequency translations as efficiently as possible.

**Fig 15.2—Multiplying two sine waves of different frequencies produces a new output spectrum.** Viewed with an oscilloscope, the result of multiplying two signals is a composite wave that seems to have little in common with its components. A spectrum-analyzer view of the same wave reveals why: The original signals disappear entirely and are replaced by two new signals—at the *sum* and *difference* of the original signals' frequencies. Drawing B diagrams a multiplier, known in radio work as a mixer. The *X* emphasizes the stage's mathematical operation. (The circled *X* is only one of several symbols you may see used to represent mixers in block diagrams, as Fig 15.3 explains.)

Drawing C shows a very simple multiplier circuit. The diode, *D*, does the mixing. Because this circuit does other mathematical functions and adds them to the sum and difference products, its output is more complex than  $f_1 + f_2$  and  $f_1 - f_2$ , but these can be extracted from the output by filtering.

## Putting Multiplication to Work

Piecing together a coherent picture of how multiplication works in radio, communication isn't made any easier by the fact that traditional terms applied to a given multiplication approach and its products may vary with their application. If, for instance, you're familiar with standard textbook approaches to mixers, modulators and demodulators, you may be wondering why we didn't begin by working out the math involved by examining *amplitude modulation*, also known as *AM*. "Why not tell them about the *carrier* and how to get rid of it in a *balanced modulator*?" A transmitter enthusiast may ask

"Why didn't you mention *sidebands* and how we conserve spectrum space and power by getting rid of one and putting all of our power into the other?" A student of radio receivers, on the other hand, expects any discussion of the same underlying multiplication issues to touch on the topics of *LO feedthrough*, *mixer balance* (*single* or *double*?), *image rejection* and so on.

You likely expect this book to spend some time talking to you about these things, so it will. But *this* radio-amateur-oriented discussion of mixers, modulators and demodulators will take a look at their common underlying mechanism *before* turning you loose on practical mixer, modulator and

**Fig 15.3—We commonly symbolize mixers with a circled *X* (A) out of tradition, but other standards sometimes prevail (B, C and D). Although the converter/changer symbol (D) can conceivably be used to indicate frequency changing through mixing, the three-terminal symbols are arguably better for this job because they convey the idea of two signal sources resulting in a new frequency. (IEC stands for *International Electrotechnical Commission*.)**

demodulator circuits. Then you'll be able to tell the forest from the trees. Fig 15.3 shows the block symbol for a traditional mixer along with several IEC symbols for other functions mixers may perform.

It turns out that the mechanism underlying multiplication, mixing, modulation and demodulation is a pretty straightforward thing: Any circuit structure that *nonlinearly distorts* ac waveforms acts as a multiplier to some degree.

## Nonlinear Distortion?

The phrase *nonlinear distortion* sounds redundant, but isn't. Distortion, an externally imposed change in a waveform, can be linear; that is, it can occur independently of signal amplitude. Consider a radio receiver front-end filter that passes only signals between 6 and 8 MHz. It does this by *linearly distorting* the single complex waveform corresponding to the wide RF spectrum present at the radio's antenna terminals, reducing the amplitudes of frequency components below 6 MHz and above 8 MHz relative to those between 6 and 8 MHz. (Considering multiple signals on a wire as one complex waveform is just as valid, and sometimes handier, than con-

sidering them as separate signals. In this case, it's a bit easier to think of distortion as something that happens to a waveform rather than something that happens to separate signals relative to each other. It would be just as valid—and certainly more in keeping with the consensus view—to say merely that the filter attenuates signals at frequencies below 6 MHz and above 8 MHz.) The filter's output waveform certainly differs from its input waveform; the waveform has been distorted. But because this distortion occurs independently of signal level or polarity, the distortion is linear. No new frequency components are created; only the amplitude relationships among the wave's existing frequency components are altered. This is *amplitude* or *frequency* distortion, and all filters do it or they wouldn't be filters.

*Phase or delay distortion*, also linear, causes a complex signal's various component frequencies to be delayed by different amounts of time, depending on their frequency but independently of their amplitude. No new frequency components occur, and amplitude relationships among existing frequency components are not altered. Phase distortion occurs to some degree in all real filters.

In a *nonlinearly* distorting circuit, however, the output's root-mean-square (RMS) voltage or current values don't track the input's corresponding RMS voltage or current values in linear proportion. The distortion therefore varies with the signal's amplitude (and, in some nonlinear structures, polarity); the stronger the signal, the greater the distortion.

Nonlinear distortion may take the form of *harmonic distortion*, in which integer multiples of input frequencies occur, or *intermodulation distortion (IMD)*, in which different components multiply to make new ones.

Any departure from absolute linearity results in some form of nonlinear distortion, and this distortion can work for us or against us. Any so-called linear amplifier distorts nonlinearly to some degree; any device or circuit that distorts nonlinearly can work as a mixer, modulator, demodulator or frequency multiplier. An amplifier optimized for linear operation will nonetheless mix, but inefficiently; an amplifier biased for nonlinear amplification may be practically linear over a given tiny portion of its input-signal range. The trick is to use careful design and component selection to maximize nonlinear distortion when we want it, and minimize it when we don't. Once we've decided to maximize nonlinear distortion, the trick is to minimize the distortion products we don't want, and maximize the products we desire.

## Keeping Unwanted Distortion Products Down

Ideally, a mixer multiplies the signal at one of its inputs by the signal at its other input, but does not multiply a signal at the same input by itself, or multiple signals at the same input by themselves or by each other. (Multiplying a signal by itself—squaring it—generates harmonic distortion [specifically, *second-harmonic* distortion] by adding the signal's frequency to itself per equation 7. Simultaneously squaring two or more signals generates simultaneous harmonic and intermodulation distortion, as we'll see later when we explore how a diode demodulates AM.)

Consider what happens when a mixer must handle signals at two different frequencies (we'll call them  $f_1$  and  $f_2$ ) applied to its first input, and a signal at a third frequency ( $f_3$ ) applied to its other input. Ideally, a mixer multiplies  $f_1$  by  $f_3$  and  $f_2$  by  $f_3$ , but does not multiply  $f_1$  and  $f_2$  by each other. This produces output at the sum and difference of  $f_1$  and  $f_3$ , and the sum and difference of  $f_2$  and  $f_3$ , but *not* the sum and difference of  $f_1$  and  $f_2$ . **Fig 15.4** shows that feeding two signals into one input of a mixer results in the same output as if  $f_1$  and  $f_2$  are each first mixed with  $f_3$  in two separate mixers, and the outputs of these mixers are combined. This shows that a mixer, even though constructed with nonlinearly distorting components, actually behaves as a *linear frequency shifter*. Traditionally, we refer to this process as

mixing and to its outputs as *mixing products*, but we may also call it *frequency conversion*, referring to a device or circuit that does it as a *converter*, and to its outputs as *conversion products*.

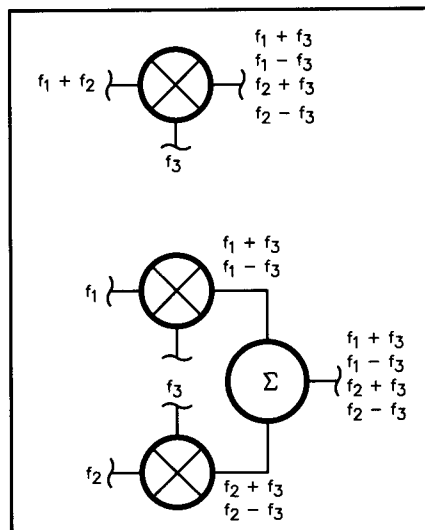

Real mixers, however, at best act only as *reasonably* linear frequency shifters, generating some unwanted IMD products—spurious signals, or *spurs*—as they go. Receivers are especially sensitive to unwanted mixer IMD because the signal-level spread over which they must operate without generating unwanted IMD is often 90 dB or more, and includes infinitesimally weak signals in its span. In a receiver, IMD products so tiny that you'd never notice them in a transmitted signal can easily obliterate weak signals. This is why receiver designers apply so much effort to achieving “high dynamic range.”

The degree to which a given mixer, modulator or demodulator circuit produces unwanted IMD is often *the* reason why we use it, or don't use it, instead of another circuit that does its wanted-IMD job as well or even better.

## Other Mixer Outputs

In addition to desired sum-and-difference products and unwanted IMD products, real mixers also put out some energy at their input frequencies. Some mixer implementations may *suppress* these outputs—that is, reduce one or both of their input signals by a factor of 100 to 1,000,000, or 20 to 60 dB. This is good because it helps keep input signals at the desired mixer-output sum or difference frequency from showing up at the IF terminal—an effect reflected in a receiver's *IF rejection* specification. Some mixer types, especially those used in the vacuum-tube era, suppress their input-signal outputs very little or not at all.

Input-signal suppression is part of an overall picture called *port-to-port isolation*. Mixer input and output connections are traditionally called *ports*. By tradition, the port to which we apply the shifting signal is the *local-oscillator (LO)* port. The convention for naming the other two ports (one of which must be an output, and the other of which must be an input) is usually that the higher-frequency port is called the *RF (radio frequency)* port and the lower-frequency port is called the *IF (intermediate frequency)* port. If a mixer's output frequency is lower than its input frequency, then the RF port is an input and the IF port is an output. If the output frequency is higher than the input frequency, the IF port may be the input and the RF port may be the output. (We hedge with *may be* because usage varies. When in doubt, check a diagram carefully to deter-

**Fig 15.4—Feeding two signals into one input of a mixer results in the same output as if  $f_1$  and  $f_2$  are each first mixed with  $f_3$  in two separate mixers, and the outputs of these mixers are combined.**

mine which port is the “gozinta” and which port is the “gozouta.”)

It's generally a good idea to keep a mixer's input signals from appearing at its output port because they represent energy that we'd rather not pass on to subsequent circuitry. It therefore follows that it's usually a good idea to keep a mixer's LO-port energy from appearing at its RF port, or its RF-port energy from making it through to the IF port. But there are some notable exceptions.

## Mixers and Amplitude Modulation

Now that we've just discussed what a fine thing it is to have a mixer that doesn't let its input signals through to its output port, we can explore a mixing approach that outputs one of its input signals so strongly that the fed-through signal's amplitude at least equals the combined amplitudes of the system's sum and difference products! This system, *amplitude modulation*, is the oldest means of translating information into radio form and back again. It's a frequency-shifting system in which the original unmodulated signal, traditionally called the *carrier*, emerges from the mixer along with the sum and difference products, traditionally called *sidebands*.

We can easily make the carrier pop out of our mixer along with the sidebands merely by building enough *dc level shift* into the information we want to mix so that its waveform never goes negative. Back at equation 1 and 2, we decided to keep our mixer math relatively simple by setting the peak voltage of our mixer's input signals directly equal to their sine values. Each input signal's peak voltage therefore varies between +1 and -1, so all we need to do to keep our modulating-signal term (provided with a subscript *m* to reflect its role as the modulating or information waveform) from going negative is add 1 to it. Identifying the carrier term with a subscript *c*, we can write

$$\text{AM signal} = (1 + m \sin 2\pi f_m t) \sin 2\pi f_c t \quad (8)$$

Notice that the modulation ( $2\pi f_m t$ ) term has company in the form of a coefficient, *m*. This variable expresses the modulating signal's varying amplitude—variations that ultimately result in amplitude modulation. Expanding equation 8 according to equation 6 gives us

$$\begin{aligned} \text{AM signal} &= \sin 2\pi f_c t \\ &+ \frac{1}{2} m \cos(2\pi f_c - 2\pi f_m) t \\ &- \frac{1}{2} m \cos(2\pi f_c + 2\pi f_m) t \end{aligned} \quad (9)$$

**Fig 15.5—Graphed in terms of amplitude versus time (A), the envelope of a properly modulated AM signal exactly mirrors the shape of its modulating waveform, which is a sine wave in this example. This AM signal is modulated as fully as it can be—100%—because its envelope just hits zero on the modulating wave's negative peaks. Graphing the same AM signal in terms of amplitude versus frequency (B) reveals its three spectral components: Carrier, upper sideband and lower sideband. B shows sidebands as single-frequency components because the modulating waveform is a sine wave. With a complex modulating waveform, the modulator's sum and difference products really do show up as bands on either side of the carrier (C).**

The modulator's output now includes the carrier ( $\sin 2\pi f_c t$ ) in addition to sum and difference products that vary in strength according to *m*. According to the conventions of talking about modulation, we call the sum product, which comes out at a frequency higher than that of the carrier, the *upper sideband (USB)*, and the difference product, which comes out a frequency lower than that of the carrier, the *lower sideband (LSB)*. We have achieved amplitude modulation.

## Why We Call It Amplitude Modulation

We call the modulation process described in equation 8 *amplitude modulation* because the complex waveform consisting of the sum of the sidebands and carrier varies with the information signal's magnitude (*m*). Concepts long used to illustrate AM's mechanism may mislead us into thinking that the *carrier* varies in strength with modulation, but careful study of equation 9 shows that this doesn't happen. The carrier,  $\sin 2\pi f_c t$ , goes into the modulator—we're in the modulation business now, so it's fitting to use the term *modulator* instead of *mixer*—as a sinusoid with an unvarying maximum value of |1|. The modulator multiplies the carrier by the dc level (+1) that we added to the information signal ( $m \sin 2\pi f_m t$ ). Multiplying  $\sin 2\pi f_c t$  by 1 merely returns  $\sin 2\pi f_c t$ . We have proven that the carrier's amplitude does not vary as a result of amplitude modulation.

## Overmodulation

Since an AM signal's information content resides entirely in its sidebands, it follows that the more energetic we make the sidebands, the more information energy will be available for an AM receiver to “recover” when it demodulates the signal. Even in an ideal modulator, there's a practical limit to how strong we can make an AM signal's sidebands relative to its carrier, however. Beyond that limit, we severely distort the waveform we want to translate into radio form.

We reach AM's distortion-free modulation limit when the sum of the sidebands and carrier at the modulator output just reaches zero at the modulating waveform's most negative peak (Fig 15.5). We call this condition *100% modulation*, and it occurs when *m* equals 1. (We enumerate *modulation percentage* in values from 0 to 100%. The lower the number, the less information energy in the sidebands. You may also see modulation enumerated in terms of a *modulation factor* from 0 to 1, which directly equals *m*; a modulation factor of 1 is the same as 100% modulation.) equation 9 shows that each sideband's

voltage is half that of the carrier. Power varies as the square of voltage, so the power in each sideband of a 100%-modulated signal is therefore  $(1/2)^2$  times, or 1/4, that of the carrier. A transmitter capable of 100% modulation when operating at a carrier power of 100 W therefore puts out a 150-W signal at 100% modulation, 50 W of which is attributable to the sidebands. (The *peak* envelope power [PEP] output of a double-sideband, full-carrier AM transmitter at 100% modulation is four times its carrier PEP. This is why our solid-state, “100-W” MF/HF transceivers are usually rated for no more than about 25 W carrier output at 100% amplitude modulation.)

One-hundred-percent modulation is a brick-wall limit because an amplitude modulator can't reduce its output to less than zero. Trying to increase modulation beyond the 100% point results in *overmodulation* (Fig 15.6), in which the modulation envelope no longer mirrors the shape of the modulating wave (Fig 15.6A).

**Fig 15.6—Overmodulating an AM transmitter results in a modulation envelope (A) that doesn't faithfully mirror the modulating waveform. This distortion creates additional sideband components that broaden the transmitted signal (B).**

An overmodulated wave contains more energy than it did at 100% modulation, but some of the added energy now exists as *harmonics of the modulating waveform* (Fig 15.6B). This distortion makes the modulated signal take up more spectrum space than it needs. In voice operation, overmodulation commonly happens only on syllabic peaks, making the distortion products sound like crashy, transient noise we refer to as *splatter*.

### Modulation Linearity

If we increase an amplitude modulator's modulating-signal input by a given per-

**Fig 15.7—An ideal AM transmitter exhibits a straight-line relationship (A) between its instantaneous envelope amplitude and the instantaneous amplitude of its modulating signal. Distortion, and thus an unnecessarily wide signal, results if the transmitter cannot respond linearly across the modulating signal's full amplitude range.**

centage, we expect a proportional modulation increase in the modulated signal. We expect good *modulation linearity*. Suboptimal amplitude modulator design may not allow this, however. Above some modulation percentage, a modulator may fail to increase modulation in proportion to an increase its input signal (Fig 15.7). Distortion, and thus an unnecessarily wide signal, results.

### Using AM to Send Morse Code

Fig 15.6A closely resembles what we see when a properly adjusted CW transmitter sends a string of dots (Fig 15.8). Keying a carrier on and off produces a wave that varies in amplitude and has double (upper and lower) sidebands that vary in spectral composition according to the duration and envelope shape of the on-off transitions. The emission mode we call CW is therefore a form of AM. The concepts of modulation percentage and overmodulation are usually not applied to generating an on-off-keyed Morse signal, however. This is related to how we copy CW by ear, and the fact that, in CW radio communication, we usually don't translate the received signal all the way back into its original pre-modulator (*baseband*) form, as a closer look at the process reveals.

In CW transmission, we usually open and close a keying line to make dc transitions that turn the transmitted carrier on and off. CW reception usually does not entirely reverse this process, however. Instead of demodulating a CW signal all the way back to its baseband self—a shift-

**Fig 15.8—Telegraphy by on-off-keying a carrier is also a form of AM, called CW (short for *continuous wave*) for reasons of tradition. Waveshaping in a CW transmitter often causes a CW signal's RF envelope (the amplitude-versus-time display at A) to contain less harmonic energy than the faster transitions of its keying waveform (B) suggest should be the case. C, an amplitude-versus-frequency display, shows that even a properly shaped CW signal has many sideband components.**

ing dc level—we want the presences and absences of its carrier to create long and short audio tones. Because the carrier is RF and not AF, we must mix it with a locally generated RF signal—from a *beat-frequency oscillator (BFO)*—that's close enough in frequency to produce a difference signal at AF. What goes into our transmitter as shifting dc comes out of our receiver as thump-delimited tone bursts of dot and dash duration. We have achieved CW communication.

The dots and dashes of a CW signal must start and stop abruptly enough so we can clearly distinguish the carrier's presences and absences from noise, especially when fading prevails. The keying sidebands, which sound like little more than thumps when listened to on their own, help our brains be sure when the carrier tone starts and stops.

It so happens that we always need to hear one or more harmonics of the fundamental keying waveform for the code to sound sufficiently crisp. If the transmitted signal will be subject to propagational fading—a safe assumption for any long-distance radio communication—we *harden* our keying by making the transmitter's output rise and fall more quickly. This puts more energy into more keying sidebands and makes the signal more copiable in the presence of fading—in particular, *selective fading*, which linearly distorts a modulated signal's complex waveform and randomly changes the sidebands' strength and phase relative to the carrier and each other. The appropriate keying hardness also depends on the keying speed. The faster the keying in WPM, the faster the on-off times—the harder the keying—must be for the signal to remain ear-readable through noise and fading.

Instead of thinking of this process in terms of modulation percentage, we just ensure that a CW transmitter produces sufficient keying-sideband energy for solid reception. Practical CW transmitters rarely do their keying with a modulator stage as such. Instead, one or more stages are turned on and off to modulate the carrier with Morse, with rise and fall times set by R and C values associated with the stages' keying and/or power supply lines. A transmitter's CW *waveshaping* is therefore usually hardwired to values appropriate for reasonably high-speed sending (35 to 55 WPM or so) in the presence of fading. As a result, we generally cannot vary keying hardness at will as we might vary a voice transmitter's modulation with a front-panel control. Rise and fall times of 1 to 5 ms (5 ms rise and fall times equate to a keying speed of 36 WPM in the presence of fading and 60 WPM if fading is absent) are common.

The faster a CW transmitter's output changes between zero and maximum, the more bandwidth its carrier and sidebands occupy. Making a CW signal's keying too hard is therefore spectrum-wasteful and unneighborly because it makes the signal wider than it needs to be. Keying sidebands that are stronger and wider than necessary are traditionally called *clicks* because of what they sound like on the air. There is a more detailed discussion of keying waveforms in the **Transceivers** chapter.

### ***The Many Faces of Amplitude Modulation***

We've so far examined mixers, multipliers and modulators that produce complex output signals of two types. One, the action of which equation 7 expresses, produces only the frequency sum of and frequency difference between its input signals. The other, the amplitude modulator characterized by equations 8 and 9, produces carrier output in addition to the frequency sum of and frequency difference between its input signals. Exploring the AM process led us to a discussion on-off-keyed CW, which is also a form of AM.

Amplitude modulation is nothing more and nothing less than varying an output signal's amplitude according to a varying voltage or current. All of the output signal types mentioned above are forms of amplitude modulation, and there are others. Their names and applications depend on whether the resulting signal contains a carrier or not, and both sidebands or not. Here's a brief overview of AM-signal types, what they're called, and some of the jobs you may find them doing:

- ***Double-sideband (DSB), full-carrier AM*** is often called just *AM*, and often what's meant when radio folk talk about just *AM*. (When the subject is broadcasting, *AM* can also refer to broadcasters operating in the 525- to 1705-kHz region, generically called *the AM band* or *the broadcast band* or *medium wave*. These broadcasters used only double-sideband, full-carrier AM for many years, but many now use combinations of amplitude modulation and *angle modulation*, which we'll explore shortly, to transmit stereophonic sound.) Equations 8 and 9 express what goes on in generating this signal type. What we call *CW*—Morse code done by turning a carrier on and off—is a form of DSB, full-carrier AM.
- ***Double-sideband, suppressed-carrier AM*** is what comes out of a circuit that does what equation 7 expresses—a sum (upper sideband), a difference (lower

sideband) and no carrier. We didn't call its sum and difference outputs upper and lower sidebands earlier in equation 7's neighborhood, but we'd do so in a transmitting application. In a transmitter, we call a circuit that suppresses the carrier while generating upper and lower sidebands a *balanced modulator*, and we quantify its *carrier suppression*, which is always less than infinite. In a receiver, we call such a circuit a *balanced mixer*, which may be *single-balanced* (if it lets either its RF signal or its LO [carrier] signal through to its output) or *double-balanced* (if it suppresses both its input signal and LO/carrier in its output), and we quantify its *LO suppression* and *port-to-port isolation*, which are always less than infinite. (Mixers [and amplifiers] that afford no balance whatsoever are sometimes said to be *single-ended*.) Sometimes, DSB suppressed-carrier AM is called just *DSB*.

- ***Vestigial sideband (VSB), full-carrier AM*** is like the DSB variety with one sideband partially filtered away for bandwidth reduction. Commercial television systems that transmit AM video use VSB AM.
- ***Single-sideband, suppressed-carrier AM*** is what you get when you generate a DSB, suppressed carrier AM signal and throw away one sideband with filtering or phasing. We usually call this signal type just *single sideband (SSB)* or, as appropriate, *upper sideband (USB)* or *lower sideband (LSB)*. In a modulator or demodulator system, the *unwanted sideband*—that is, the sum or difference signal we don't want—may be called just that, or it may be called the *opposite sideband*, and we refer to a system's *sideband rejection* as a measure of how well the opposite sideband is suppressed. In receiver mixers not used for demodulation and transmitter mixers not used for modulation, the unwanted sum or difference signal, or the input signal that produces the unwanted sum or difference, is the *image*, and we refer to a system's *image rejection*. A pair of mixers specially configured to suppress either the sum or the difference output is an *image-reject mixer (IRM)*. In receiver demodulators, the unwanted sum or difference signal may just be called the opposite sideband, or it may be called the *audio image*. A receiver capable of rejecting the opposite sideband or audio image is said to be capable of *single-signal* reception.
- ***Single-sideband, full-carrier AM*** is akin to full-carrier DSB with one sideband missing. Commercial and military communicators may call it *AM equivalent (AME)* or *compatible AM (CAM)*—com-

patible because it can be usefully demodulated in AM and SSB receivers and because it occupies about the same amount of spectrum space as SSB.)

- **Independent sideband (ISB) AM** consists of an upper sideband and a lower sideband containing different information (a carrier of some level may also be present). Radio amateurs sometimes use ISB to transmit simultaneous slow-scan-television and voice information; international broadcasters sometimes use it for point-to-point audio feeds as a backup to satellite links.

## Mixers and AM Demodulation

Translating information from radio form back into its original form—demodulation—is also traditionally called *detection*. If the information signal we want to detect consists merely of a baseband signal frequency-shifted into the radio realm, almost any low-distortion frequency-shifter that works according to equation 7 can do the job acceptably well.

Sometimes we recover a radio signal's information by shifting the signal right back to its original form with no intermediate frequency shifts. This process is called *direct conversion*. More commonly, we first convert a received signal to an *intermediate frequency* so we can amplify, filter and level-control it prior to detection. This is *superheterodyne* reception, and most modern radio receivers work in this way. Whatever the receiver type, however, the received signal ultimately makes its way to one last mixer or demodulator that completes the final translation of information back into audio, or into a signal form suitable for device control or computer processing. In this last translation, the incoming signal is converted back to recovered-information form by mixing it with one last RF signal. In heterodyne or *product* detection, that final frequency-shifting signal comes from a BFO. The incoming-signal energy goes into one mixer input port, BFO energy goes into the other, and audio (or whatever form the desired information takes) results.

If the incoming signal is full-carrier AM and we don't need to hear the carrier as a tone, we can modify this process somewhat, if we want. We can use the carrier itself to provide the heterodyning energy in a process called *envelope detection*.

### Envelope Detection and Full-Carrier AM

Fig 15.5 graphically represents how a full-carrier AM signal's *modulation envelope* corresponds to the shape of the modulating wave. If we can derive from the modulated signal a voltage that varies ac-

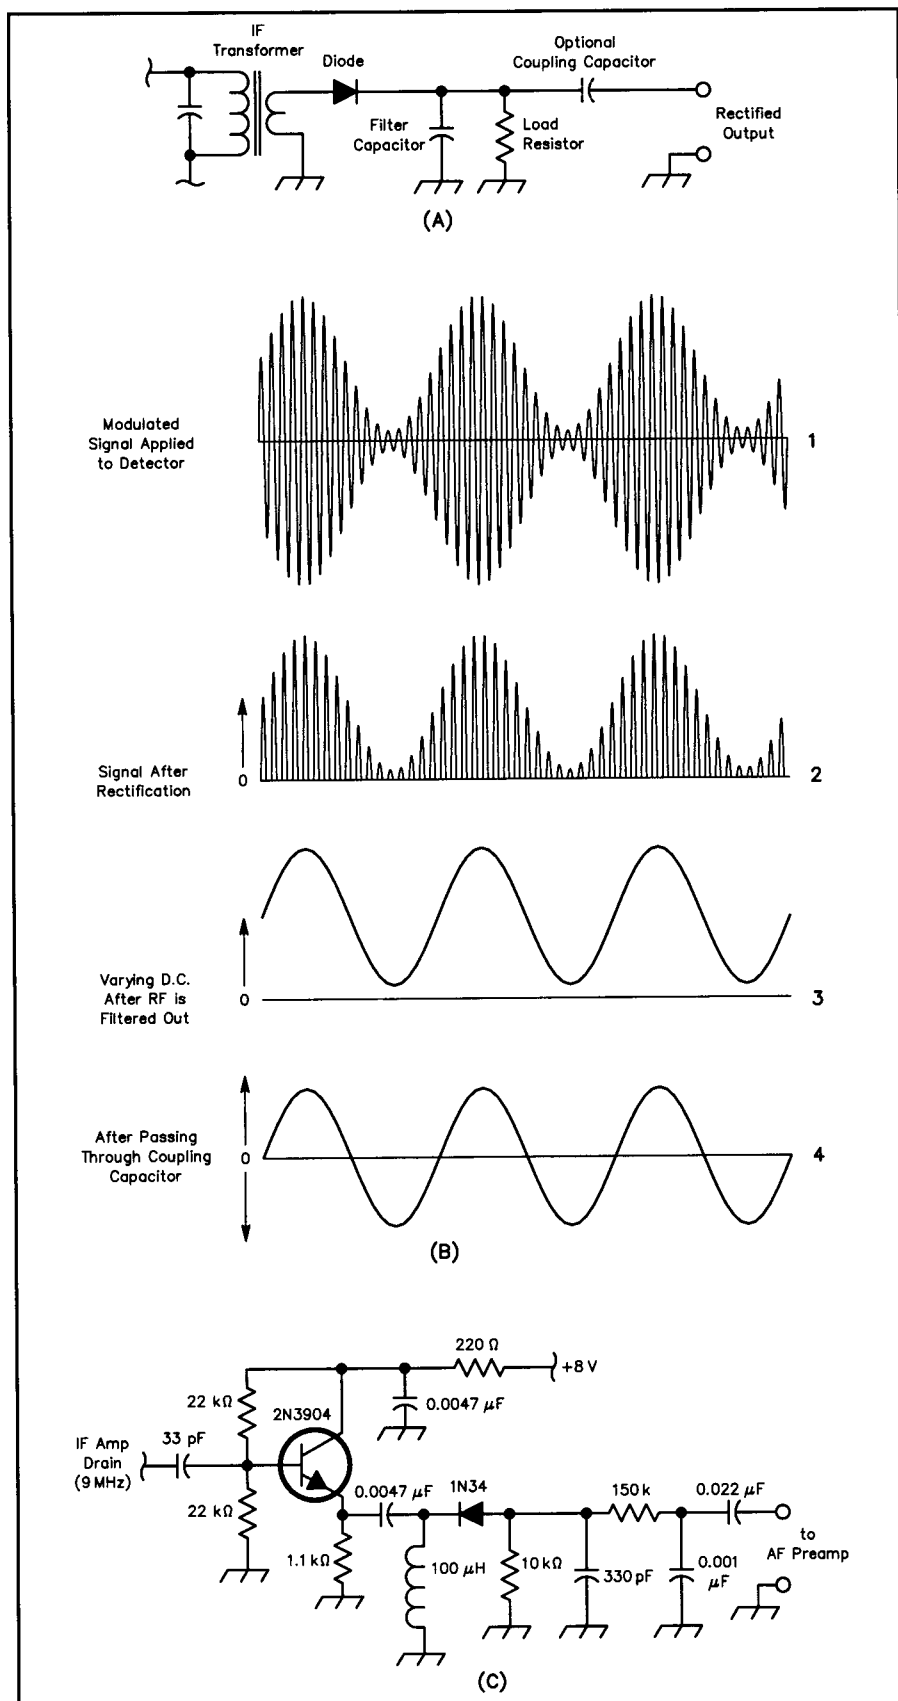

Fig 15.9—Radio's simplest demodulator, the diode rectifier (A), demodulates an AM signal by multiplying its carrier and sidebands to produce frequency sums and differences, two of which sum into a replica of the original modulation (B). Modern receivers often use an emitter follower to provide low-impedance drive for their diode detectors (C).

According to the modulation envelope, we will have successfully recovered the information present in the sidebands. This process is called envelope detection, and we can achieve it by doing nothing more complicated than half-wave-rectifying the modulated signal with a diode (Fig 15.9).

That a diode demodulates an AM signal by allowing its carrier to multiply with its sidebands may jar those long accustomed to seeing diode detection ascribed merely to "rectification." But a diode is certainly nonlinear. It passes current in only one direction, and its output voltage is (within limits) proportional to the square of its input voltage. These nonlinearities allow it to multiply.

Exploring this mathematically is tedious with full-carrier AM because the process squares three summed components (carrier, lower sideband and upper sideband). Rather than fill the better part of a page with algebra, we'll instead characterize the outcome verbally: In "just rectifying" a DSB, full-carrier AM signal, a diode detector produces

- Direct current (the result of rectifying the carrier);
- A second harmonic of the carrier;
- A second harmonic of the lower sideband;
- A second harmonic of the upper sideband;
- Two difference-frequency outputs (upper sideband minus carrier, carrier minus lower sideband), each of which is equivalent to the modulating wave-form's frequency, and both of which sum to produce the recovered information signal; and
- A second harmonic of the modulating waveform (the frequency difference between the two sidebands).

Three of these products are RF. Low-pass filtering, sometimes little more than a simple RC network, can remove the RF products from the detector output. A capacitor in series with the detector output line can block the carrier-derived dc component. That done, only two signals remain: the recovered modulation and, at a lower level, its second harmonic—in other words, second-harmonic distortion of the desired information signal.

## Mixers and Angle Modulation

Amplitude modulation served as our first means of translating information into radio form because it could be implemented as simply as turning an electric noise generator on and off. (A spark transmitter consisted of little more than this.) By the 1930s, we had begun experimenting with translating information into radio

form and back again by modulating a radio wave's angular velocity (frequency or phase) instead of its overall amplitude. The result of this process is *frequency modulation (FM)* or *phase modulation (PM)*, both of which are often grouped under the name *angle modulation* because of their underlying principle.

A change in a carrier's frequency or phase for the purpose of modulation is called *deviation*. An FM signal deviates according to the amplitude of its modulating waveform, independently of the modulating waveform's frequency; the higher the modulating wave's amplitude, the greater the deviation. A PM signal deviates according to the amplitude and frequency of its modulating waveform; the higher the modulating wave's amplitude and/or frequency, the greater the deviation.

An angle-modulated signal can be mathematically represented as

$$\begin{aligned} f_c(t) &= \cos(2\pi f_c t + m \sin(2\pi f_m t)) \\ &= \cos(2\pi f_c t) \cos(m \sin(2\pi f_m t)) \\ &\quad - \sin(2\pi f_c t) \sin(m \sin(2\pi f_m t)) \end{aligned} \quad (10)$$

In it, we see the carrier frequency ( $2\pi f_c t$ ) and modulating signal ( $\sin 2\pi f_m t$ ) as in the equation for AM (equation 8). We again see the modulating signal associated with a coefficient,  $m$ , that relates to degree of modulation. (In the AM equation,  $m$  is the modulation factor; in the angle-modulation equation,  $m$  is the *modulation index* and, for FM, equals the deviation divided by the modulating frequency.) We see that angle-modulation occurs as the cosine of the sum of the carrier frequency ( $2\pi f_c t$ ) and the modulating signal ( $\sin 2\pi f_m t$ ) times the modulation index ( $m$ ). In its expanded form, we see the appearance of sidebands above and below the carrier frequency.

Angle modulation is a multiplicative process, so, like AM, it creates sidebands on both sides of the carrier. Unlike AM, however, angle modulation creates an *infinite* number of sidebands on either side of the carrier! This occurs as a direct result of modulating the carrier's angular velocity, to which its frequency and phase directly relate. If we continuously vary a wave's angular velocity according to another periodic wave's cyclical amplitude variations, the rate at which the modulated wave repeats its cycle—its frequency—passes through an infinite number of values. (How many individual amplitude points are there in one cycle of the modulating wave? An infinite number. How many corresponding discrete frequency or phase values does the cor-

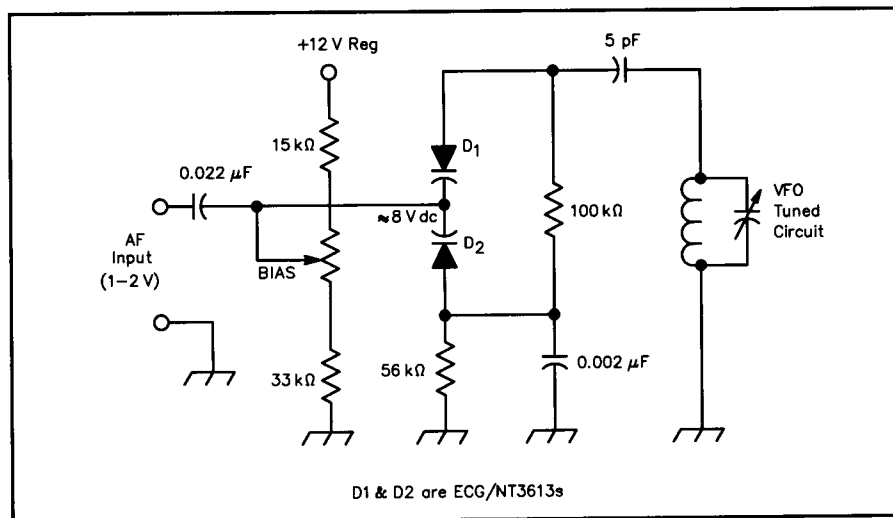

responding angle-modulated wave pass through as the modulating signal completes a cycle? An infinite number!) In AM, the carrier frequency stays at one value, so AM produces two sidebands—the sum of its carrier's unchanging frequency value and the modulating frequency, and the difference between the carrier's unchanging frequency value and the modulating frequency. In angle modulation, the modulating wave shifts the frequency or phase of the carrier through an infinite number of different frequency or phase values, resulting in an infinite number of sum and difference products.

Wouldn't the appearance on the air of just a few such signals result in a bedlam of mutual interference? No, because most of angle modulation's uncountable sum and difference products are vanishingly weak in practical systems, and because they don't show up just anywhere in the spectrum. Rather, they emerge from the modulator spaced from the average ("resting," unmodulated) carrier frequency by integer multiples of the modulating frequency (Fig 15.10). The strength of the sidebands relative to the carrier, and the strength and phase of the carrier itself,

**Fig 15.10—Angle-modulation produces a carrier and an infinite number of upper and lower sidebands spaced from the average ("resting," unmodulated) carrier frequency by integer multiples of the modulating frequency. (This drawing is a simplification because it only shows relatively strong, close-in sideband pairs; space constraints prevent us from extending it to infinity.) The relative amplitudes of the sideband pairs and carrier vary with modulation index,  $m$ .**

**Fig 15.11**—One or more tuning diodes can serve as the variable reactance in a reactance modulator. This HF reactance modulator circuit uses two diodes in series to ensure that the tuned circuit's RF-voltage swing cannot bias the diodes into conduction. D1 and D2 are "30-volt" tuning diodes that exhibit a capacitance of 22 pF at a bias voltage of 4. The BIAS control sets the point on the diode's voltage-versus-capacitance characteristic around which the modulating waveform swings.

**Fig 15.12**—A series reactance modulator acts as a variable shunt around a reactance—in this case, a 47-pF capacitor—through which the carrier passes.

vary with the degree of modulation—the modulation index. (The *overall* amplitude of an angle-modulated signal does not change with modulation, however; when energy goes out of the carrier, it shows up in the sidebands, and vice versa.) In practice, we operate angle-modulated transmitters at modulation indexes that make all but a few of their infinite sidebands small in amplitude. (A mathematical tool called *Bessel functions*, part of the set of which is shown graphically in the **Modulation Sources** chapter, lets us determine the relative strength of the carrier and sidebands according to modulation index.) Selectivity in transmitter and receiver circuitry further modify this relationship, especially for

sidebands far away from the carrier.

### Angle Modulators

Vary a reactance in or associated with an oscillator's frequency-determining element(s), and you vary the oscillator's frequency. Vary the tuning of a tuned circuit through which a signal passes, and you vary the signal's phase. A circuit that does this is called a *reactance modulator*, and can be little more than a tuning diode or two connected to a tuned circuit in an oscillator or amplifier (**Fig 15.11**). Varying a reactance through which the signal passes (**Fig 15.12**) is another way of doing the same thing.

The difference between FM and PM depends solely on how, and not how much, deviation occurs. A modulator that causes deviation in proportion to the modulating wave's amplitude and frequency is a phase modulator. A modulator that causes deviation only in proportion to the modulating signal's amplitude is a frequency modulator.

### Increasing Deviation by Frequency Multiplication

Maintaining modulation linearity is just as important in angle modulation as it is in AM, because unwanted distortion is always our enemy. A given angle-modulator circuit can frequency- or phase-shift a carrier only so much before the shift stops occurring in strict proportion to the amplitude (or, in PM, the amplitude and frequency) of the modulating signal.

If we want more deviation than an angle modulator can linearly achieve, we can

operate the modulator at a suitable subharmonic—submultiple—of the desired frequency, and process the modulated signal through a series of *frequency multipliers* to bring it up to the desired frequency. The deviation also increases by the overall multiplication factor, relieving the modulator of having to do it all directly. A given FM or PM radio design may achieve its final output frequency through a combination of mixing (frequency shift, no deviation change) and frequency multiplication (frequency shift *and* deviation change).

### The Truth About "True FM"

Something we covered a bit earlier bears closer study:

An FM signal deviates according to the amplitude of its modulating waveform, independently of the modulating waveform's frequency; the higher the modulating wave's amplitude, the greater the deviation. A PM signal deviates according to the amplitude *and* frequency of its modulating waveform; the higher the modulating wave's amplitude *and/or* frequency, the greater the deviation.

The practical upshot of this excerpt is that we can use a phase modulator to generate FM. All we need to do is run a PM transmitter's modulating signal through a low-pass filter that (ideally) halves the signal's amplitude for each doubling of frequency (a reduction of "6 dB per octave," as we sometimes see such responses characterized) to compensate for its phase modulator's "more deviation with higher frequencies" characteristic. The result is an FM, not PM, signal. FM achieved with a phase modulator is sometimes called *indirect FM* as opposed to the *direct FM* we get from a frequency modulator.

We sometimes see radio gear manufacturers claim that one piece of gear is better than another solely because it generates "true FM" as opposed to indirect FM. We can immunize ourselves against such claims by keeping in mind that direct and indirect FM *sound exactly alike in a receiver* when done correctly.

Depending on the nature of the modulation source, there is a practical difference between a frequency modulator and a phase modulator. Answering two questions can tell us whether this difference matters: Does our modulating signal contain a dc level or not? If so, do we need to accurately preserve that dc level through our radio communication link for successful communication? If both answers are yes, we must choose our hardware and/or information-encoding

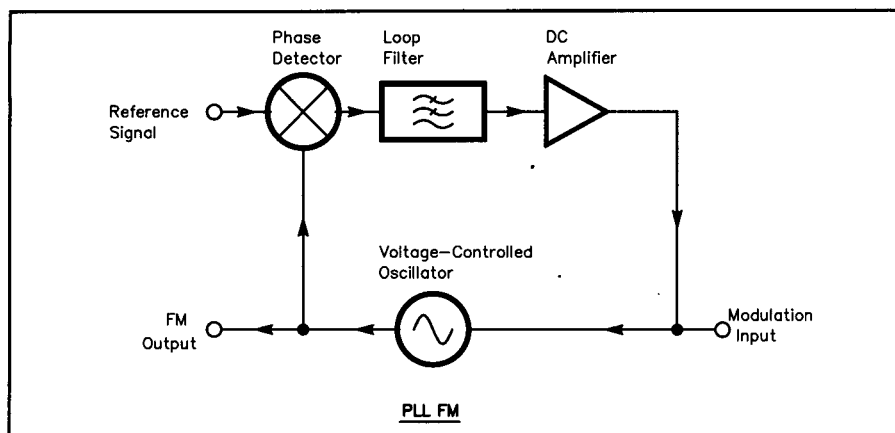

Fig 15.13—Frequency modulation, PLL-style.

approach carefully, because a frequency modulator can convey shifts in its modulating wave's dc level, while a phase modulator, which responds only to instantaneous changes in frequency and phase, cannot.

Consider what happens when we want to frequency-modulate a phase-locked-loop-synthesized transmitted signal. Fig 15.13 block-diagrams a PLL frequency modulator. Normally, we modulate a PLL's VCO because it's the easy thing to do. As long as our modulating frequency results in frequency excursions too fast for the PLL to follow and correct—that is, as long as our modulating frequency is outside the PLL's *loop bandwidth*—we achieve the FM we seek. Trying to modulate a dc level by pushing the VCO to a particular frequency and holding it there fails, however, because a PLL's loop response includes dc. The loop sees the modulation's dc component as a correctable error and dutifully “fixes” it. FMing a PLL's VCO therefore can't buy us the dc response “true FM” is supposed to allow.

We can dc-modulate a PLL modulator, but we must do so by modulating the loop's *reference*. The PLL then adjusts the VCO to adapt to the changed reference, and our dc level gets through. In this case, the modulating frequency must be *within* the loop bandwidth—which dc certainly is—or the VCO won't be corrected to track the shift.

### Mixers and Angle Demodulation

With the awesome prospect of generating an infinite number of sidebands still fresh in our minds, we may be a bit disappointed to learn that we commonly demodulate angle modulation by doing little more than turning it into AM and then envelope- or product-detecting it! But this is what happens in many of our FM

receivers and transceivers, and we can get a handle on this process by realizing that a form of angle-modulation-to-AM conversion begins quite early in an angle-modulated signal's life because of distortion of the modulation by amplitude-linear circuitry—something that happens to angle-modulated signals, it turns out, in any linear circuit that doesn't have an amplitude-versus-frequency response that's utterly flat out to infinity.

Think of what happens, for example, when we sweep a constant-amplitude

signal up in frequency—say, from 1 kHz to 8 kHz—and pass it through a 6-dB-per-octave filter (Fig 15.14A). The filter's rolloff causes the output signal's amplitude to decrease as frequency increases. Now imagine that we linearly sweep our constant-amplitude signal *back and forth* between 1 kHz and 8 kHz at a constant rate of 3 kHz per second (Fig 15.14B). The filter's output *amplitude* now varies cyclically over time as the input signal's *frequency* varies cyclically over time. Right before our eyes, a frequency change turns into an amplitude change. The process of converting angle modulation to amplitude modulation has begun.

This is what happens whenever an angle-modulated signal passes through circuitry with an amplitude-versus-frequency response that isn't flat out to infinity. As the signal deviates across the frequency-response curves of whatever circuitry passes it, its angle modulation is, to some degree, converted to AM—a form of crosstalk between the two modulation types, if we wish to look at it that way. (Variations in system phase linearity also cause distortion and FM-to-AM conversion, because the sidebands do not have the proper phase relationship with respect to each other and with respect to the carrier.)

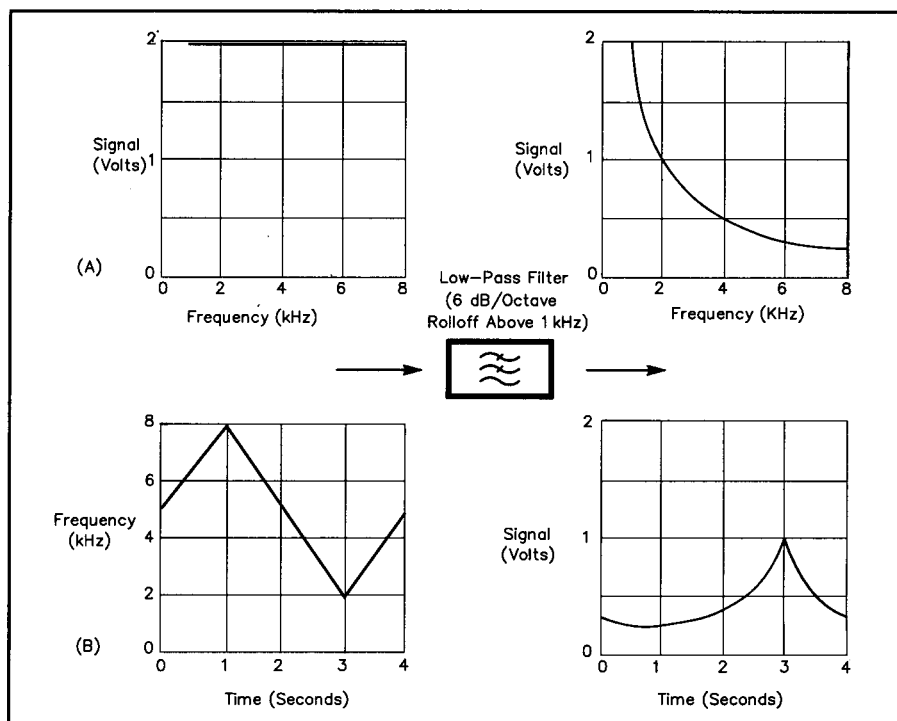

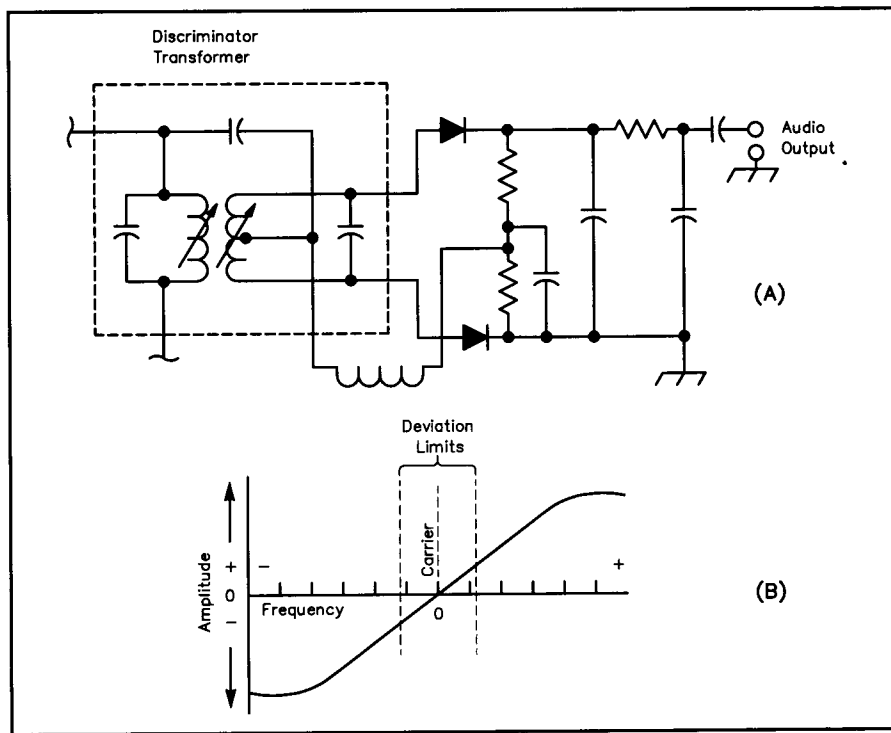

Fig 15.14—Frequency-sweeping a constant-amplitude signal and passing it through a low-pass filter results in an output signal that varies in amplitude with frequency (A). Sweeping the input signal back and forth between two frequency limits causes the output signal's amplitude to vary between two limits (B). This is the principle behind the angle-demodulation process called *frequency discrimination*.

**Fig 15.15—A discriminator (A) converts an angle-modulated signal's deviation into an amplitude variation (B) and envelope-detects the resulting AM signal. For undistorted demodulation, the discriminator's amplitude-versus-frequency characteristic must be linear across the input signal's deviation. A crystal discriminator uses a crystal as part of its frequency-selective circuitry.**

All we need to do to put this effect to practical use is develop a circuit that does this frequency-to-amplitude conversion linearly (and, since more output is better, steeply) across the frequency span of the modulated signal's deviation. Then we envelope-demodulate the resulting AM, and we're in.

**Fig 15.15** shows such a circuit—a *discriminator*—and the sort of amplitude-versus-frequency response we expect from it. (It's possible to use an AM receiver to recover understandable audio from a narrow angle-modulated signal by "off-tuning" the signal so its deviation rides up and down on one side of the receiver's IF selectivity curve. This *slope detection* process served as an early, suboptimal form of frequency discrimination.)

### Quadrature Detection

It's also possible to demodulate an angle-modulated signal merely by multiplying it with a time-delayed copy of itself in a double-balanced mixer (**Fig 15.16**). For simplicity's sake, we'll represent the mixer's RF input signal as just a sine wave with an amplitude,  $A$

$$A \sin(2\pi ft) \quad (11)$$

and its time-delayed twin, fed to the mixer's LO input, as a sine wave with an amplitude,  $A$ , and a time delay of  $d$ :

$$A \sin(2\pi ft + d) \quad (12)$$

Setting this special mixing arrangement into motion, we see

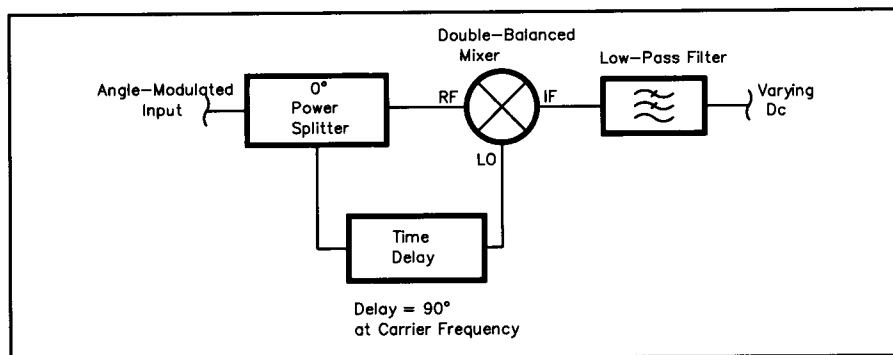

$$\begin{aligned} & A \sin(2\pi ft) \cdot A \sin(2\pi ft + d) \\ &= \frac{A^2}{2} \cos(2\pi fd) \\ &- \frac{A^2}{2} \cos(2\pi fd) \cos(2 \cdot 2\pi ft) \\ &+ \frac{A^2}{2} \sin(2\pi fd) \sin(2 \cdot 2\pi ft) \end{aligned} \quad (13)$$

Two of the three outputs—the second and third terms—emerge at twice the input frequency; in practice, we're not interested in these, and filter them out. The remaining term—the one we're after—varies in amplitude and sign according to how far and in what direction the carrier shifts away from its resting or center frequency (at which the time delay,  $d$ , causes the mixer's RF and LO inputs to be exactly  $90^\circ$  out of phase—in *quadrature*—with each other). We can examine this effect by replacing  $f$  in equations 11 and 12 with the sum term  $f_c + f_s$ , where  $f_c$  is the center frequency and  $f_s$  is the frequency shift. A  $90^\circ$  time delay is the same as a quarter cycle of  $f_c$ , so we can restate  $d$  as

$$d = \frac{1}{4f_c} \quad (14)$$

The first term of the detector's output then becomes

$$\begin{aligned} & \frac{A^2}{2} \cos(2\pi(f_c + f_s)d) \\ &= \frac{A^2}{2} \cos\left(2\pi(f_c + f_s) \frac{1}{4f_c}\right) \\ &= \frac{A^2}{2} \cos\left(\frac{\pi}{2} + \frac{\pi f_s}{2f_c}\right) \end{aligned} \quad (15)$$

**Fig 15.16—In quadrature detection, an angle-modulated signal multiplies with a time-delayed copy of itself to produce a dc voltage that varies with the amplitude and polarity of its phase or frequency excursions away from the carrier frequency. A practical quadrature detector can be as simple as a  $0^\circ$  power splitter (that is, a power splitter with in-phase outputs), a diode double-balanced mixer, a length of coaxial cable  $\frac{1}{4}\lambda$  (electrical) long at the carrier frequency, and a bit of low-pass filtering to remove the detector output's RF components. IC quadrature detectors achieve their time delay with one or more resistor-loaded tuned circuits (**Fig 15.17**).**

$$\frac{A^2}{2} \cos\left(\frac{\pi}{2}\right) = 0 \quad (16)$$

An ideal quadrature detector puts out 0 V dc when no modulation is present (with the carrier at  $f_c$ ). The output of a real quadrature detector may include a small *dc offset* that requires compensation. If we need the detector's response all the way down to dc, we've got it; if not, we can put a suitable blocking capacitor in the output line for ac-only coupling.

because it doesn't require a special discriminator transformer, and because the necessary balanced-detector circuitry can easily be implemented in IC structures along with limiters and other receiver circuitry. The synchronous AM detector project later in this chapter uses such a chip, the Philips Components-Signetics NE604A, to do limiting and phase detection as part of a phase-locked loop (PLL); **Fig 15.17** shows another example.

Back at Fig 15.14, we saw how a PLL can be used as an angle modulator. A PLL also makes a fine angle *demodulator*. Applying an angle-modulated signal to a PLL keeps its phase detector and VCO hustling to maintain loop lock through the input signal's angle variations. The loop's error voltage therefore tracks the input signal's modulation, and its variations mirror the modulation signal. Turning the loop's varying dc error voltage into audio is just a blocking capacitor away.

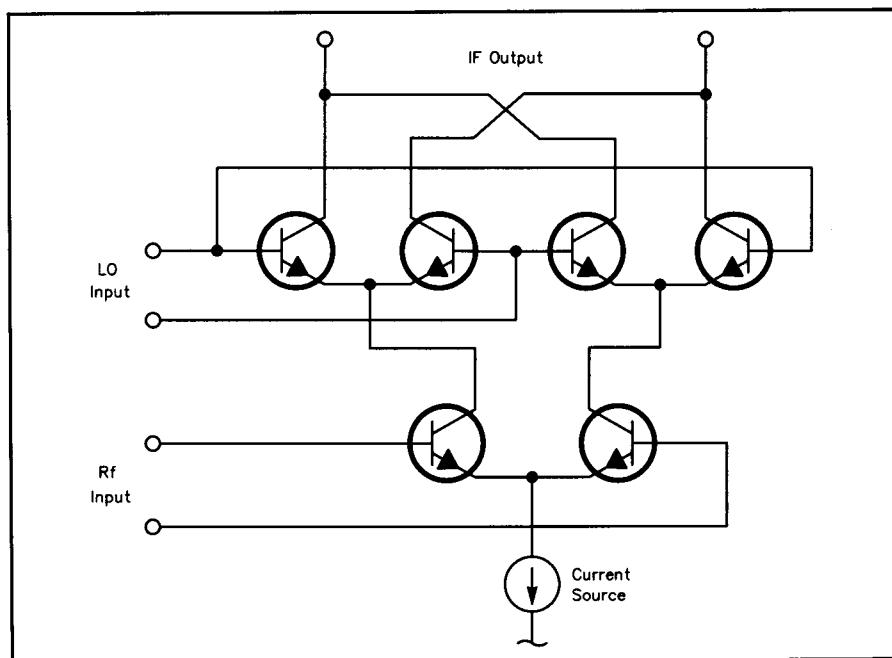

stant frequency offset from  $f_c$  (a dc component) simply causes a PLL demodulator to swing its VCO over to the new input frequency, resulting in a proportional dc offset on the VCO control-voltage line. Another way of looking at the difference between a PLL angle modulator and a PLL angle demodulator is that a PLL demodulator works with a varying reference signal (the input signal), while a PLL angle modulator generally doesn't.

By now, it's almost household knowledge that FM radio communication systems are superior to AM in their ability to suppress and ignore static, manmade electrical noise and (through an angle-modulation-receiver characteristic called *capture effect*) cochannel signals sufficiently weaker than the desired signal. AM-noise immunity is not intrinsic to angle modulation, however; it must be designed into the angle-modulation receiver.

## PRACTICAL BUILDING BLOCKS FOR MIXING, MODULATION AND DEMOMULATION

## Sine-Wave Mixing, Square-Wave Mixing

[illegible]**Mixers, Modulators and Demodulators 15.13**

**Fig 15.18—The Gilbert cell mixer. The Motorola MC1496 and Philips Components-Signetics NE602A are based on this circuit.**

patented by H. E. Jones.) A Gilbert cell consists of two differential transistor pairs whose bias current is controlled by one of the input signals. The other signal drives the differential pairs' bases, but only after being "predistorted" in a diode circuit. (This circuit distorts the signal equally and oppositely to the inherent distortion of the differential pair.) The resulting output signal is an accurate multiplication of the input voltages.

Early Gilbert-cell ICs, such as the Motorola MC1495 multiplier, had a number of disadvantages, including critical external adjustments, narrow bandwidth, and limited dynamic range. Modern Gilbert cells, such as the Burr-Brown MPY600 and Analog Devices AD834, overcome most of these disadvantages, and have led to an increase in usage of analog multipliers as mixers. Most practical radio mixers do not work exactly as analog multipliers, however. In practice, they act more like fast analog *switches*.

In using a mixer as fast switching device, we feed its LO input with a single-frequency square wave rather than a sine wave, and feed sine waves, audio, or other complex signals to the mixer's RF input. The RF port serves as the mixer's "linear" input, and therefore must preferably exhibit low intermodulation and harmonic distortion. Feeding a  $\pm 1$ -V square wave into the LO input alternately multiplies the linear input by +1 or -1. Multiplying the RF-port signal by +1 just transfers it to the output with no change. Multiplying the

RF-port signal by -1 does the same thing, except that the signal inverts (flips 180° in phase). The LO port need not exhibit low intermodulation and harmonic distortion; all it has to do is preserve the switching signal's fast rise and fall times.

Using square-wave LO drive allows us to simplify the Gilbert multiplier by dispensing with its predistortion circuitry. The Motorola MC1496, still in wide use despite its age, is an example of this. The Philips Components-Signetics NE602A and its relatives, popular with Amateur Radio experimenters, are modern MC1496 descendants. The vast majority of Gilbert-cell mixers in current use are square-wave LO-drive types. In practice, though, we don't have to square the LO signals we apply to them to make them work well. All we need to do is drive their LO inputs with a sine wave of sufficient amplitude to overdrive the associated transistors' bases. This clips the LO waveform, effectively resulting in square-wave drive.

### Reversing-Switch Mixers

We can multiply a signal by a square wave without using an analog multiplier at all. All we need is a pair of balun transformers and four diodes (**Fig 15.19A**).

With no LO energy applied to the circuit, none of its diodes conduct (**Fig 15.19B**). RF-port energy (1) can't make it to the LO port because there's no direct connection between the secondaries of T1 and T2, and (2) doesn't produce

IF output because T2's secondary balance results in energy cancellation at its center tap, and because no complete IF-energy circuit exists through T2's secondary with both of its ends disconnected from ground.

Applying a square wave to the LO port biases the diodes so that, 50% of the time (**Fig 15.19C**), D1 and D2 are on and D3 and D4 are reverse-biased off. This unbalances T2's secondary by leaving its upper wire floating and connecting its lower wire to ground through T1's secondary and center tap. With T2's secondary unbalanced, RF-port energy emerges from the IF port.

The other 50% of the time (**Fig 15.19D**), D3 and D4 are on and D1 and D2 are reverse-biased off. This unbalances T2's secondary by leaving its lower wire floating, and connects its upper wire to ground through T1's secondary and center tap. With T2's secondary unbalanced, RF-port energy again emerges from the IF port—shifted 180° relative to the first case because T2's active secondary wires are now, in effect, transposed relative to its primary.

A reversing switch mixer's output spectrum is the same as the output spectrum of a multiplier fed with a square wave. This can be analyzed by thinking of the square wave in terms of its Fourier series equivalent, which consists of the sum of sine waves at the square wave frequency and all of its odd harmonics. The amplitude of the equivalent series' fundamental sine wave is  $4/\pi$  times (2.1 dB greater than) the amplitude of the square wave. The amplitude of each harmonic is inversely proportional to its harmonic number, so the third harmonic is only 1/3 as strong as the fundamental (9.5 dB below the fundamental), the 5th harmonic is only 1/5 as strong (14 dB below the fundamental) and so on. The input signal mixes with each harmonic separately from the others, as if each harmonic were driving its own separate mixer, just as we illustrated with two sine waves in **Fig 15.4**. Normally, the harmonic outputs are so widely removed from the desired output frequency that they are easily filtered out, so a reversing-switch mixer is just as good as a sine-wave-driven analog multiplier for most practical purposes, and usually better—for radio purposes—in terms of dynamic range and noise.

An additional difference between multiplier and switching mixers is that a switching mixer's signal flow is reversible. It really only has one dedicated input (the LO input). The other terminals are can be thought of as I/O (input/output) ports, since either one can be the input as long as the other is the output.

**Fig 15.19—A reversing-switch mixer uses fast switching devices, balanced transformers and square-wave LO drive to reverse the RF-port signal's phase at a rate determined by the LO frequency. (Diodes are shown, but BJTs and FETs can also be used, as we'll soon see.)** With no LO drive (B), no RF-port energy shows up at the IF port because T2's secondary has no ground return. When the LO waveform goes positive, D1 and D2 turn on and D3 and D4 turn off, unbalancing T2's secondary and giving the IF port a ground return through T1's secondary and its center tap. When the LO waveform goes negative, D1 and D2 turn off and D3 and D4 turn on, again unbalancing T2's secondary and again giving the IF port a ground return. RF-port energy gets through to the IF port in both states; alternately operating T2's secondary halves results in 180° phase reversal from state to state.

3.9 dB. This is 2.1 dB better than an ideal multiplier, in which the peak output voltages of the sum and difference products are each half that of (6 dB lower than) the input signal, as reflected in the  $1/2$  coefficients in the right-hand terms of equation 7.

The switches and transformers in an ideal reversing-switch mixer dissipate no power, so an ideal reversing-switch mixer is lossless. If the LO driving signal contained no harmonics, half of the mixer's output power would show up in the sum product and half in the difference product, resulting in a 3-dB *conversion loss* relative to the RF-port signal. Some of the mixer's output goes into the sum and difference products of harmonic mixing, however; hence, the additional 0.9 dB of conversion loss, or 3.9 dB overall for an ideal reversing switch mixer. In practical mixers, switch and transformer losses increase conversion loss to a typical value of 6 dB.

### The Diode Double-Balanced Mixer: A Basic Building Block

The most common implementation of a reversing switch mixer is the diode *double-balanced mixer* (DBM). DBMs can serve as mixers (including image-reject types), modulators (including single- and double-sideband, phase, biphasic, and quadrature-phase types) and demodulators, limiters, attenuators, switches, phase detectors, and frequency doublers. In some of these applications, they work in conjunction with power dividers, combiners and hybrids.

#### The Basic DBM Circuit

We have already seen the basic diode DBM circuit (Fig 15.19). In its simplest form, a DBM contains two or more unbal-

### Conversion Loss

At the instant of peak output voltage, a switching mixer's waveform is a full-wave-rectified sine wave. Thus its average output voltage equals that of a full-

wave-rectified sine wave, which we know from power supply theory to be  $2/\pi$ , or 0.636, times the peak of the sine wave. The conversion loss of an ideal reversing-switch mixer is therefore  $20 \log 2/\pi$ , or

anced-to-balanced transformers and a Schottky diode ring consisting of  $4 \times n$  diodes, where  $n$  is the number of diodes in each leg of the ring. Each leg commonly consists of up to four diodes.

As we've seen, the degree to which a mixer is *balanced* depends on whether either, neither or both of its input signals (RF and LO) emerge from the IF port along with mixing products. An unbalanced mixer suppresses neither its RF nor its LO; both are present at its IF port. A single-balanced mixer suppresses its RF or LO, but not both. A double-balanced mixer suppresses its RF and LO inputs. Diode and transformer uniformity in the Fig 15.19 circuit results in equal LO potentials at the center taps of T1 and T2. The LO potential at T1's secondary center tap is zero (ground); therefore, the LO potential at the IF port is zero.

Balance in T2's secondary likewise results in an RF null at the IF port. The RF potential between the IF port and ground is therefore zero—except when the DBM's switching diodes operate, of course!

The Fig 15.19 circuit normally also affords high RF-IF isolation because its balanced diode switching precludes direct connections between T1 and T2. A diode DBM can be used as a current-controlled switch or attenuator by applying dc to its IF port, albeit with some distortion. This causes opposing diodes (D2 and D4, for

instance) to conduct to a degree that depends on the current magnitude, connecting T1 to T2.

One extension of the single-diode-ring DBM is a *double* double-balanced mixer (DDBM) with high dynamic range and larger signal handling capability than a single-ring design. Fig 15.20 diagrams such a DDBM, which uses transmission-line transformers and two diode rings. This type of mixer has higher 1-dB compression point (usually 3 to 4 dB lower than the LO drive) than a DBM. Low distortion is a typical characteristic of DDBMs. Depending on the ferrite core material used (ferrites with a magnetic permeability— $\mu$ —of 100 to 15,000), frequencies as low as a few hundred hertz and as high as a few gigahertz can be covered.

### Diode DBM Components

Commercially manufactured diode DBMs generally consist of: (A) a supporting base; (B) a diode ring; (C) two or more ferrite-core transformers commonly wound with two or three twisted-pair wires; (D) encapsulating material; and (E) an enclosure.

### Diodes

Hot-carrier (Schottky) diodes are the devices of choice for diode-DBM rings because of their low ON resistance, although ham-built DBMs for noncritical

MF/HF use commonly use switching diodes like the 1N914 or 1N4148. The forward voltage drop,  $V_f$ , across each diode in the ring determines the mixer's optimum local-oscillator drive level. Depending on the forward voltage drop of each of its diodes and the number of diodes in each ring leg, a diode DBM may be categorized as a Level 0, 3, 7, 10, 13, 17, 23 or 27 device. The numbers indicate the mixer's optimal LO drive level in dBm. As a rule of thumb, the LO signal must be must 20 dB larger than the RF and IF signals for proper operation. This ensures that the LO signal, rather than the RF or IF signals, switches the mixer's diodes on and off—a critical factor in minimizing IMD and maximizing dynamic range.

Schottky diodes are characterized by loss and contact resistance ( $R_s$ ), junction capacitance ( $C_j$ ), and forward voltage drop ( $V_f$ ) at a known current, typically 1 mA or 10 mA. The lower the diode-to-diode  $V_f$  difference in millivolts, the better the diode match at dc. (Some early diode DBM designs used diodes in series with a parallel resistor/capacitor combination for automatic biasing.) Better diode matching (in  $V_f$  and  $C_j$ ) results in higher isolation among the ports. Diodes capable of operating at higher frequencies have lower junction capacitance and lower parasitic inductance. Fig 15.21 shows the equivalent circuit for Schottky diodes of three package types.

Fig 15.20—Five transmission-line transformers and two Schottky-quad rings form this double double-balanced mixer (DDBM). Such designs can provide lower distortion, better signal-handling capability and higher interport isolation than single-ring designs.

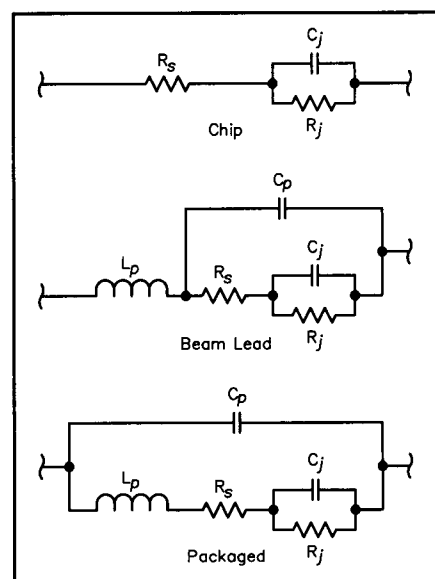

Fig 15.21—Its semiconductive properties aside, a Schottky diode can be represented as a network consisting of resistance, capacitance and/or inductance. Of these, the junction capacitance ( $C_j$ ) plays an especially critical role in a double-balanced mixer's high-end response. ( $R_j$ =junction resistance,  $R_s$ =contact resistance,  $L_p$ =parasitic inductance and  $C_p$ =parasitic capacitance.)

Manufacturers of diodes suitable for DBMs characterize their diodes as low-barrier, medium-barrier, high-barrier and very-high-barrier (usually two or more diodes in each leg), with typical  $V_f$  values of 220 mV, 350 mV, 600 mV and 1 V or more, respectively. Fig 15.22 shows a typical current-voltage (I-V) characteristic for a low-barrier Schottky quad capable of operating up to 4 GHz. Note that as current through the diodes increases, the  $V_f$  difference among the ring's diodes also increases, affecting the balance.

**Fig 15.22—Current-voltage (I-V) characteristic for Schottky diode quad, showing worst-case voltage imbalance (the spread between the two curves) among the four diodes.**

**Fig 15.23—A diode DBM's port-to-port isolation depends on how well its diodes match and how well its transformers are balanced. This graph shows LO-IF and LO-RF isolation versus frequency for a Synergy Microwave CLP-4A3 mixer.**

At higher frequencies, diode packaging becomes critical and expensive. As the frequency of operation increases, the effect of junction capacitance and package capacitance cannot be ignored. Part or all of the capacitance can be compensated at the mixer's highest operating frequency by properly designing the unbalanced-to-balanced transformers. The transformer inductance and diode junction capacitance form a low-pass network with its cutoff frequency higher than the frequency of operation. Compensated in this way, diodes with a junction capacitance of 0.2 pF can be used up to 8 to 10 GHz.

### Transformers

From the DBM schematic shown in Fig 15.19, it's clear that the LO and RF transformers are unbalanced on the input side and balanced on the diode side. The diode ends of the balanced ports are 180° out of phase throughout the frequency range of interest. This property causes signal cancellations that result in higher port-to-port isolation. Fig 15.23 plots LO-RF and LO-IF isolation versus frequency for Synergy Microwave's CLP-4A3 DBM. Isolations on the order of 70 dB occur at lower end of the band as a direct result of the balance among the four diode-ring legs and the RF phasing of the balanced ports.

As we learned in our discussion of generic switching mixers, transformer efficiency plays an important role in determining a mixer's conversion loss and drive-level requirement. Core loss, copper loss and impedance mismatch all contribute to transformer losses.

Ferrite in toroidal, bead, balun (multihole), or rod form can serve as DBM transformer cores. Radio amateurs commonly use Fair-rite Mix 43 ferrite ( $\mu$ , 950), but if the mixer will be used over a wide temperature range, the core material must be evaluated in terms of temperature coefficient and curie temperature (the temperature at which a ferromagnetic mate-

rial loses its magnetic properties). In some materials,  $\mu$  may change drastically across the desired temperature range, causing a frequency-response shift with temperature. Once a suitable core material and form have been selected, frequency requirements determine the necessary core size. For a given core shape and size, the number of turns, wire size, and the number of twists determine transformer performance. Wire placement also plays an important role.

RF transformers combine lumped and distributed capacitance and inductance. The interwinding capacitance and characteristic impedance of a transformer's twisted wires sets the transformer's high-frequency response. The core's  $\mu$  and size, and the number of winding turns, determine the transformer's lower frequency limit. Covering a specific frequency range requires a compromise in the number of turns used with a given core. Increasing a transformer's core size and number of turns improves its low-frequency response. Cores may be stacked to meet low-frequency performance specs.

Inexpensive mixers operating up to 2 GHz most commonly use twisted trifilar (three-wire) windings made of a wire size between #36 and #32. The number of twists per unit length of wire determines a winding's characteristic impedance. Twisted wires are analogous to transmission lines, and can be analyzed in terms of distributed interwinding capacitance. Decreasing the number of twists lowers the interwinding capacitance and increases the frequency of operation. On the other hand, using fewer twists per inch than four makes winding difficult because the wires tend to separate instead of behaving as a single cable.

The transmission-line effect predominates at the higher end of a transformer's frequency range. If two impedances,  $Z_1$  and  $Z_2$ , need to be matched through a transmission line of characteristic impedance,  $Z_0$ , then

$$Z_0 = \sqrt{Z_1 \cdot Z_2} \quad (17)$$

Fig 15.24 shows two types of transformers using twisted wires: (A) a three-wire type in which the primary winding is isolated from the secondary winding with a center tap, and (B) a two-wire (transmission-line) type in which two sets of transmission lines are interconnected to form a center tap at the secondary with a direct connection between primary and secondary. The primary-to-secondary turns ratio determines the impedance match as shown in equation 17. The properties of these two transformer types can be summarized as follows:

1. By virtue of its construction, the

**Fig 15.24—Transformers for DBMs: three-wire (A), and transmission-line (B).**

**Fig 15.25—How a typical commercial DBM is wired. The use of different wire colors for the transformers' various windings speeds assembly and minimizes error. U1, a Schottky-diode quad, contains D1-D4 of Fig 15.19.**

**Fig 15.26—Conversion loss versus frequency for a typical diode DBM. The LO drive level is +7 dBm.**

three-wire transformer is less symmetrical at higher frequencies than the transmission-line type.

2. The transformers' lower cutoff frequency ( $f_L$ ) is determined by the equation  $\omega L > 4R$  (18)

where

$L$  = inductance of the winding  
 $R$  = system impedance; for example, 50  $\Omega$ , 75  $\Omega$  and so on; and  
 $\omega = 2\pi f_L$ .

3. The transmission-line transformer's upper cutoff frequency ( $f_H$ ) is determined by the highest frequency at which its

wires' twists (that is, the coupling between them) allow it to function as a transmission line of the proper characteristic impedance.

4. Transformers convert one impedance,  $Z_1$  (primary) to another,  $Z_2$  (secondary) according to the relationship

$$Z_2 = Z_1 (N)^2 \quad (19)$$

where  $N$  = secondary to primary turns ratio. Within certain limits, if  $Z_1$  is varied,  $Z_2$  also varies to a new value multiplied by  $N^2$ . Thus, a mixer designed for a 50- $\Omega$  system may work in a 75- $\Omega$  system with minor modifications.

### Diode DBMs in Practice

Fig 15.25 shows the wiring of a typical commercial DBM made with toroidal cores. The wires are wrapped around the package pins and diode leads, and then soldered. In this unit, the LO transformer's primary winding connects across pins 7 and 8; the RF-transformer primary, across pins 1 and 2. The pin pairs 3-4 and 5-6 are connected externally to form the transformers' secondary center taps, one of which (5-6, that of the LO transformer) connects to a common ground point while the other (3-4, that of the RF transformer) serves as the IF port.

The DBM shown in Fig 15.25 has a decoupled IF port. If necessary, this DBM can be operated at a particular polarity (positive or negative) by appropriately connecting the LO, RF, IF and common ground points.

### DBM Specifications

Most of the parameters important in building or selecting a diode DBM also apply to other mixer types. They include: conversion loss and amplitude flatness across the required IF bandwidth; variation of conversion loss with input frequency; variation of conversion loss with LO drive, 1-dB compression point; LO-RF, LO-IF and RF-IF isolation; intermodulation products; noise figure (usually within 1 dB of conversion loss); port SWR; and dc offset, which is directly related to isolation among the RF, LO and IF ports.

### Conversion Loss

Fig 15.26 shows a plot of conversion loss versus intermediate frequency in a typical DBM. The curves show conversion loss for two fixed RF-port signals, one at 100 kHz and the another at 500 MHz, while varying the LO frequency from 100 kHz to 500 MHz.

Fig 15.27 plots a diode DBM's simulated output spectrum. Note that the RF input is -20 dBm and the IF output (the

frequency difference between the RF and LO signals) is -25 dBm, implying a conversion loss of 5 dB. This figure also applies to the sum of both signals (RF + LO).

We minimize a diode DBM's conversion loss, noise figure and intermodulation by keeping its LO drive high enough to switch its diodes on fully and rapidly. Fig 15.28 plots noise figure for the DDBM shown in Fig 15.20. Its 4-dB noise figure assumes ideal transformers and somewhat idealized diodes; typical mixers have a noise figure of 5 to 6 dB. Fig 15.29 plots conversion gain (loss) for the same mixer circuit.

Insufficient LO drive results in increased noise figure and conversion loss. IMD also increases because RF-port signals have a greater chance to control the mixer diodes when the LO level is too low.

### Dynamic Range: Compression, Intermodulation and More

The output of a linear stage—including a mixer, which we want to act as a linear frequency shifter—tracks its input signal decibel by decibel, every 1-dB change input change in its input signal(s) corresponding to an identical 1-dB output change. This is the stage's *first-order* response.

Because no device is perfectly linear, however, two or more signals applied to it generate sum and difference frequencies. These IMD products occur at frequencies and amplitudes that depend on the order of the IMD response as follows:

- *Second-order* IMD products change 2 dB for every decibel of input-signal change (this figure assumes that the IMD comes from equal-level input signals), and appear at frequencies that result from the simple addition and subtraction of input-signal frequencies. For example, assuming that its input bandwidth is sufficient to pass them, an amplifier subjected to signals, at 6 and 8 MHz will produce second-order IMD products at 2 MHz (8-6) and 14 MHz (8+6).
- *Third-order* IMD products change 3 dB for every decibel of input-signal change (this also assumes equal-level input signals), and appear at frequencies corresponding to the sums and differences of twice one signal's frequency plus or minus the frequency of another. Assuming that its input bandwidth is sufficient to pass them, an amplifier subjected to signals at 14.02 MHz ( $f_1$ ) and 14.04 MHz ( $f_2$ ) produces third-order IMD products at 14.00 ( $2f_1 - f_2$ ), 14.06 ( $2f_2 - f_1$ ), 42.08 ( $2f_1 + f_2$ ) and 42.10 ( $2f_2 + f_1$ ) MHz. The subtraction

POWER SPECTRUM AT Output Port#1

Fig 15.27—Simulated diode-DBM output spectrum. Note that the desired output products (the highest two products,  $RF - LO$  and  $RF + LO$ ) emerge at a level 5 dB below the mixer's RF input (-20 dBm). This indicates a mixer conversion loss of 5 dB. (Microwave SCOPE simulation)

Fig 15.28—Noise figure versus LO drive for a DDBM built along the lines of Fig 15.20.

Fig 15.29—Conversion gain (loss) for a DDBM. Increasing a mixer's LO level beyond that sufficient to turn its switching devices all the way on merely makes them dissipate more LO power and does not improve performance.

tive products (the 14.02- and 14.04-MHz products in this example) are close to the desired signal and can cause significant interference. Thus, third-order-IMD performance is of great importance in receiver mixers and RF amplifiers.

It can be seen that the IMD order determines how rapidly IMD products change level per unit change of input level.  $n$ th-order IMD products therefore change by  $n$  dB for every decibel of input-level change.

IMD products at orders higher than three can and do occur in communication systems, but the second- and third-order products are most important in receiver front ends. In transmitters, third- and higher-odd-order products are important because they widen the transmitted signal.

### Intercept Point

The second type of dynamic range concerns the receiver's *intercept point*, sometimes simply referred to as *intercept*. Intercept point is typically measured by applying two or three signals to the antenna input, tuning the receiver to count the number of resulting spurious responses, and measuring their level relative to the input signal.

Because a device's IMD products increase more rapidly than its desired output as the input level rises, it might seem that steadily increasing the level of multiple signals applied to an amplifier would eventually result in equal desired-signal and IMD levels at the amplifier output. Real devices are incapable of doing this, however. At some point, every device *overloads*, and changes in its output level no longer equally track changes at its input. The device is then said to be operating in *compression*; the point at which its first-order response deviates from linearity by 1 dB is its *1-dB compression point*. Pushing the process to its limit ultimately leads to *saturation*, at which point input-signal increases no longer increase the output level.

The power level at which a device's second-order IMD products equal its first-order output (a point that must be extrapolated because the device is in compression by this point) is its *second-order intercept point*. Likewise, its *third-order intercept point* is the power level at which third-order responses equal the desired signal. Fig 15.30 graphs these relationships.

Input filtering can improve second-order intercept point; device nonlinearities determine the third, fifth and higher-odd-number intercept points. In preamplifiers, third-order intercept point is directly related to dc input power; in mixers, to the local-oscillator power applied.

## Testing and Calculating Intermodulation Distortion in Receivers

Second and third-order IMD can be measured using the setup of Fig A. The outputs of two signal generators are combined in a 3-dB hybrid coupler. Such couplers are available from various companies, and can be homemade. The 3-dB coupler should have low loss and should itself produce negligible IMD. The signal generators are adjusted to provide a known signal level at the output of the 3-dB coupler, say, -20 dBm for each of the two signals. This combined signal is then fed through a calibrated variable attenuator to the device under test. The shielding of the cables used in this system is important: At least 90 dB of isolation should exist between the high-level signal at the input of the attenuator and the low-level signal delivered to the receiver.

The measurement procedure is simple: adjust the variable attenuator to produce a signal of known level at the frequency of the expected IMD product ( $f_1 \pm f_2$  for second-order,  $2f_1 - f_2$  or  $2f_2 - f_1$  for third-order IMD).

To do this, of course, you have to figure out what equivalent input signal level at the receiver's operating frequency corresponds to the level of the IMD product you are seeing. There are several ways of doing this. One way—the way used by the ARRL Lab in their receiver tests—uses the minimum discernible signal. This is defined as the signal level that produces a 3-dB increase in the receiver audio output power. That is, you measure the receiver output level with no input signal, then insert a signal at the operating frequency and adjust the level of this input signal until the output power is 3 dB greater than the no-signal power. Then, when doing the IMD measurement, you adjust the attenuator of Fig A to cause a 3-dB increase in receiver output. The level of the IMD product is then the same as the MDS level you measured.

There are several things I dislike about doing the measurement this way. The problem is that you have to measure noise power. This can be difficult. First, you need an RMS voltmeter or audio power meter to do it at all. Second, the measurement varies with time (it's noise!), making it difficult to nail down a number. And third, there is the question of the audio response of the receiver; its noise output may not be flat across the output spectrum. So I prefer to measure, instead of MDS, a higher reference level. I use the receiver's S meter as a reference. I first determine the input signal level it takes to get an S1 reading. Then, in the IMD measurement, I adjust the attenuator to again give an S1 reading. The level of the IMD product signal is now equal to the level I measured at S1. Note that this technique gives a different IMD level value than the MDS technique. That's OK, though. What we are trying to determine is the *difference* between the level of the signals applied to the receiver input and the level of the IMD product. Our calculations will give the same result whether we measure the IMD product at the MDS level, the S1 level or some other level.

An easy way to make the reference measurement is with the setup of Fig A. You'll have to switch in a lot of attenuation (make sure you have an attenuator with enough range), but doing it this way keeps all of the possible variations in the measurement fairly constant. And this way, the difference between the reference level and the input level needed to produce the desired IMD product signal level is simply the difference in attenuator settings between the reference and IMD measurements.

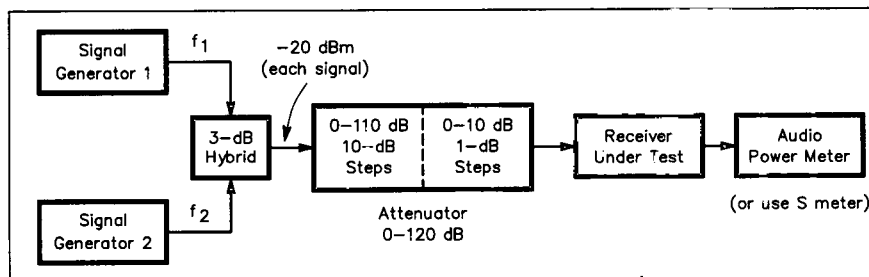

Fig A—Test setup for measurement of IMD performance. Both signal generators should be types such as HP 608, HP 8640, or Rhode & Schwarz SMDU, with phase-noise performance of -140 dBc/Hz or better at 20 kHz from the signal frequency.

Fig 15.30—A linear stage's output tracks its input decibel by decibel on a 1:1 slope—its *first-order* response. *Second-order intermodulation distortion (IMD) products* produced by two equal-level input signals ("tones") rise on a 2:1 slope—2 dB for every 1 dB of input increase. *Third-order IMD products* likewise increase 3 dB for every 1 dB of increase in two equal tones. For each IMD order  $n$ , there is a corresponding *intercept point*  $IP_n$ , at which the stage's first-order and  $n$ th order products are equal in amplitude. The first-order output of real amplifiers and mixers falls off (the device overloads and goes into *compression*) before IMD products can intercept it, but intercept point is nonetheless a useful, valid concept for comparing radio system performance. The higher an amplifier or mixer's intercept point, the stronger the input signals it can handle without overloading. The input and output powers shown are for purposes of example; every device exhibits its own particular IMD profile. (After W. Hayward, *Introduction to Radio Frequency Design*, Fig 6.17)

## Calculating Intercept Points

Once we know the levels of the signals applied to the receiver input and the level of the IMD product, we can easily calculate the intercept point using the following equation:

$$IP_n = \frac{n \cdot P_A - P_{IM_n}}{n - 1} \quad (A)$$

Here,  $n$  is the order,  $P_A$  is the receiver input power (of one of the input signals),  $P_{IM_n}$  is the power of the IMD product signal, and  $IP_n$  is the  $n$ th-order intercept point. All powers should be in dBm. For second and third-order IMD, equation A results in the equations:

$$IP_2 = \frac{2 \cdot P_A - P_{IM_2}}{2 - 1} \quad (B)$$

$$IP_3 = \frac{3 \cdot P_A - P_{IM_3}}{3 - 1} \quad (C)$$

You can measure higher-order intercept points, too.

## Example Measurements

To get a feel for this process, it's useful to consider some actual measured values.

The first example is a Rohde & Schwarz model EK085 receiver with digital preselection. For measuring second-order IMD, signals at 6.00 and 8.01 MHz, at -20 dBm each, were applied at the input of the attenuator. The difference in attenuator settings between the reference measurement and the level needed to produce the desired IMD product signal level was found to be 125 dB. The calculation of the second-order IP is then:

$$\begin{aligned} IP_2 &= \frac{2(-20 \text{ dBm}) - (-20 \text{ dBm} - 125 \text{ dB})}{2 - 1} \\ &= -40 \text{ dBm} + 20 \text{ dBm} + 125 \text{ dB} \\ &= +105 \text{ dBm} \end{aligned}$$

For  $IP_3$ , we set the signal generators for 0 dBm at the attenuator input, using frequencies of 14.00 and 14.01 MHz. The difference in attenuator settings between the reference and IMD measurements was 80 dB, so:

$$\begin{aligned} IP_3 &= \frac{3(0 \text{ dBm}) - (0 \text{ dBm} - 80 \text{ dB})}{3 - 1} \\ &= \frac{0 \text{ dBm} + 80 \text{ dB}}{2} = +40 \text{ dBm} \end{aligned}$$

We also measured the  $IP_3$  of a Yaesu FT-1000D at the same frequencies, using attenuator-input levels of -10 dBm. A difference in attenuator readings of 80 dB resulted in the calculation:

$$\begin{aligned} IP_3 &= \frac{3(-10 \text{ dBm}) - (-10 \text{ dBm} - 80 \text{ dB})}{3 - 1} \\ &= \frac{-30 \text{ dBm} + 10 \text{ dBm} + 80 \text{ dB}}{2} = \frac{-20 \text{ dBm} + 80 \text{ dB}}{2} \\ &= +30 \text{ dBm} \end{aligned}$$

## Synthesizer Requirements

To be able to make use of high third-order intercept points at these close-in spacings requires a low-noise LO synthesizer. You can estimate the required noise performance of the synthesizer for a given  $IP_3$  value. First, calculate the value of receiver input power that would cause the IMD product to just come out of the noise floor, by solving equation A for  $P_A$ , then take the difference between the calculated value of  $P_A$  and the noise floor to find the dynamic range. Doing so gives the equation:

$$ID_3 = \frac{2}{3}(IP_3 + P_{\min}) \quad (D)$$

Where  $ID_3$  is the third-order IMD dynamic range in dB and  $P_{\min}$  is the noise floor in dBm. Knowing the receiver bandwidth, BW (2400 Hz in this case) and noise figure, NF (8 dB) allows us to calculate the noise floor,  $P_{\min}$ :

$$\begin{aligned} P_{\min} &= -174 \text{ dBm} + 10 \log(\text{BW}) + \text{NF} \\ &= -174 \text{ dBm} + 10 \log(2400) + 8 \\ &= -132 \text{ dBm} \end{aligned}$$

The synthesizer noise should not exceed the noise floor when an input signal is present that just causes an IMD product signal at the noise floor level. This will be accomplished if the synthesizer noise is less than:

$$\begin{aligned} ID + 10 \log(\text{BW}) &= 114.7 \text{ dB} + 10 \log(2400) \\ &= 148.5 \text{ dBc/Hz} \end{aligned}$$

in the passband of the receiver. Such synthesizers hardly exist.—Dr. Ulrich L. Rohde, KA2WEU

## Applying Diode DBMs

At first glance, applying a diode DBM is easy: We feed the signal(s) we want to frequency-shift (at or below the maximum level called for in the mixer's specifications, such as -10 dBm for the Mini-Circuits SBL-1 and Synergy Microwave S-1, popular Level 7 parts) to the DBM's RF port, feed the frequency-shifting signal (at the proper level) to the LO port, and extract the sum and difference products from the mixer's IF port.

There's more to it than that, however, because diode DBMs (along with most other modern mixer types) are *termination-sensitive*. That is, their ports—par-

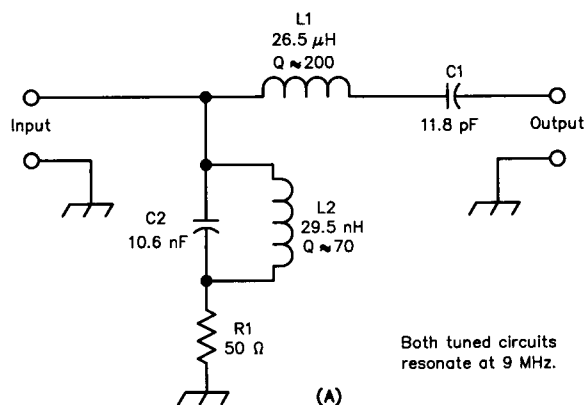

ticularly their IF (output) ports—must be resistively terminated with the proper impedance (commonly 50  $\Omega$ , resistive). A wideband, resistive output termination is particularly critical if a mixer is to achieve its maximum dynamic range in receiving applications. Such a load can be achieved by

- terminating the mixer in a 50- $\Omega$  resistor or attenuator pad (a technique usually avoided in receiving applications because it directly degrades system noise figure);
- terminating the mixer with a low-noise, high-dynamic-range *post-mixer ampli-*

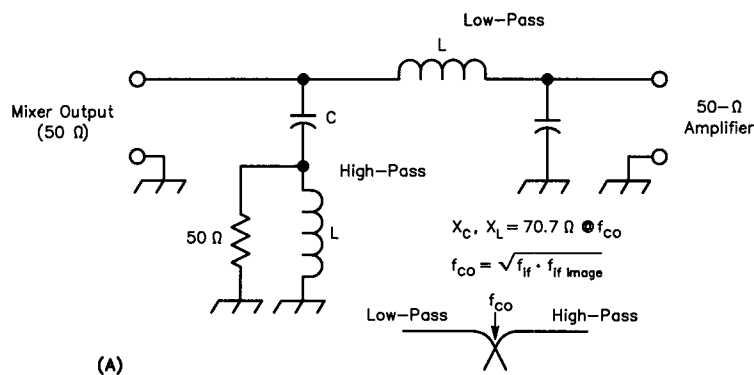

*fier* designed to exhibit a wideband resistive input impedance; or

- terminating the mixer in a *diplexer*, a frequency-sensitive signal splitter that appears as a two-terminal resistive load at its input while resistively dissipating unwanted outputs and passing desired outputs through to subsequent circuitry.

*Termination-insensitive* mixers are available, but this label can be misleading. Some termination-insensitive mixers are nothing more than a termination-sensitive mixer packaged with an integral post-mixer amplifier. True

**Fig 15.31—A diplexer resistively terminates energy at unwanted frequencies while passing energy at desired frequencies. This band-pass diplexer (A) uses a series-tuned circuit as a selective pass element, while a high-C parallel-tuned circuit keeps the network's terminating resistor from dissipating desired-frequency energy. Computer simulation of the diplexer's response with ARRL Radio Designer 1.0 (B, C and D) characterizes the diplexer's Insertion loss and good input match from 1 to 100 MHz (B) and from 8.8 to 9.2 MHz (C); and the real and imaginary components of the diplexer's input impedance from 8.8 to 9.2 MHz with a 50-Ω load at the diplexer's output terminal. The high-C, low-L nature of the L2-C2 circuit requires that C2 be minimally inductive; a 10,000-pF chip capacitor is recommended. This diplexer was described by Ulrich L. Rohde and T. T. N. Bucher in *Communications Receivers: Principles and Design*.**

31-AUG-94 COMPACT SOFTWARE - ARRL Radio Designer 1.0 09:04:41

File: c:\dpn\lphpdpx.ckt  
Simulation, Low-Pass/High-Pass Diplexer for a 3.984-MHz IF

**Fig 15.32**—All of the inductors and capacitors in this high-pass/low-pass diplexer (A) exhibit a reactance of  $70.7 \Omega$  at its tuned circuits' 3-dB cutoff frequency (the geometric mean of the IF and IF image). B and C show *ARRL Radio Designer* simulations of this circuit configured for use in a receiver that converts 7 MHz to 3.984 MHz using a 10.984-MHz LO. The IF image is at 17.984 MHz, giving a 3-dB cutoff frequency of 8.465 MHz. The inductor values used in the simulation were therefore  $1.33 \mu\text{H}$  ( $Q = 200$  at 25.2 MHz); the capacitors, 265 pF ( $Q = 1000$ ). This drawing shows idler load and "50- $\Omega$  Amplifier" connections suitable for a receiver in which the IF image falls at a frequency *above* the desired IF. For applications in which the IF image falls *below* the desired IF, interchange the 50- $\Omega$  idler load resistor and the diplexer's "50- $\Omega$  Amplifier" connection so the idler load terminates the diplexer low-pass filter and the 50- $\Omega$  amplifier terminates the high-pass filter.

termination-insensitive mixers are less common and considerably more elaborate. Amateur builders will more likely use one of the many excellent termination-sensitive mixers available in connection with a diplexer, post-mixer amplifier or both.

**Fig 15.31** shows one diplexer implementation. In this approach, L1 and C1 form a series-tuned circuit, resonant at the desired IF, that presents low impedance between the diplexer's input and output terminals at the IF. The high-impedance parallel-tuned cir-

cuit formed by L2 and C2 also resonates the desired IF, keeping desired energy out of the diplexer's 50- $\Omega$  load resistor, R1.

The preceding example is called a *band-pass diplexer*. **Fig 15.32** shows another type: a *high-pass/low-pass diplexer* in which each inductor and capacitor has a reactance of  $70.7 \Omega$  at the 3-dB cutoff frequency. It can be used after a "difference" mixer (a mixer in which the IF is the difference between the signal frequency and LO) if the desired IF and its image frequency are far enough apart

so that the image power is "dumped" into the network's 51- $\Omega$  resistor. (For a "summing" mixer—a mixer in which the IF is the sum of the desired signal and LO—interchange the 50- $\Omega$  idler load resistor and the diplexer's "50- $\Omega$  Amplifier" connection.) Richard Weinreich, KØUVU, and R. W. Carroll described this circuit in November 1968 *QST* as one of several absorptive TVI filters.

**Fig 15.33** shows a BJT post-mixer amplifier design made popular by Wes Hayward, W7ZOI, and John Lawson,

K5IRK. RF feedback (via the 1-k $\Omega$  resistor) and emitter degeneration (the ac-coupled 5.6- $\Omega$  emitter resistor) work together to keep the stage's input impedance low and uniformly resistive across a wide bandwidth.

### Amplitude Modulation with a DBM

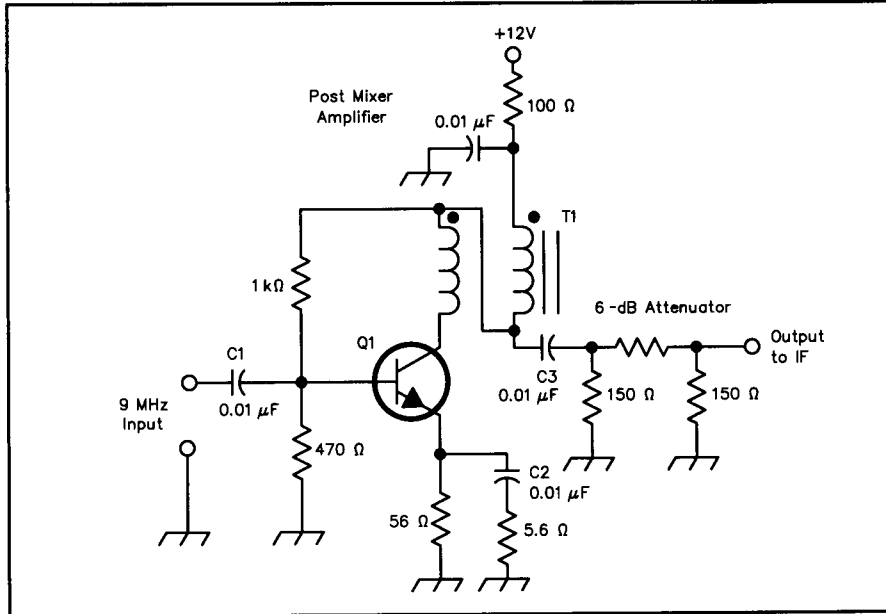

We can generate DSB, suppressed-carrier AM with a DBM by feeding the carrier to its RF port and the modulating signal to the IF port. This is a classical *balanced modulator*,

and the result—sidebands at radio frequencies corresponding to the carrier signal plus audio and the RF signal minus audio—emerges from the DBM's LO port. If we also want to transmit some carrier along with the sidebands, we can dc-bias the IF port (with a current of 10 to 20 mA) to upset the mixer's balance and keep its diodes from turning all the way off. (This technique is sometimes used for generating CW with a balanced modulator otherwise intended to generate DSB as part of an SSB-generation process.) Fig 15.34 shows a more elegant approach to generating full-carrier AM with a DBM.

As we saw earlier when considering the many faces of AM, two DBMs, used in conjunction with carrier and audio phasing, can be used to generate SSB, suppressed-carrier AM. Likewise, two DBMs can be used with RF and LO phasing as an image-reject mixer.

### Phase Detection with a DBM

As we saw in our exploration of quadrature detection, applying two signals of equal frequency to a DBM's LO and RF ports produces an IF-port dc output proportional to the cosine of the signals' phase difference (Fig 15.35). (This assumes that the DBM has a dc-coupled IF port, of course. If it doesn't—and some DBMs don't—phase-detector operation is out.) Any dc output offset introduces error into this process, so critical phase-detection applications use low-offset DBMs optimized for this service.

**Fig 15.33—The post-mixer amplifier from Hayward and Lawson's *Progressive Communications Receiver* (November 1981 *QST*). This amplifier's gain, including the 6-dB loss of the attenuator pad, is about 16 dB; its noise figure, 4 to 5 dB; its output intercept, 30 dBm. The 6-dB attenuator is essential if a crystal filter follows the amplifier; the pad isolates the amplifier from the filter's highly reactive input impedance. This circuit's input match to 50  $\Omega$  below 4 MHz can be improved by replacing 0.01- $\mu$ F capacitors C1, C2 and C3 with low-inductance 0.1- $\mu$ F units (chip capacitors are preferable).**

**Q1**—TO-39 CATV-type bipolar transistor,  $f_T$  = 1 GHz or greater. 2N3866, 2N5109, 2SC1252, 2SC1365 or MRF586 suitable. Use a small heat sink on this transistor.

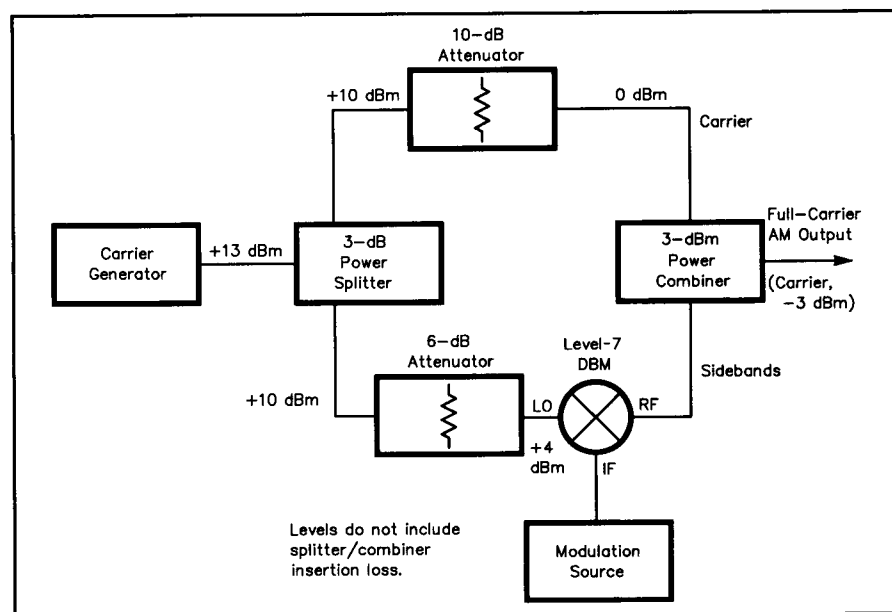

**T1**—Broadband ferrite transformer,  $\approx 42$   $\mu$ H per winding; 10 bifilar turns of #28 enameled wire on an FT73-43 core.

**Fig 15.35—A phase detector's dc output is the cosine of the phase difference between its input and reference signals.**

**Fig 15.36—Mixing a carrier with a square wave generates biphas-shift keying (BPSK), in which the carrier phase is shifted 180° for data transmission. In practice, as in this drawing, the carrier and data signals are phase-coherent so the mixer switches only at carrier zero crossings.**

**Fig 15.34—Generating full-carrier AM with a diode DBM.**

## Biphase-Shift Keying Modulation with a DBM

Back in our discussion of square-wave mixing, we saw how multiplying a switching mixer's linear input with a square wave

causes a  $180^\circ$  phase shift during the negative part of the square wave's cycle. As Fig 15.36 shows, we can use this effect to produce *biphase-shift keying* (BPSK), a digital system that conveys data by means of carrier phase reversals. A related system,

*quadrature phase-shift keying* (QPSK) uses two DBMs and phasing to convey data by phase-shifting a carrier in  $90^\circ$  increments.

## Transistors as Mixer Switching Elements

We've covered diode DBMs in depth because their home-buildability, high performance and suitability for direct connection into  $50\text{-}\Omega$  systems makes them attractive to Amateur Radio builders. The abundant availability of high-quality manufactured diode mixers at reasonable prices make them excellent candidates for home-construction projects. Although diode DBMs are common in telecommunications as a whole, their conversion loss and relatively high LO power requirement have usually driven the manufacturers of high-performance MF/HF Amateur Radio receivers and transceivers to other solutions. Those solutions have generally involved single- or double-balanced FET mixers—MOSFETs in the late 1970s and early 1980s, JFETs from the early 1980s to date. Many of the JFET designs are variations of a single-balanced mixer circuit introduced to *QST* readers in 1970!

Fig 15.37 shows the circuit as it was presented by William Sabin in "The Solid-State Receiver," *QST*, July 1970. Two 2N4416 JFETs operate in a common-source configuration, with push-pull RF input and parallel LO drive. Fig 15.38 shows a similar circuit as implemented in the ICOM IC-765 transceiver. In this version, the JFETs (2SK125s) operate in common-gate, with the LO applied across a  $220\text{-}\Omega$  resistor between the gates and ground.

Bipolar junction transistors can also work well in switching mixers. In June 1994 *QST*, Ulrich Rohde, KA2WEU, published a medium-frequency mixer well-suited to shortwave applications and home-built projects. Shown in Fig 15.39, it consists of two transistors in a push-pull, single-balanced configuration. Because of the degenerative feedback introduced by the  $20\text{-}\Omega$  emitter resistors, the two transistors need not be matched. This mixer's advantage lies in its achievement of a  $33\text{-dBm}$  output intercept with only  $17\text{ dBm}$  of local oscillator drive. (Typically, a diode DBM with the same IMD performance requires  $25$  to  $27\text{ dBm}$  of LO drive.) Tests indicate that the upper frequency limit of this mixer lies in the  $500\text{-MHz}$  region. The circuit's lower frequency limit depends on the transformer inductances and the ferrites used for the transformer cores.

Examining the state of the art in the 1990s, however, we find that the best receive-mixer dynamic ranges are achieved

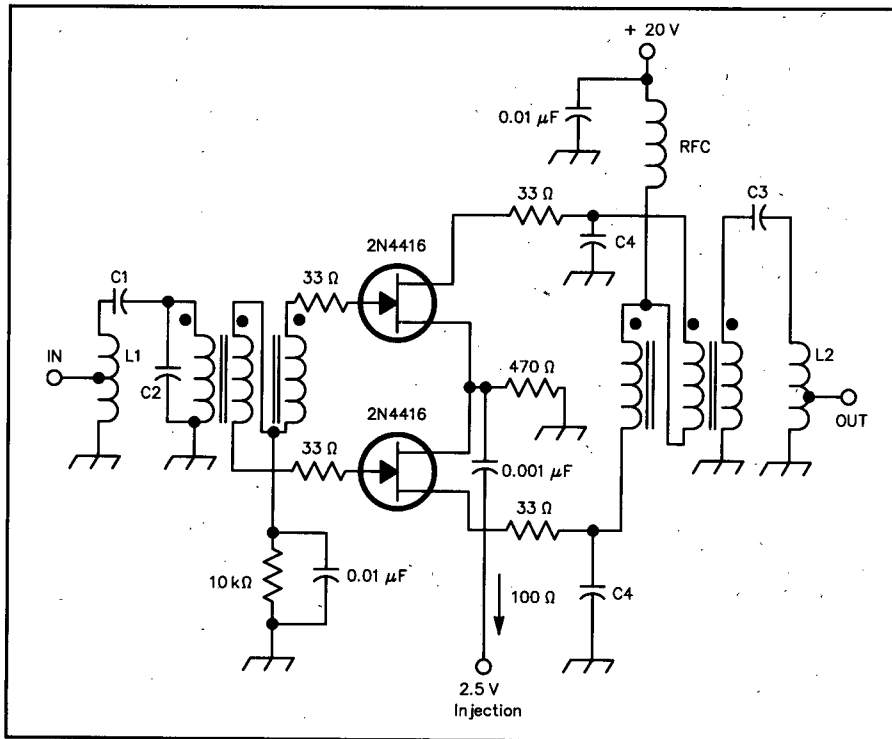

Fig 15.37—Two 2N4416 JFETs provide high dynamic range in this mixer circuit from Sabin 1970. L1, C1 and C2 form the input tuned circuit; L2, C3 and C4 tune the mixer output to the IF. The trifilar input and output transformers are broadband transmission-line types.

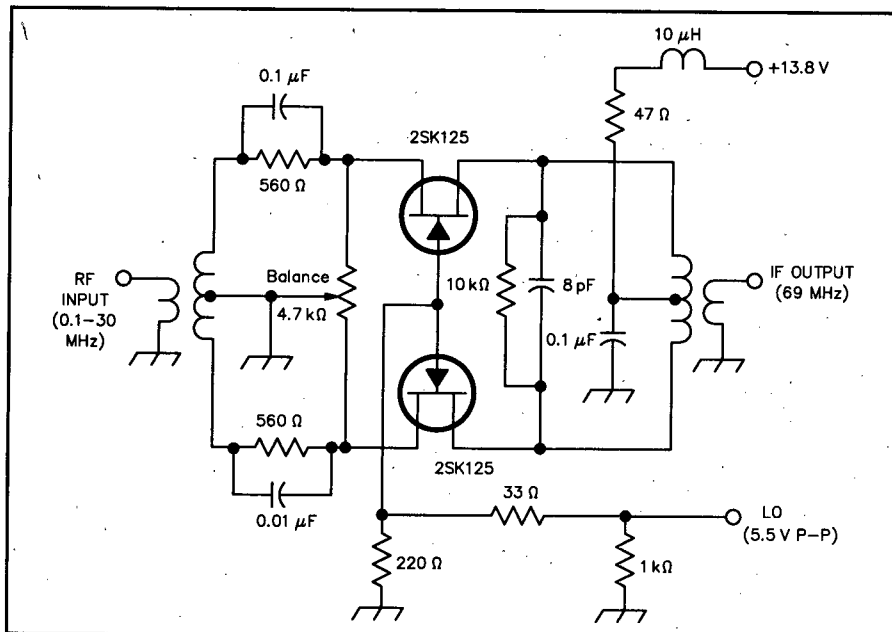

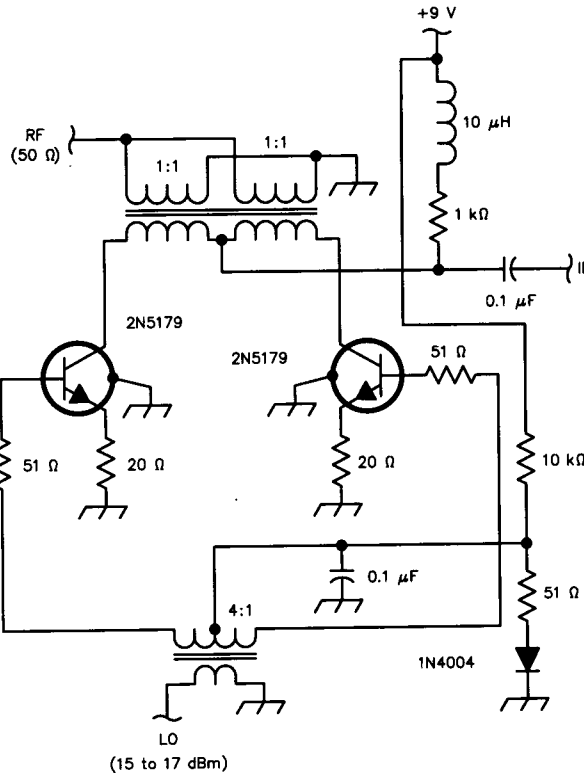

Fig 15.38—The ICOM IC-765's single-balanced 2SK125 mixer achieves a high dynamic range (per *QST* Product Review, an  $IP_3$  of  $10.5\text{ dBm}$  at  $14\text{ MHz}$  with preamp off) with arrangement very much like Sabin's. The first receive mixer in many commercial Amateur Radio transceiver designs of the 1980s and 1990s used a 2SK125 pair in much this way.

**Fig 15.39**—This single-balanced, push-pull BJT mixer achieves a high dynamic range ( $IP_3 \approx 33$  dBm) with 15 to 17 dBm of LO drive. Its insertion loss is approximately 6 dB. A diode-ring mixer would require 25 to 27 dBm of LO drive to achieve the same  $IP_3$ .

with quads of RF MOSFETs operating as passive switches, with no drain voltage applied. The best of these techniques involves following a receiver's first mixer with a diplexer and low-loss roofing crystal filter, rather than terminating the mixer in a strong wideband amplifier.

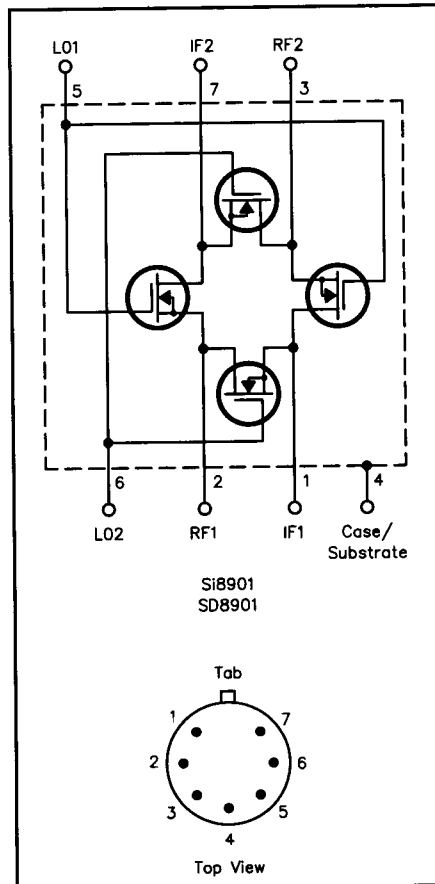

### A High-Dynamic-Range MF/HF Front End

Jacob Mahkinson, N6NWP, achieved outstanding results with the more traditional arrangement shown in Figs 15.40, 15.41, 15.42, 15.43 and 15.44. A monolithic DMOS FET quad, the Calogic SD8901 (Fig 15.40), serves as the core of his system, which was experimentally built for 14-MHz reception with a 9-MHz IF. The system was described in February 1993 *QST*.

#### The Mixer

Fig 15.41 shows the mixer/diplexer schematic. T1 matches the 50-Ω source (the preamplifier) to U2's RF port, and T2 matches U2's IF port to a 50-Ω load—the post-mixer amplifier.

In a commutation mixer, there is a compromise between conversion loss and intermodulation distortion. The impedance ratios of transmission-line transformers T1 and T2 are chosen to achieve low intermodulation distortion while keeping conversion loss at an acceptable level.

**Fig 15.40**—The N6NWP front end uses a Calogic SD8901 DMOS FET quad mixer.

The LO waveform applied to U2 is of great importance. To achieve a high intercept point, the LO drive must approach an ideal square wave with a 50% duty cycle. Flip-flop U1B divides the LO signal frequency by two and provides 50% duty cycle square waves at its complimentary outputs. The offset bias adjustment potentiometers, R6 and R7, allow compensation for mismatch among the SD8901's MOSFETs and ensure that the commutation mixer switches operate in a 50% duty cycle mode. U1A provides a signal that can be applied to a digital frequency counter.

The mixer's intercept point also depends on the LO drive level. Zener diode D1 establishes the power supply voltage for U1 and, therefore, the voltage swing at the mixer LO port. In the interest of obtaining a high intercept point, a 9.1-V diode is used at D1. This voltage exceeds the 74HC74's maximum supply specification. Experiments with samples from different manufacturers show that there is a considerable safety margin, however: The 74HC74s tested failed when the power supply was adjusted to around 11 V. Those who feel uncomfortable in exceeding the part's maximum rating may use a 6.8-V Zener diode at the cost of a few decibels in the intercept point value.

A band-pass diplexer follows the mixer. It comprises L1, C8, C9, L2, C10, C11, R10 and R11. The 9-MHz signal passes through this network with minimum attenuation, while out-of-passband signals over a wide frequency range are dissipated. Resistor R10 presents a 50-Ω impedance to the mixer, while R11 presents a 50-Ω impedance to the input of the post-mixer amplifier. C7 cancels the inductive reactance of the mixer's input source.

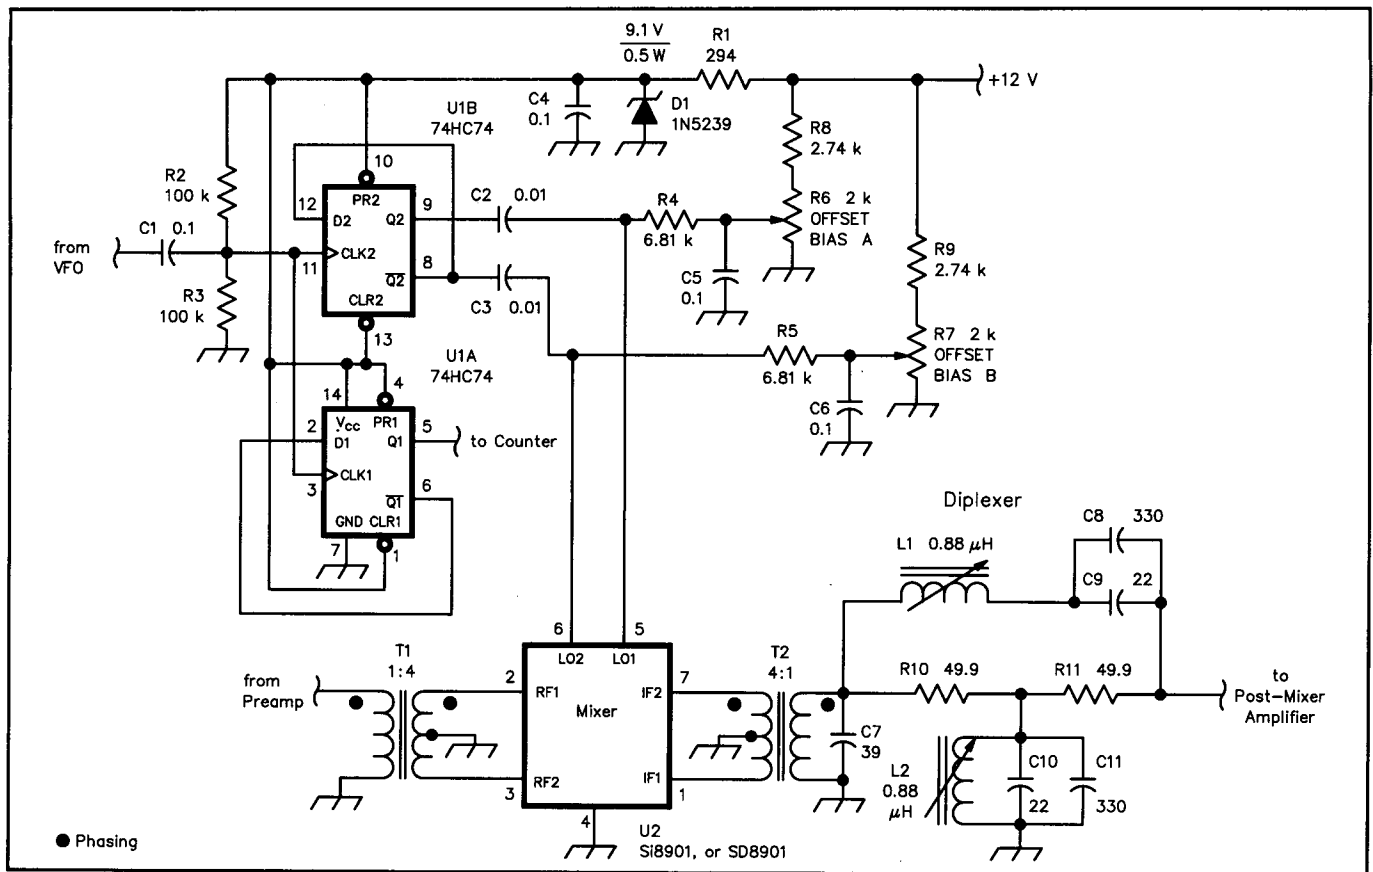

The measured performance of the mixer/diplexer circuit is: third-order output intercept, 35 dBm; 1-dB output compression point, 16 dBm; 1-dB output desensitization (blocking) point, 15 dBm; insertion loss, 7 dB.

#### The Preamplifier

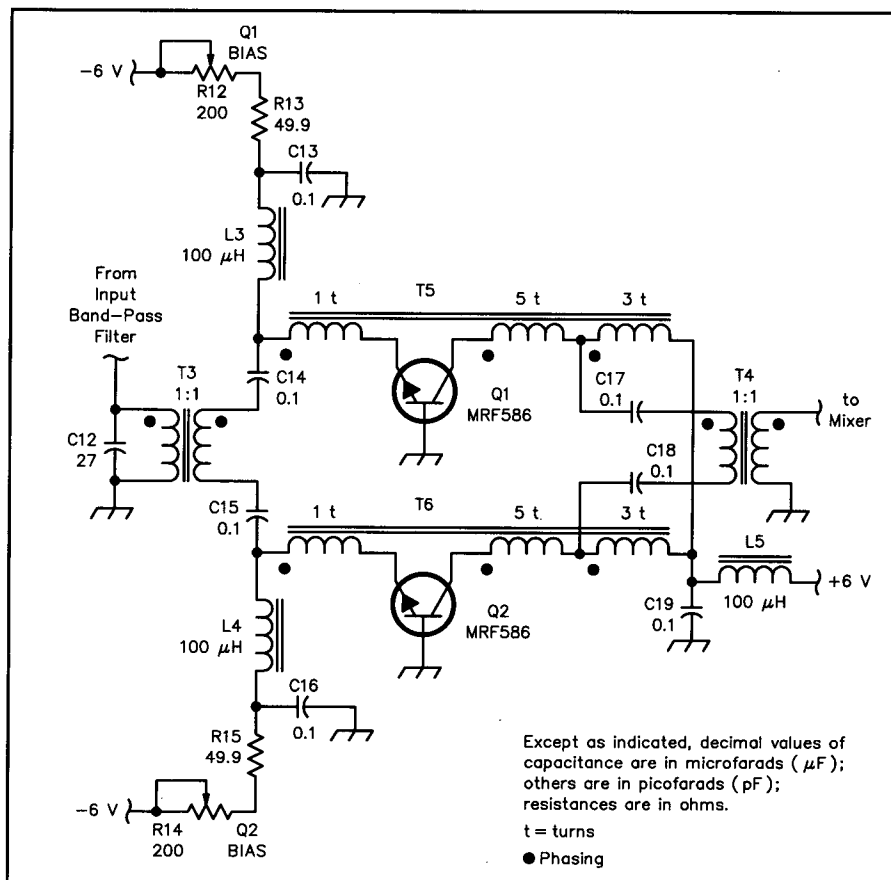

The push-pull preamplifier (Fig 15.42) uses MRF586s in a "noiseless feedback" configuration. BIAS controls R12 and R14 allow the collector current of each transistor to be adjusted to the desired value of 25 mA. T3 matches the amplifier input to the 50-Ω band-pass input filter; T4 matches the preamp output to the mixer signal port.

Transformers T5 and T6 couple part of the collector signal back into the emitter (negative feedback), set the gain to 8 dB, and set the input and output impedances to 50 Ω. C12 cancels the inductive reac-

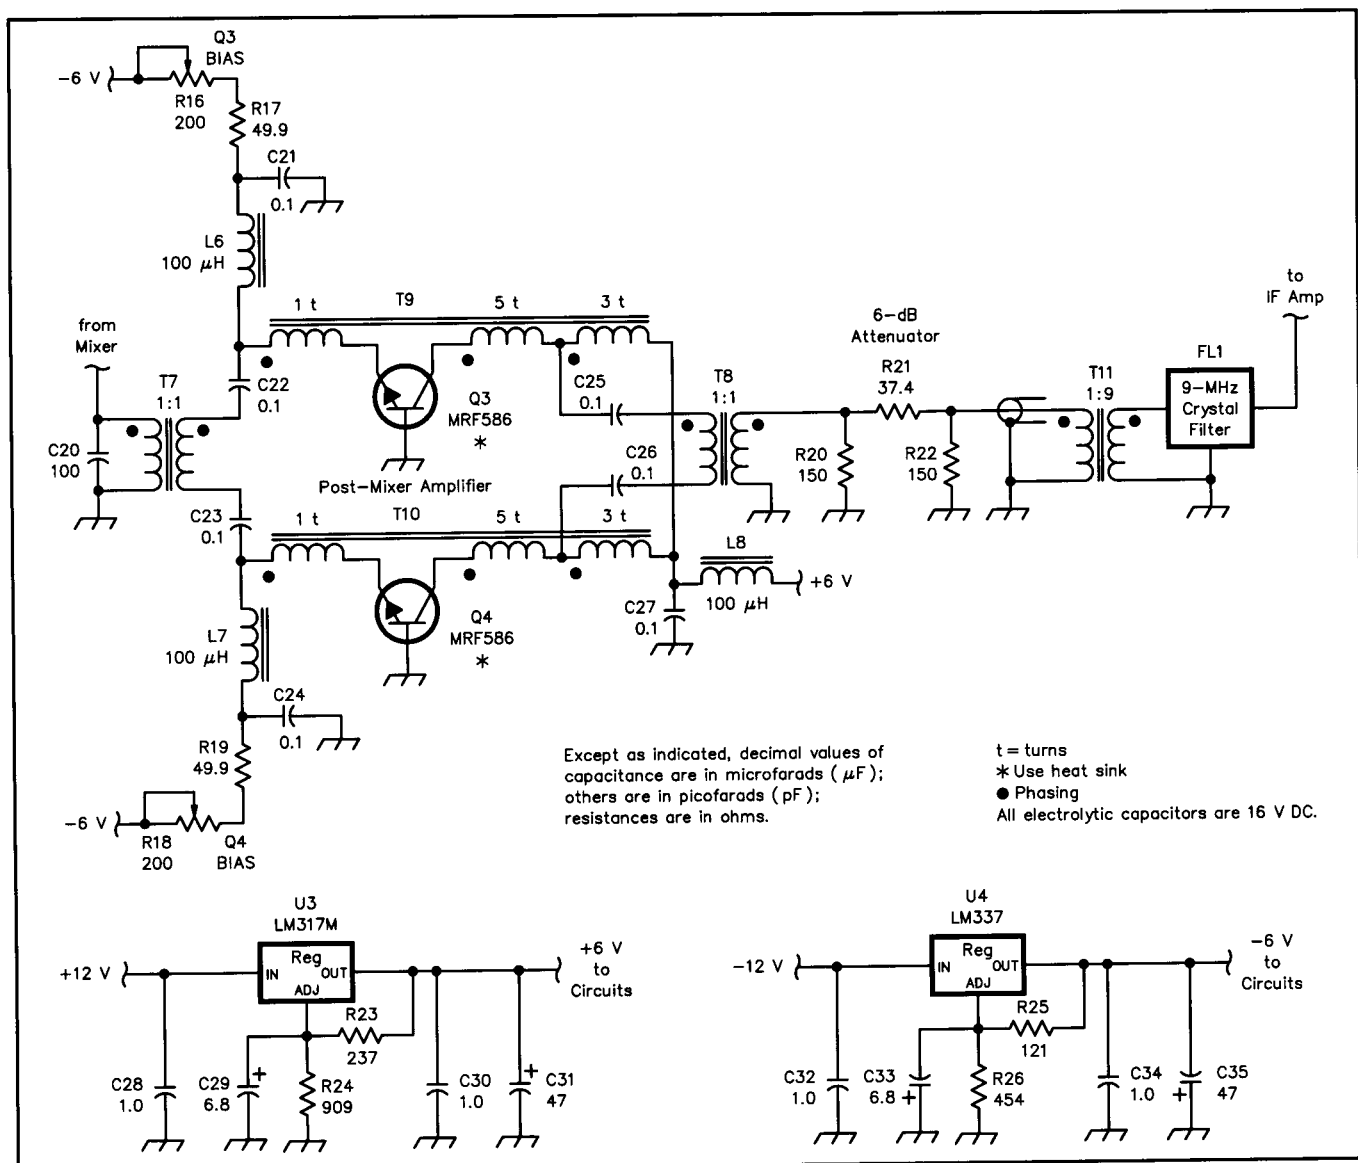

**Fig 15.41**—The front end's mixer circuitry uses the SD8901 in conjunction with a 74HC74 dual flip-flop, a diplexer network and a VFO operating in the 10.5-MHz region—twice the frequency necessary to convert 14-MHz signals to the system's 9-MHz IF. Both 74HC74 sections divide the LO frequency by two and square it; one section (U1A) provides LO output for a frequency counter, and the other (U1B) drives the mixer's LO port. The OFFSET BIAS controls adjust mixer balance. D1 sets the 74HC74's supply voltage at a level considerably higher than the part's specified 6-V maximum; see text. See the parts list sidebar for component information.

**Fig 15.42**—The front end's input preamplifier consists of two MRF586 transistors operating in push-pull. The BIAS controls individually adjust the transistors' collector currents to the desired 25 mA. See the parts list sidebar for component information, and Fig 15.44 for how to wind T5 and T6.

**Fig 15.43**—Another push-pull MRF586 pair, this time biased to a collector current of 40 mA per device, serves as the front end's post-mixer amplifier. A 1:9 transformer steps the amplifier's 50- $\Omega$  output up to 450  $\Omega$  for a reasonable match to the system's 500- $\Omega$  crystal filter (manufactured by KVG). The 6-dB pad is *essential* in preserving this stage's high dynamic range: It buffers the amplifier from the crystal filter's highly reactive input impedance. See the parts list sidebar for component information, and Fig 15.44 for how to wind T9 and T10.

**Fig 15.44**—Transformers T5, T6, T9 and T10 are wound with #32 wire on two-hole ferrite cores (see the parts list sidebar for core information). Wind the 1-turn winding (1-2) first, the 3-turn winding (4-3) second and the 5-turn winding (5-4) third.

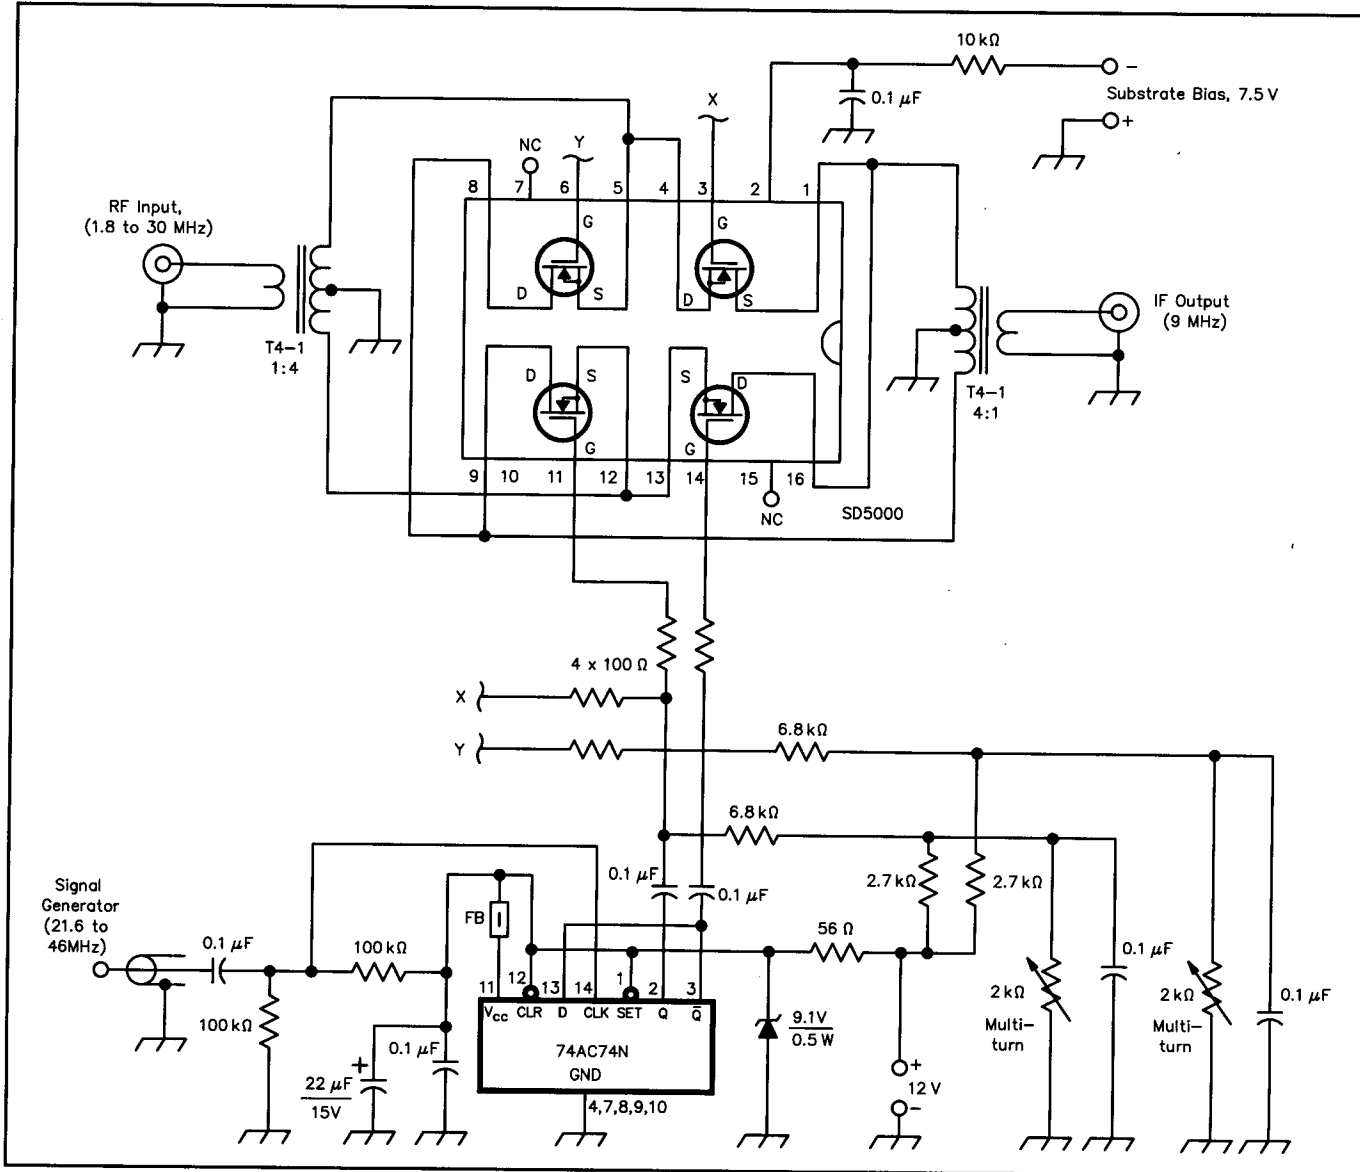

## Parts List for the N6NWP High-Dynamic Range Front End

Unless indicated otherwise, all of the circuits' resistors are 1/4-W 1% tolerance, and all of the capacitors are 20%-tolerance ceramic. C7-C12 and C20 are dipped mica, polyester film or epoxy-coated ceramic.

- U1—74HC74 CMOS flip-flop.  
U2—Calogic Corporation SD8901HD mixer.  
U3—LM317MP adjustable voltage regulator IC.  
U4—LM337MP adjustable voltage regulator IC.  
Q1-Q4—Motorola MRF586 RF transistor. Use heat sink (Thermalloy 2228B or Aavid 3257) on Q3 and Q4.

- T1, T2—Mini-Circuits T4-1 4:1 RF transformer.  
T3, T4, T7, T8—Mini-Circuits T1-1 1:1 RF transformer.  
T11—Mini-Circuits T9-1 9:1 RF transformer.  
L3-L8—100- $\mu$ H RF choke.  
L1, L2—Toko 332PN-T1012Z (Digi-Key TK5130) 1.0- $\mu$ H variable inductor.  
R6, R7—2-k $\Omega$  multiturn potentiometer.  
R12, R14, R16, R18—200- $\Omega$  multiturn potentiometer.

- D1—9.1-V, 0.5-W Zener diode,  
1N5239 suitable. See text.  
C7—39 pF  $\pm 10\%$ .  
C8, C10—330 pF  $\pm 5\%$ .  
C9, C11—22 pF  $\pm 5\%$ .  
C12—27 pF  $\pm 10\%$ .  
C20—100 pF  $\pm 10\%$ .  
T5, T6, T9, T10—homemade trifilar  
transformer wound with #32 enam-  
eled wire on Amidon BN-43-2402  
core (Fair-Rite 2843002402) as per  
Fig. 15.44.

**Fig 15.45—Colin Horrabin's DMOS FET quad switching mixer implements Mahkinson's approach with advanced CMOS flip-flops (74AC74Ns operated within their supply ratings) and the Siliconix SD5000 quad DMOS FET. Substrate bias (–7.5 V) is necessary to keep the SD5000's built-in diodes turned off. The ferrite bead on the 74AC74N's  $V_{CC}$  pin, and the 100- $\Omega$  resistors in series with the SD5000's gate-drive lines, maximize the mixer's dynamic range by damping ringing, thus keeping the mixer's LO waveform square. The GATE BIAS trimmers are set for best mixer balance at a gate-bias level of about 4.5 V.**

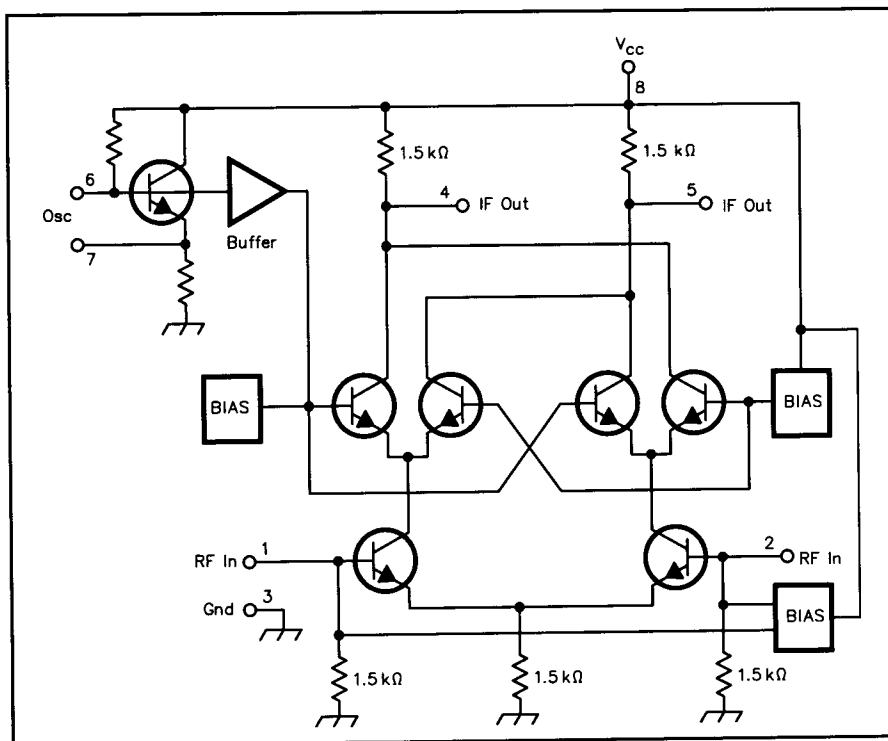

Fig 15.46—The NE602A's equivalent circuit reveals its Gilbert-cell heritage.

tance of the mixer's source impedance at 14 MHz. (In a multiband receiver, this capacitor may be part of switchable preselector filters.) The measured performance of the circuit is: third-order output intercept, 48 dBm; 1-dB output compression point, 25 dBm; gain, 8.0 dB; noise figure, 2.0 dB; -1-dB frequency response 1 to 40 MHz. This performance fully meets the preamplifier design goals.

#### Post-Mixer Amplifier

The post-mixer amplifier (Fig 15.43) uses the same basic configuration as the preamplifier. BIAS controls R16 and R18 allow adjustment of the MRF586s' collector current to 40 mA per device. This value is 15 mA higher than the preamplifier's device standing currents to overcome the negative effects of load on the post-mixer amplifier's intercept point. T11, a transmission-line transformer, matches the crystal filter's impedance (500  $\Omega$  in this case) to the amplifier's 50- $\Omega$  output impedance. C20 cancels the inductive reactance of the amplifier's input source. The measured performance of the post-mixer amplifier,

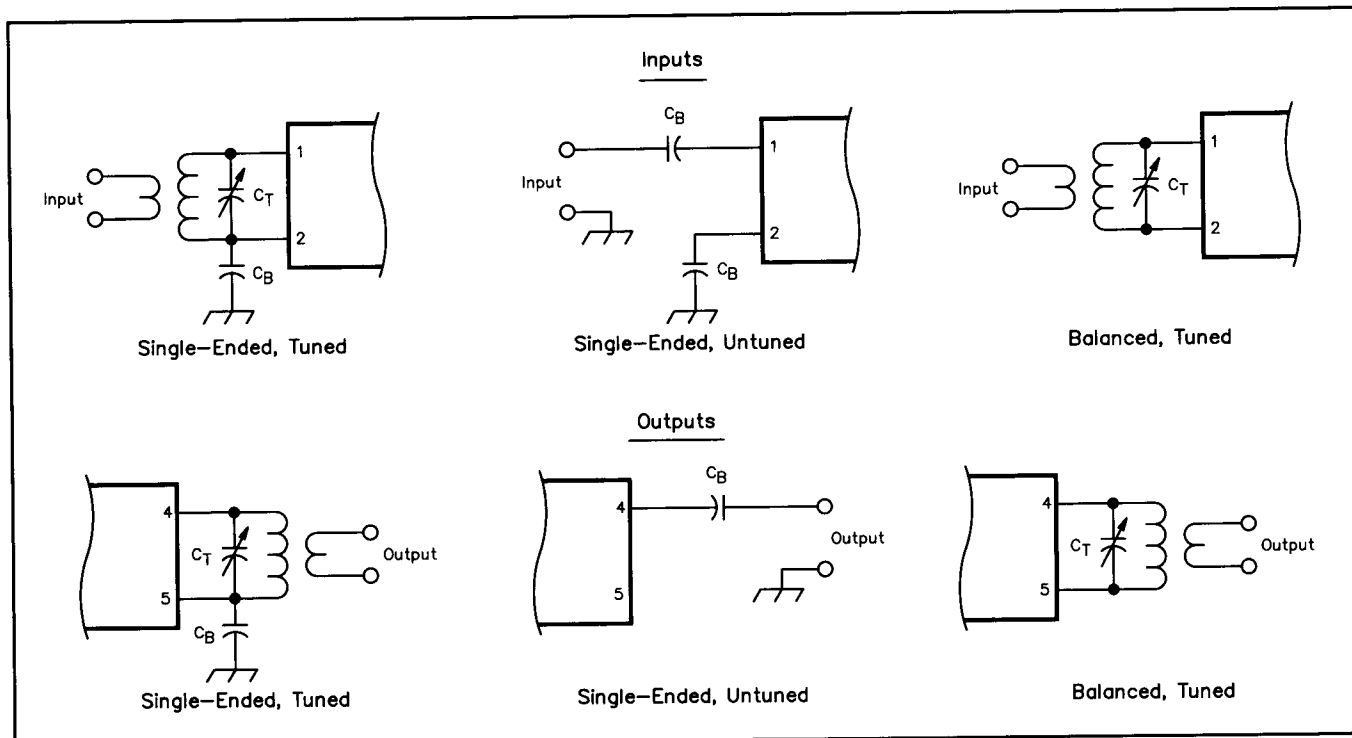

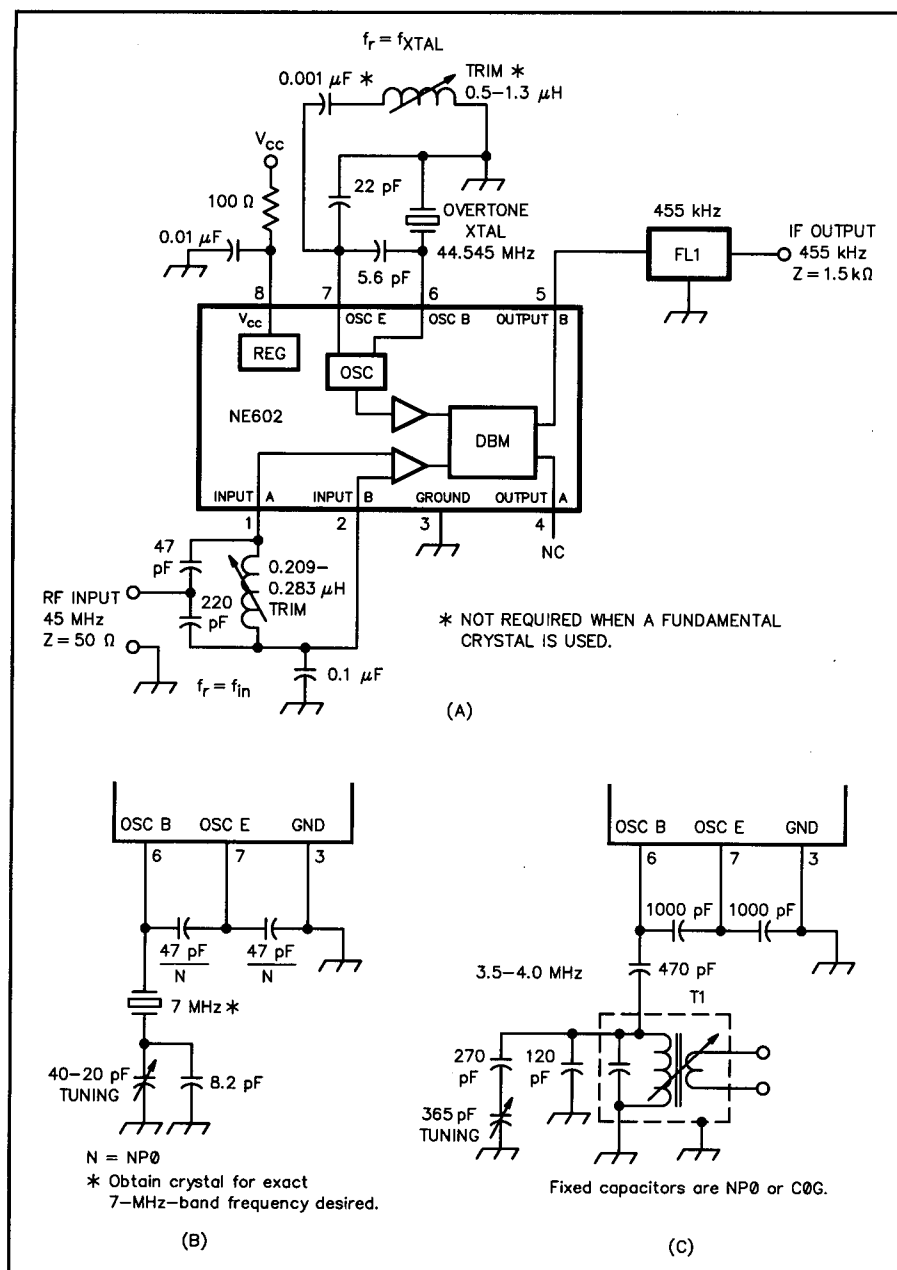

Fig 15.47—The NE602A's inputs and outputs can be single- or double-ended (balanced). The balanced configurations minimize second-order IMD and harmonic distortion, and unwanted envelope detection in direct-conversion service.  $C_T$  tunes its inductor to resonance;  $C_B$  is a bypass or dc-blocking capacitor. The arrangements pictured don't show all the possible input/output configurations; for instance, you can also use a center-tapped broadband transformer to achieve a balanced, untuned input or output.

**Fig 15.48—Three NE602A oscillator configurations: crystal overtone (A); crystal fundamental (B); and LC-controlled (C). T1 in C is a Mouser 10.7-MHz IF transformer, green core, 7:1 turns ratio, part no. 42IF123.**

terminated by a 9-MHz filter via the 6-dB pad, is: third-order input intercept, 34 dBm; 1-dB input compression point, 18 dBm; gain, 8.0 dB; and noise figure, 2.5 dB.

### Using the Siliconix SD5000 DMOS FET Quad in a Switching Mixer

Mahkinson's circuit operates its 74HC74N flip-flops above their maximum supply-voltage limit, and the SD8901 is relatively difficult to obtain. Following up on Mahkinson's design in the Radio Society of Great Britain's *Radio Communication* (Technical Topics, September 1993)

Colin Horrabin, G3SBI, used 74AC74N "advanced CMOS" flip-flops in conjunction with the easier-to-obtain SD5000 Siliconix quad DMOS FET (Fig 15.45). Input intercepts of at least 42 dBm (HF bands) and 46 dBm (1.8 MHz) were obtained with this arrangement.

### The Ubiquitous NE602: A Popular Gilbert Cell Mixer

Introduced as the NE602 in the mid-1980s, the Philips Components-Signetics NE602A mixer-oscillator IC has become greatly popular with amateur experiment-

ers for transmit mixers, receive mixers and balanced modulators. Fig 15.46 shows its equivalent circuit. The NE602A's typical current drain is 2.4 mA; its supply voltage range is 4.5 to 8.0.

As we learned in exploring sine-wave versus square-wave mixing, the NE602's mixer is a Gilbert cell multiplier. Its inputs (RF) and outputs (IF) can be single- or double-ended (balanced) according to design requirements (Fig 15.47). Each input's equivalent ac impedance is approximately 1.5 k $\Omega$  in parallel with 3 pF; each output's resistance is 1.5 k $\Omega$ . The mixer can typically handle signals up to 500 MHz. At 45 MHz, its noise figure is typically 5.0 dB; its typical conversion gain, 18 dB. Considering the NE602A's low current drain, its input  $IP_3$  (measured at 45 MHz with 60-kHz spacing) is usefully good at -15 dBm. Factoring in the mixer's conversion gain results in an equivalent output  $IP_3$  of about 5 dBm.

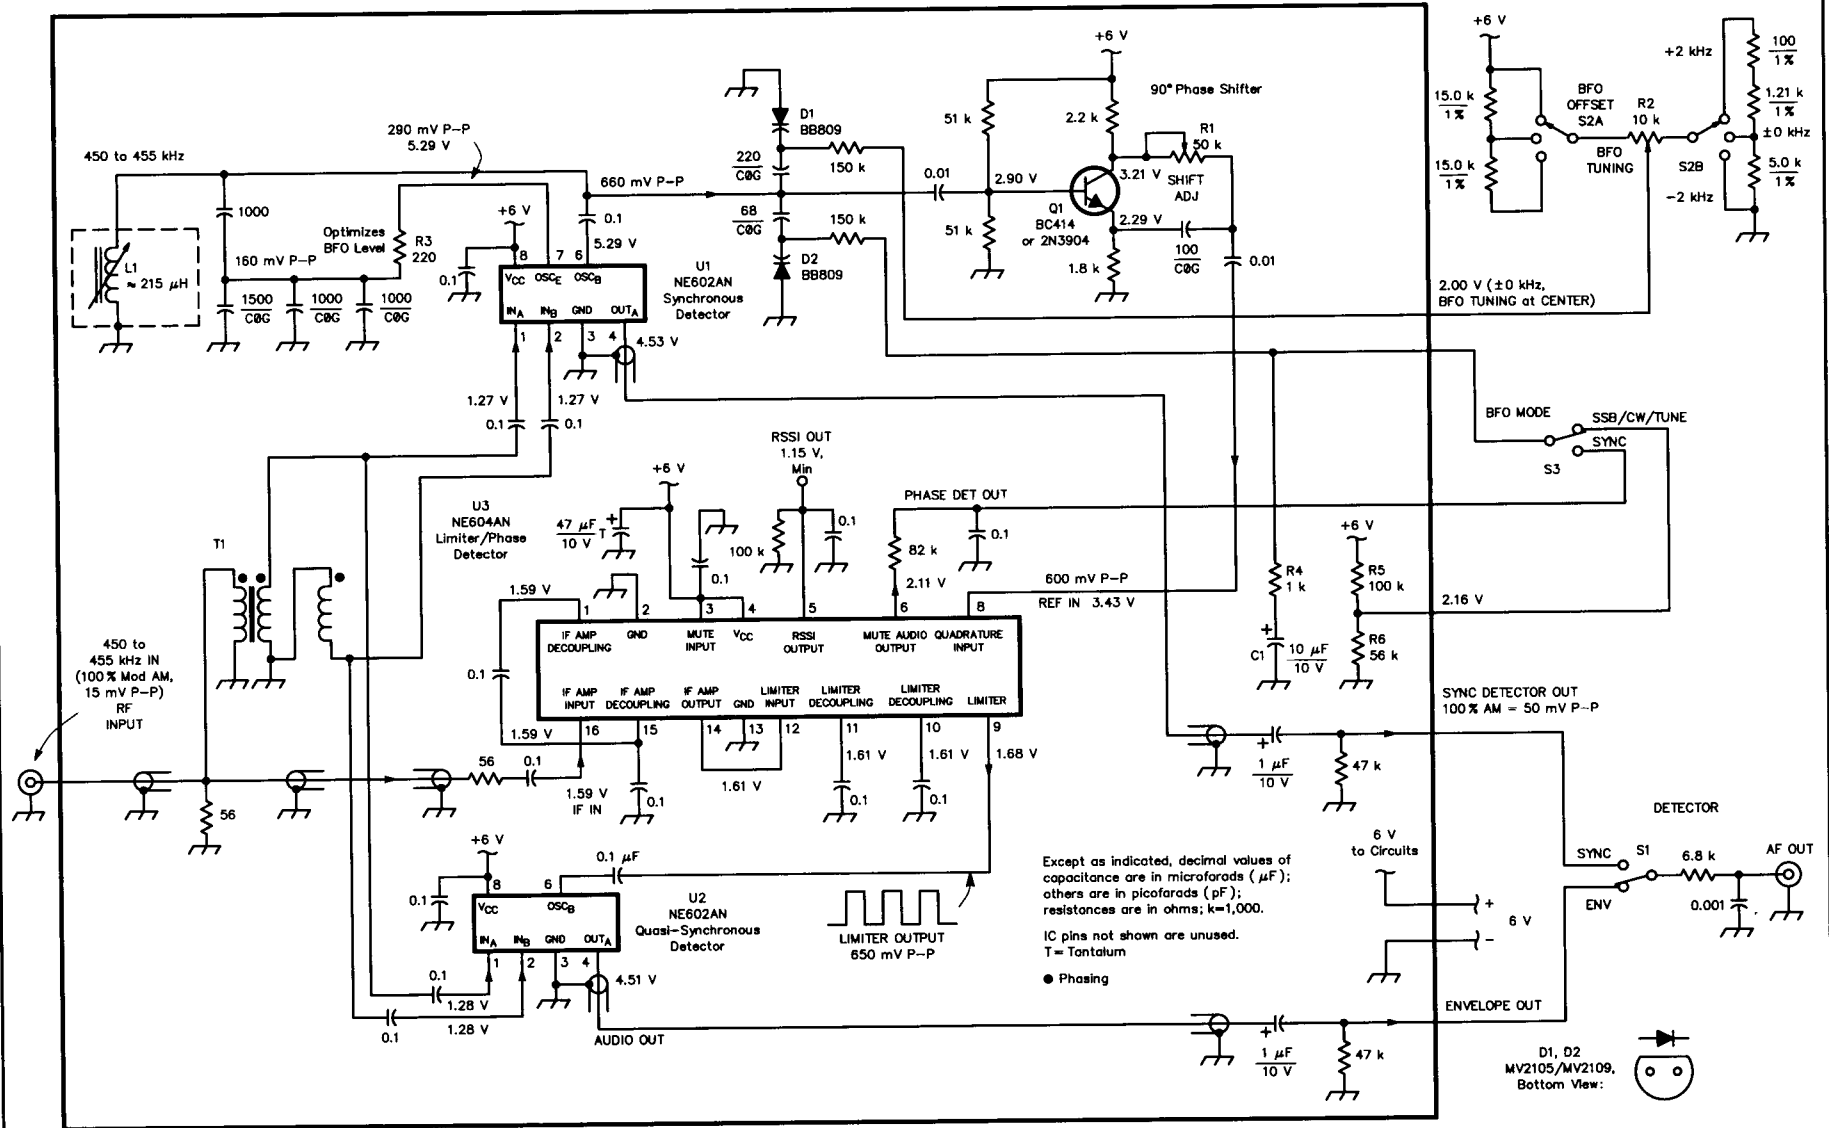

The NE602A's on-board oscillator can operate up to 200 MHz in LC and crystal-controlled configurations (Fig 15.48 shows three possibilities). Alternatively, energy from an external LO can be applied to the chip's pin 6 via a dc blocking capacitor. At least 200 mV P-P of external LO drive is required for proper mixer operation.

### NE602A Usage Notes

The '602 was intended to be used as the second mixer in double-conversion FM cellular radios, in which the first IF is typically 45 MHz, and the second IF is typically 455 kHz. Such a receiver's second mixer can be relatively weak in terms of dynamic range because of the adjacent-signal protection afforded by the high selectivity of the first-IF filter preceding it. When used as a first mixer, the '602 can provide a two-tone third-order dynamic range between 80 and 90 dB, but this figure is greatly diminished if a preamplifier is used ahead of the '602 to improve the system's noise figure.

When the '602 is used as a second mixer, the sum of the gains preceding it should not exceed about 10 dB. NE602 product detection therefore should not follow a high-gain IF section unless appropriate attenuation is inserted between the '602 and the IF strip.

The '602 is generally *not* a good choice for VHF and higher-frequency mixers because of its input noise and diminishing IMD performance at high frequencies. There are applications, however, where 6-dB noise figures and 60- to 70-dB dynamic range performance is adequate. If your target specifications exceed these numbers, you should consider other mix-

**Fig 15.49—The synchronous detector operates in the 450- to 455-kHz region. Except as otherwise specified, its fixed-value resistors are 1/4-W, 5%-tolerance units, and its capacitors' working voltages can be 10 or higher. See the References chapter for a list of part suppliers addresses that includes addresses of the firms mentioned below.**

**D1, D2—BB809 or BB409 tuning diode.** Each of these, a "28-V" diode, exhibits approximately 33 pF at 2 V and an unusually high voltage-versus-capacitance slope of 10. Two paralleled 30-V Motorola tuning diodes (one MV2109 [ $\approx 45$  pF at 2 V] and one MV2105 [ $\approx 18$  pF at 2 V], both with a slope of 3) may serve as a substitute for each BB809 or BB409.

**L1—Approximately 215  $\mu$ H.** Toko RWRS-T1019Z (nominally 220  $\mu$ H, Q of 100 at 796 kHz, available as Digi-Key Corp no. TK1223), suitable.

**R1—50-k $\Omega$  trimmer.**

**R2—10-k $\Omega$  linear control.**

**T1—13 trifilar turns of #28 enameled wire, twisted, on an FT-37-77 toroidal ferrite core.**

**U1, U2—Signetics NE602N, NE602AN, SA602N, SA602AN mixer/oscillator IC.**

**U3—Signetics NE604N, NE604AN, SA604N or SA604AN FM receiver subsystem IC.**

uct detection is that synchronous detection *phase locks* its carrier to that of the incoming signal. No tuning error occurs if the received signal happens to fall between a synthesized receiver's tuning steps, and the detector's PLL compensates for modest tuning drift. The result is a dramatic fidelity improvement over diode-detected AM. This circuit, designed by Jukka Vermasvuori, OH2GF, and originally published in July 1993 *QST*, requires only a digital voltmeter for alignment.

### The Synchronous Detector Circuit

See Fig 15.49. The unit uses popular NE602AN (mixer/oscillator) and NE604AN (FM subsystem) ICs to provide both synchronous and quasi-synchronous detection. (This discussion refers to U1 and U2 as NE602ANs, but NE602Ns, SA602Ns and SA602ANs will work equally well in this application. Likewise, an NE604N, NE604AN, SA604N or SA604AN will work well at U3 in this application.) Operating at a supply voltage of 6, the circuit draws 10 mA. U1, an NE602AN, acts as the BFO and product detector necessary for synchronous detection. Feeding U1's balanced inputs in push-pull helps keep BFO energy from backing out of the input pins and into U3's limiting circuitry. To take advantage of the chip's internal biasing, the input transformer (T1) is isolated with dc blocking capacitors. (U1 also supplies balanced audio output, but usefully reducing this to a single-ended output would have required an operational amplifier. Doing so would reduce even-harmonic distortion in recovered audio, but would not justify the increased circuit complexity and power consumption.)

U1's oscillator amplitude is optimized to 660 mV P-P (as measured across L1) by the 220- $\Omega$  resistor at the oscillator output at pin 7. The BFO frequency is adjusted by two variable-capacitance diodes (D1 and D2) in addition to the tank coil, L1. D2 receives its control voltage via switch S3 (BFO MODE), which selects control voltage from either U3's phase detector (SYNC) or a constant voltage from a resistive divider (CW/SSB/TUNE).

The fixed CW/SSB/TUNE voltage (2.16, set by the ratio of R5 and R6) corresponds to the phase detector's optimum output voltage at lock.

R2, BFO TUNING, drives D1 to provide manual detector tuning without upsetting the D2's control-voltage optimization. S2, BFO OFFSET, presets R2's tuning range into the optimum regions for LSB ( $-2$  kHz), DSB AM ( $\pm 0$  kHz) and USB ( $+2$  kHz). (These offsets are for a radio in which received sidebands are inverted relative to their on-

air sense.) The BFO TUNING control therefore provides fine adjustment for detector lock around coarse receiver tuning steps (1 kHz in the Sangean AT-808 with which this circuit was originally used).

U3's phase detector requires a 90° phase shift between the incoming and reference phases to give the correct zero-phase output (again, approximately 2.16 V). The all-pass stage, Q1, operates as an isolation stage and adjustable phase shifter to generate the 90° phase shift.

U3 is an NE604N FM IF subsystem IC that contains limiting-amplifier stages (total gain, 101 dB) and a quadrature detector. Band limiting can be inserted between the limiter stages, but experiments with various RC and LC filters brought no improvement, and instead led to increased delay that upset the carrier/sideband phase relationships necessary for good quasi-synchronous detection. The Fig 15.49 circuit uses U3's quadrature detector as a phase detector that outputs control voltage for D2.

The most difficult aspect of the phase-locking chain is the selection of a time constant for the locking loop. Signal fading, in conjunction the relative absence

### Quasi-Synchronous Detection

Synchronous detection can be mimicked by amplifying and limiting the AM signal sufficiently (at IF) so that only carrier remains, and substituting this signal for the BFO at the product detector. This *quasi-synchronous detection* acts much like envelope ("diode") detection and works best when the received signal does not fall to zero, as can often occur with SSB and, with AM, during fading. As the signal fades and the carrier-to-noise (C/N) ratio decreases, noise renders the detector's switching action inconsistent, and detection quality deteriorates rapidly. Thus, under conditions of low C/N ratio, quasi-synchronous detection exhibits a distinct detection threshold, as does a diode detector. The chief advantage of quasi-synchronous detection over simple diode rectification is its much lower threshold compared to a diode. The detector circuit presented in Fig 15.49 includes a quasi-synchronous detector for flexibility and A/B comparison with the synchronous circuit.

—Jukka Vermasvuori, OH2GF

ers at VHF and up.

### NE602A Relatives

The NE602A (SA602A for operation over a wider temperature range) began life as the NE602/SA602, a part with a slightly lower IP<sub>3</sub> than the A version. The pinout-identical NE612A/SA612A costs less as a result of wider tolerances. All of these parts should nonetheless work satisfactorily in most "NE602" experimenter projects. The same mixer/oscillator topology, modified for slightly higher dynamic range at the expense of somewhat less mixer gain, is also available in the Philips Components-Signetics mixer/oscillator/FM IF chips NE/SA605 (input IP<sub>3</sub>, typically  $-10$  dBm) and NE/SA615 (input IP<sub>3</sub>, typically  $-13$  dBm).

### A Synchronous AM Detector for 455 kHz

Much like switching a receiver or transmitter to SSB and receiving AM as SSB, its carrier at zero beat, synchronous detection overcomes fading-related distortion by supplying an unfading carrier to the receiver. The difference between synchronous AM detection and normal SSB prod-

or presence of phase-modulation components in the transmitted signal, play important roles in detector lock. Were fading not a problem, a short time constant—one allowing fast locking—would suffice for DSB AM. For SSB AM with carrier (which includes a PM component at all modulation frequencies), however, and DSB AM with fading (during which a fast PLL may unlock on the sudden phase shifts that can accompany fast, deep carrier fades), a long time constant is necessary. Particularly for SSB with carrier, the loop bandwidth must be reduced to below the lowest expected modulation frequency. C1 and R4 set the PLL time constant in Fig 15.49.

The received signal strength indicator (RSSI) output at pin 5 of U3 follows the input level logarithmically, giving an output of 1.1 V on noise only (RF INPUT shorted in Fig 15.49) and 3.3 V at an RF INPUT level of 3 mV. The RSSI output is adaptable as an AGC-detector output, making the NE604AN attractive for simple IF-AGC designs. Because of the NE604AN's high gain, circuit layout can be critical and requires short leads and physically small bypass capacitors. Coupling must be minimized between pin 9 of U3 and the U1 oscillator components.

U2, an NE602AN, operates as a quasi-synchronous detector. The BFO energy it requires is readily available as a square wave at pin 9 of U3. Except for the fact that its BFO input is derived from limited input signal instead of a VCO, U2 functions the same way as U1.

### Construction

Two evaluation models were constructed using ground-plane construction, mounting the ICs upside down and soldering their ground pins directly to ground with minimal lead length. The later version is constructed onto a long and narrow piece of circuit board intended to

be the bottom plate of an add-on box to be fixed underside of a Sangean ATS-808 receiver. (Fig 15.50 shows this version's general layout.)

With the circuitry arranged per Fig 15.50 and receiver-detector IF-AF connections made with small-diameter coaxial cable to avoid crosstalk, BFO-signal leakage is unmeasurable at U3; that is, the voltage at RSSI does not change when the BFO is temporarily disabled under no-signal conditions.

### Obtaining IF Drive

A simple BJT emitter follower (Fig 15.51) can connect the synchronous detector to a solid-state transceiver. The detector can also be driven from the

unbypassed cathode resistor of a vacuum-tube receiver's final IF stage (Fig 15.51B). If test equipment is not available to allow accurate measurement of the detector's input level, just keep the detector drive comfortably below that at which distortion begins.

IF signal can be obtained from the ATS-808 receiver via a 56-pF capacitor connected to the hot end of the '808's transformer T9 (at pin 16 of the '808's U1, a TA7758P IC). Connecting the detector cable detunes T9, which, though difficult to reach, must be retuned by turning its slug outwards a few turns to obtain maximum audio output. The detector's audio output (AF OUT) returns to the AT-808 by means of the '808's TONE switch, which

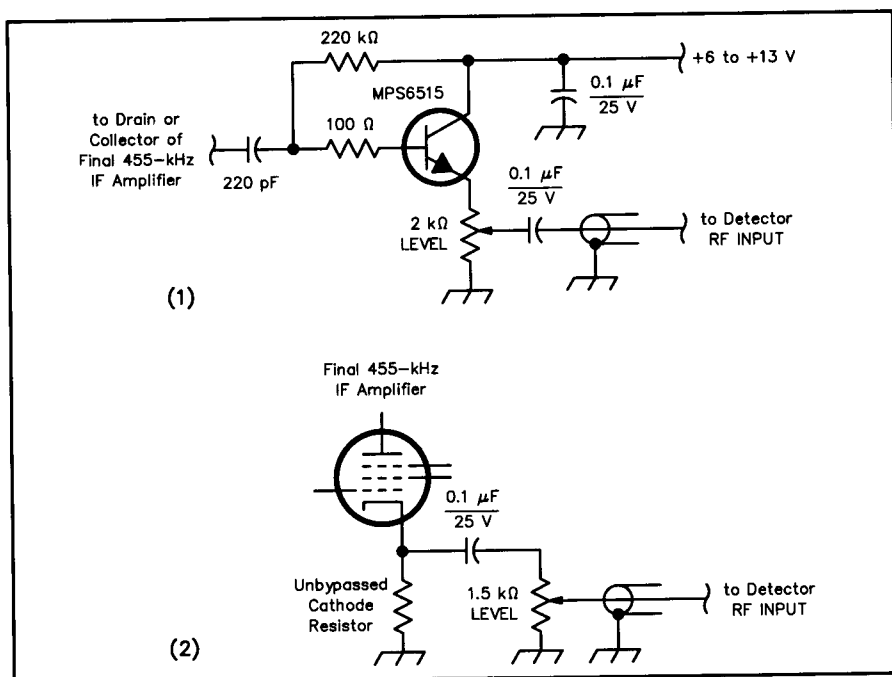

Fig 15.51—Simple circuitry can connect the synchronous detector to a solid-state transceiver (1) or a vacuum-tube receiver (2) if a 455-kHz output tap is not already available.

Fig 15.50—One recommended layout for the synchronous detector. U3's high gain requires care in construction—see text.

can be rewired to select audio from the outboard detector.

The key to success with this circuit is getting *interference-free* IF drive. U3's RSSI output can be of critical importance in scoping out possible BFO leakage and/or unwanted signal input. With the detector's RF input shorted, a voltmeter connected to RSSI should indicate about 1.1. If it doesn't, U1's BFO signal may be getting into U3. The RSSI indication shouldn't be much higher than this with the detector connected to the receiver, with the receiver's RF gain control turned all the way down for minimal noise input to the detector. (The receiver used must be in "AM" mode—BFO off.) If the RSSI voltage is above the 1-V range at this point, a receiver oscillator or some other signal, however inaudible, may be driving U3's limiter. *The detector will be unable to achieve and hold lock if anything other than the receiver IF signal captures its limiter.* The NE604's limiter stages, specified to work up to at least 21 MHz, are capable of 101 dB of overall gain and specified to be several decibels into limiting with *as little as 3 mV* (−92 dBm) applied across a 50-Ω load at the '604's input!

### Operation

After checking the circuit, connect it to a 6-V power supply. The total current consumption should be approximately 10 mA. Switch the DETECTOR switch to ENVELOPE; band noise should now be audible. Tune in a strong AM signal, switch S3, BFO MODE, to SSB/CW/TUNE, and set the DETECTOR switch to SYNC. The detector may sound very quiet at this point. Adjust L1's core until the signal swoops into audibility. This proves that the BFO is oscillating. If possible, measure the BFO level across L1 with an oscilloscope and 10:1 probe; it should be about 660 mV. (If test-equipment unavailability disallows this measurement, go to the next paragraph.) If it's not, experiment with R3's value to make it so.

Accurately tune the receiver to a strong, pure carrier, such as a beacon. Adjust R2, BFO TUNING, for a wiper voltage of 2.00 with S2, BFO OFFSET, set to ±0 kHz. Mark as CENTER this point in its knob's travel. With the BFO MODE switch in the SSB/CW/TUNING position, use a nonmetallic tool to adjust L1, the VCO coil, for zero beat with the incoming carrier. Returning S3 to the SYNC position

should allow carrier lock if R1, SHIFT ADJ, is reasonably near adjustment. Adjust SHIFT ADJ for carrier lock if necessary. This completes coarse adjustment of SHIFT ADJ. Return the BFO MODE switch to the SSB/CW/TUNING position; the BFO should still be at or very close to zero beat with the incoming signal.

Return the BFO MODE switch to the SYNC position. After the detector locks, fine-tune SHIFT ADJ to minimize detected low-frequency hiss. (If a sufficiently strong unmodulated local signal is not available off-air, transmit into a dummy antenna with a PLL-synthesized transceiver and make this adjustment by listening to its signal. It should be possible to find a SHIFT ADJ setting at which detected hiss distinctly nulls. As a less desirable alternative, tune in an unfading AM signal modulated with a 1-kHz tone and adjust SHIFT ADJ for maximum tone recovery.) Once this is done, the detector's carrier phase is within exactly 0° or 180° of the BFO signal applied to the amplitude detector (U1), and the detector's response to phase noise has been minimized. Also significantly, this alignment procedure sets the detector to lock in a range centered on the control voltage that corresponds to optimum locking sensitivity and minimum phase noise demodulation. This completes alignment.

To zero-beat and lock a given station: Set the BFO TUNING control to its center (2.00 V) position, BFO MODE switch to CW/SSB/TUNE and BFO OFFSET to match the sideband(s)—LSB, USB or both—desired. Tune the receiver as close to zero beat as its tuning steps allow. Adjust BFO TUNING for zero beat. Switch the BFO MODE switch to SYNC to lock the detector.

Toggling S1, DETECTOR, between ENVELOPE and SYNC allows easy comparison of the effects of detection mode under adverse propagation conditions. The synchronous mode will be considerably superior much of the time. The quasi-synchronous (ENVELOPE) mode may give crisper audio under average or poor signal conditions; this effect may be due to increasing distortion as the signal approaches the noise floor, however.

Properly adjusted, the synchronous detector operates at less than 1% total harmonic distortion. (The quasi-synchronous detector provides comparable performance—but only on a nonfading test signal.) Measurements confirm the importance of setting R1, SHIFT ADJ,

properly: Improper adjustment can increase low-order harmonic-distortion products by 3 to 12 dB in addition to increasing the detector's sensitivity to phase noise.

# Filters and Projects

16

This chapter contains basic design information and examples of the most common filters used by radio amateurs. It was prepared by Reed Fisher, W2CQH, and includes a number of design approaches, tables and filters by

Ed Wetherhold, W3NQN, and others. The chapter is divided into two major sections. The first section contains a discussion of filter theory with some design examples. It includes the tools needed to predict the performance of a candidate filter before a

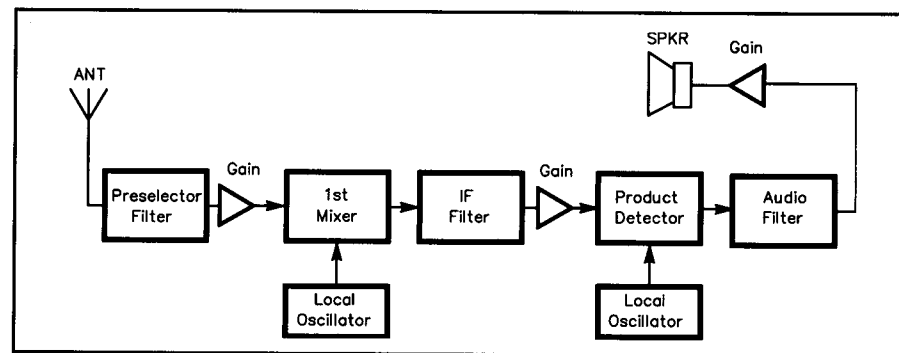

design is started or a commercial unit purchased. Extensive references are given for further reading and design information. The second section contains a number of selected practical filter designs for immediate construction.

## Basic Concepts

A filter is a network that passes signals of certain frequencies and rejects or attenuates those of other frequencies. The radio art owes its success to effective filtering. Filters allow the radio receiver to provide the listener with only the desired signal and reject all others. Conversely, filters allow the radio transmitter to generate only one signal and attenuate others that might interfere with other spectrum users.

The simplified SSB receiver shown in **Fig 16.1** illustrates the use of several common filters. Three of them are located between the antenna and the speaker. They provide the essential receiver filter functions. A preselector filter is placed between the antenna and the first mixer. It passes all frequencies between 3.8 and 4.0 MHz with low loss. Other frequencies, such as out-of-band signals, are rejected to prevent them from overloading the first mixer (a common problem with shortwave broadcast stations). The preselector filter is almost always built with LC filter technology.

An intermediate frequency (IF) filter is placed between the first and second mixers. It is a band-pass filter that passes the desired SSB signal but rejects all others. The age of the receiver probably determines which of several filter technologies is used. As an example, 50 kHz or 455 kHz

**Fig 16.1—One-band SSB receiver. At least three filters are used between the antenna and speaker.**

LC filters and 455 kHz mechanical filters were used through the 1960s. Later model receivers usually use quartz crystal filters with center frequencies between 3 and 9 MHz. In all cases, the filter bandwidth must be less than 3 kHz to effectively reject adjacent SSB stations.

Finally, a 300 Hz to 3 kHz audio band-pass filter is placed somewhere between the detector and the speaker. It rejects unwanted products of detection, power supply hum and noise. Today this audio filter is usually implemented with active filter technology.

The complementary SSB transmitter

block diagram is shown in **Fig 16.2**. The same array of filters appear in reverse order.

First is a 300-Hz to 3-kHz audio filter, which rejects out-of-band audio signals such as 60-Hz power supply hum. It is placed between the microphone and the balanced mixer.

The IF filter is next. Since the balanced mixer generates both lower and upper sidebands, it is placed at the mixer output to pass only the desired lower (or upper) sideband. In commercial SSB transceivers this filter is usually the same as the IF filter used in the receive mode.

**Fig 16.2—One-band transmitter. At least three filters are needed to ensure a clean transmitted signal.**

**Fig 16.3—Idealized filter responses. Note the definition of  $f_c$  is 3 dB down from the break points of the curves.**

Finally, a 3.8 to 4.0-MHz band-pass filter is placed between transmit mixer and antenna to reject unwanted frequencies generated by the mixer and prevent them from being amplified and transmitted.

This chapter will discuss the four most common types of filters: low-pass, high-pass, band-pass and band-stop. The idealized characteristics of these filters are shown in their most basic form in **Fig 16.3**.

A low-pass filter permits all frequencies below a specified cutoff frequency to be transmitted with small loss, but will attenuate all frequencies above the cutoff frequency. The “cutoff frequency” is usually specified to be that frequency where the filter loss is 3 dB.

A high-pass filter has a cutoff frequency above which there is small transmission loss, but below which there is considerable attenuation. Its behavior is opposite to that of the low-pass filter.

A band-pass filter passes a selected band of frequencies with low loss, but attenuates frequencies higher and lower than the desired passband. The passband of a filter is the frequency spectrum that is conveyed with small loss. The transfer characteristic is not necessarily perfectly uniform in the passband, but the variations usually are small.

A band-stop filter rejects a selected band of frequencies, but transmits with low loss frequencies higher and lower than the desired stop band. Its behavior is opposite to that of the band-pass filter. The stop band is the frequency spectrum in which attenuation is desired. The attenuation varies in the stop band rising to high values at frequencies far removed from the cutoff frequency.

### FILTER FREQUENCY RESPONSE

The purpose of a filter is to pass a desired frequency (or frequency band) and reject all other undesired frequencies. A simple single-stage low-pass filter is shown in **Fig 16.4**. The filter consists of an inductor,  $L$ . It is placed between the volt-

age source  $e_g$  and load resistance  $R_L$ . Most generators have an associated “internal” resistance, which is labeled  $R_g$ .

When the generator is switched on, power will flow from the generator to the load resistance  $R_L$ . The purpose of this low-pass filter is to allow maximum power flow at low frequencies (below the cutoff frequency) and minimum power flow at high frequencies. Intuitively, frequency filtering is accomplished because the inductor has reactance that vanishes at dc but becomes large at high frequency. Thus, the current,  $I$ , flowing through the load resistance,  $R_L$ , will be maximum at dc and less at higher frequencies.

The mathematical analysis of **Fig 16.4** is as follows: For simplicity, let  $R_g = R_L = R$ .

$$i = \frac{e_g}{2R + jX_L} \quad (1)$$

where

$$X_L = 2\pi f L$$

$f$  = generator frequency.

Power in the load,  $P_L$ , is:

$$P_L = \frac{e_g^2 R_L}{4R^2 + X_L^2} \quad (2)$$

Available (maximum) power will be delivered from the generator when:

$$X_L = 0 \text{ and } R_g = R_L$$

$$P_O = \frac{E_g^2}{4R_g} \quad (3)$$

The filter response is:

$$\frac{P_L}{P_O} = \frac{\text{power in the load}}{\text{available generator power}} \quad (4)$$

The filter cutoff frequency, called  $f_c$ , is the generator frequency where

$$2R = X_L \text{ or } f_c = \frac{R}{\pi L} \quad (5)$$

As an example, suppose  $R_g = R_L = 50 \Omega$

**Fig 16.4—A single-stage low-pass filter consists of a series inductor. DC is passed to the load resistor unattenuated. Attenuation increases (and current in the load decreases) as the frequency increases.**

Fig 16.5—Transmission loss of a simple filter plotted against normalized frequency. Note the relationship between loss and SWR.

and the desired cutoff frequency is 4 MHz. Equation 4 states that the cutoff frequency is where the inductive reactance  $X_L = 100 \Omega$ . At 4 MHz, using the relationship  $X_L = 2\pi f L$ ,  $L = 4 \mu\text{H}$ . If this filter is constructed, its response should follow the curve in Fig 16.5. Note that the gentle rolloff in response indicates a poor filter. To obtain steeper rolloff a more sophisticated filter, containing more reactances, is necessary. Filters are designed for a specific value of purely resistive load impedance called the *terminating resistance*. When such a resistance is connected to the output terminals of a filter, the impedance looking into the input terminals will equal the load resistance throughout most of the passband. The degree of mismatch across the passband is shown by the SWR scale at the left-hand side of Fig 16.5. If maximum power is to be extracted from the generator driving the filter, the generator resistance must equal the load resistance. This condition is called a “doubly terminated” filter. Most passive filters, including the LC filters described in this chapter, are designed for double termination. If a filter is not properly terminated, its passband response changes.

Certain classes of filters, called “transformer filters” or “matching networks” are specifically designed to work between unequal generator and load resistances. Band-pass filters, described later, are easily designed to work between unequal terminations.

All passive filters exhibit an undesired nonzero loss in the passband due to unavoidable resistances associated with the

reactances in the ladder network. All filters exhibit undesired transmission in the stop band due to leakage around the filter network. This phenomenon is called the “ultimate rejection” of the filter. A typical high-quality filter may exhibit an ultimate rejection of 60 dB.

Band-pass filters perform most of the important filtering in a radio receiver and transmitter. There are several measures of their effectiveness or *selectivity*. Selectivity is a qualitative term that arose in the 1930s. It expresses the ability of a filter (or the entire receiver) to reject unwanted adjacent signals. There is no mathematical measure of selectivity.

The term  $Q$  is quantitative. A band-pass filter’s *quality factor* or  $Q$  is expressed as  $Q = (\text{filter center frequency}) / (3\text{-dB bandwidth})$ . *Shape factor* is another way some filter vendors specify band-pass filters. The shape factor is a ratio of two filter bandwidths. Generally, it is the ratio (60-dB bandwidth) / (6-dB bandwidth), but some manufacturers use other bandwidths. An ideal or *brick-wall* filter would have a shape factor of 1, but this would require an infinite number of filter elements. The IF filter in a high-quality receiver may have a shape factor of 2.

## POLES AND ZEROS

In equation 1 there is a frequency called the “pole” frequency that is given by  $f_p = 0$ .

In equation 1 there also exists a frequency where the current  $i$  becomes zero. This frequency is called the *zero frequency* and is given by:  $f_0 = \text{infinity}$ . Poles and zeros are intrinsic properties of all net-

works. The poles and zeros of a network are related to the values of inductances and capacitances in the network.

Poles and zero locations are of interest to the filter theorist because they allow him to predict the frequency response of a proposed filter. For low-pass and high-pass filters the number of poles equals the number of reactances in the filter network. For band-pass and band-stop filters the number of poles specified by the filter vendors is usually taken to be half the number of reactances.

## LC FILTERS

Perhaps the most common filter found in the Amateur Radio station is the inductor-capacitor (LC) filter. Historically, the LC filter was the first to be used and the first to be analyzed. Many filter synthesis techniques use the LC filter as the mathematical model.

LC filters are usable from dc to approximately 1 GHz. Parasitic capacitance associated with the inductors and parasitic inductance associated with the capacitors make applications at higher frequencies impractical because the filter performance will change with the physical construction and therefore is not totally predictable from the design equations. Below 50 or 60 Hz, inductance and capacitance values of LC filters become impractically large.

Mathematically, an LC filter is a linear, lumped-element, passive, reciprocal network. Linear means that the ratio of output to input is the same for a 1-V input as for a 10-V input. Thus, the filter can accept an input of many simultaneous sine waves without intermodulation (mixing) between them.

*Lumped-element* means that the inductors and capacitors are physically much smaller than an operating wavelength. In this case, conductor lengths do not contribute significant inductance or capacitance, and the time that it takes for signals to pass through the filter is insignificant. (Although the different times that it takes for different frequencies to pass through the filter—known as group delay—is still significant for some applications.)

The term *passive* means that the filter does not need any internal power sources. There may be amplifiers before and/or after the filter, but no power is necessary for the filter’s equations to hold. The filter alone always exhibits a finite (nonzero) insertion loss due to the unavoidable resistances associated with inductors and (to a lesser extent) capacitors. Active filters, as the name implies, contain internal power sources.

*Reciprocal* means that the filter can pass power in either direction. Either end of the filter can be used for input or output.

## TIME DOMAIN VS FREQUENCY DOMAIN

Humans think in the time domain. Life experiences are measured and recorded in the stream of time. In contrast, Amateur Radio systems and their associated filters are often better understood when viewed in the frequency domain, where frequency is the relevant system parameter. *Frequency* may refer to a sine-wave voltage, current or electromagnetic field. The sine-wave voltage, shown in **Fig 16.6**, is a waveform plotted against time with equation  $V = A \sin(2\pi f t)$ . The sine wave has a peak amplitude  $A$  (measured in volts) and frequency,  $f$  (measured in cycles/second or Hertz). A graph showing frequency on the horizontal axis is called a spectrum. A filter response curve is plotted on a spectrum graph.

Historically, radio systems were best analyzed in the frequency domain. The radio transmitters of Hertz (1865) and Marconi (1895) consisted of LC resonant circuits excited by high-voltage spark gaps. The transmitters emitted packets of damped sine waves. The low-frequency (200-kHz) antennas used by Marconi were found to possess very narrow bandwidths, and it seemed natural to analyze antenna performance using sine-wave excitation. In addition, the growing use of 50 and 60-Hz alternating current (ac) electric

power systems in the 1890s demanded the use of sine-wave mathematics to analyze these systems. Thus engineers trained in ac power theory were available to design and build the early radio systems.

In the frequency domain, the radio world is imagined to be composed of many sine waves of different frequencies flowing endlessly in time. It can be shown by the Fourier transform (Ref 7) that all periodic waveforms can be represented by summing sine waves of different frequencies. For example, the square-wave voltage shown in **Fig 16.7** can be represented by a "fundamental" sine wave of frequency  $f = 1/t$  and all its odd harmonics:  $3f$ ,  $5f$ ,  $7f$  and so on. Thus, in the frequency domain a sine wave is a *narrowband* signal (zero bandwidth) and a square wave is a "wideband" signal.

If the square-wave voltage of Fig 16.7 is passed through a low-pass filter, which removes some of its high-frequency components, the waveform of **Fig 16.8** results. The filtered square wave now has a rise time, which is the time required to rise from 10% to 90% of its peak value ( $A$ ). The rise time is approximately:

$$\tau_R = \frac{0.35}{f_c} \quad (6)$$

where  $f_c$  is the cutoff frequency of the low-pass filter.

Thus a filter distorts a time-domain signal by removing some of its high-frequency components. Note that a filter cannot distort a sine wave. A filter can only change the amplitude and phase of sine waves. A linear filter will pass multiple sine waves without producing any intermodulation or "beats" between frequencies—this is the definition of *linear*.

The purpose of a radio system is to convey a time-domain signal originating at a source to some distant point with minimum distortion. Filters within the radio system transmitter and receiver may intentionally or unintentionally distort the source signal. A knowledge of the source signal's frequency-domain bandwidth is required so that an appropriate radio system may be designed.

**Table 16.1** shows the minimum necessary bandwidth of several common source signals. Note that high-fidelity speech and music requires a bandwidth of 20 Hz to 15 kHz, which is that transmitted by high-quality FM broadcast stations. However, telephone-quality speech requires a bandwidth of only 200 Hz to 3 kHz. Thus, to

**Fig 16.6—Ideal sine-wave voltage.** Only one frequency is present.

**Fig 16.7—Square-wave voltage.** Many frequencies are present, including  $f = 1/t$  and odd harmonics  $3f$ ,  $5f$ ,  $7f$  with decreasing amplitudes.

**Fig 16.8—Square-wave voltage filtered by a low-pass filter.** By passing the square wave through a filter, the higher frequencies are attenuated. The rectangular shape (fast rise and fall times) are *rounded* because the amplitude of the higher harmonics are decreased.

**Table 16.1**

**Typical Filter Bandwidths for Typical Signals.**

Source	Required Bandwidth
High-fidelity speech and music	20 Hz to 15 kHz
Telephone-quality speech	200 Hz to 3 kHz
Radiotelegraphy (Morse code, CW)	200 Hz
HF RTTY	1000 Hz (varies with frequency shift)
NTSC television	60 Hz to 4.5 MHz
SSTV	200 Hz to 3 kHz
1200 bit/s packet	200 Hz to 3 kHz

minimize transmit spectrum, as required by the FCC, filters within amateur transmitters are required to reduce the speech source bandwidth to 200 Hz to 3 kHz at the

expense of some speech distortion. After modulation the transmitted RF bandwidth will exceed the filtered source bandwidth if inefficient (AM or FM) modulation

methods are employed. Thus the post-modulation *emission bandwidth* may be several times the original filtered source bandwidth. At the receiving end of the radio link, band-pass filters are required to accept only the desired signal and sharply reject noise and adjacent channel interference.

As human beings we are accustomed to operation in the time domain. Just about all of our analog radio connected design occurs in the frequency domain. This is particularly true when it comes to filters. Although the two domains are convertible, one to the other, most filter design is performed in the frequency domain.

## Filter Synthesis

The image-parameter method of filter design was initiated by O. Zobel (Ref 1) of Bell Labs in 1923. Image-parameter filters are easy to design and design techniques are found in earlier editions of the *ARRL Handbook*. Unfortunately, image parameter theory demands that the filter terminating impedances vary with frequency in an unusual manner. The later addition of “m-derived matching half sections” at each end of the filter made it possible to use these filters in many applications. In the intervening decades, however, many new methods of filter design have brought both better performance and practical component values for construction.

### MODERN FILTER THEORY

The start of modern filter theory is usually credited to S. Butterworth and S. Darlington (Refs 3 and 4). It is based on this approach: Given a desired frequency response, find a circuit that will yield this response.

Filter theorists were aware that certain known mathematical polynomials had “filter like” properties when plotted on a frequency graph. The challenge was to match the filter components (L, C and R) to the known polynomial poles and zeros. This pole/zero matching was a difficult task before the availability of the digital computer. Weinberg (Ref 5) was the first to publish computer generated tables of normalized low-pass filter component values. (“Normalized” means 1-Ω resistor terminations and cutoff frequency  $\omega_c = 2\pi f_c = 1$  radian/s.)

An ideal low-pass filter response shows no loss from zero frequency to the cutoff frequency, but infinite loss above the cutoff frequency. Practical filters may approximate this ideal response in several different ways.

Fig 16.9 shows the Butterworth or “maximally-flat” type of approximation. The Butterworth response formula is:

$$\frac{P_L}{P_O} = \frac{1}{1 + \left(\frac{\omega}{\omega_c}\right)^{2n}} \quad (7)$$

where

$\omega$  = frequency of interest,

$\omega_c$  = cutoff frequency

$n$  = number of poles (reactances)

$P_L$  = power in the load resistor

$P_O$  = available generator power.

The passband is exceedingly flat near zero frequency and very high attenuation is experienced at high frequencies, but the approximation for both pass and stop bands is relatively poor in the vicinity of cutoff.

Fig 16.10 shows the Chebyshev approximation. Details of the Chebyshev response formula can be found in Refs 5 and 17. Use of this reference as well as similar references for Chebyshev filters requires detailed familiarity with Chebyshev polynomials.

### IMPEDANCE AND FREQUENCY SCALING

Fig 16.11A shows normalized component values for Butterworth filters up to ten poles. Fig 16.11B shows the schematic diagrams of the Butterworth low-pass filter. Note that the first reactance in Fig 16.11B is a shunt capacitor C1, whereas in Fig 16.11C the first reactance is a series inductor L1. Either configuration can be used, but a design using fewer inductors is usually chosen.

In filter design, the use of *normalized* values is common. Normalized generally

**Fig 16.9—Butterworth approximation of an ideal low-pass filter response. The 3-dB attenuation frequency ( $f_c$ ) is normalized to 1 radian/s.**

**Fig 16.10—Chebyshev approximation of an ideal low-pass filter. Notice the ripple in the passband.**

(C)

**Fig 16.11—Component values for Butterworth low-pass filters. Greater values of n require more stages.**

means a design based on 1-Ω terminations and a cutoff frequency (passband edge) of 1 radian/second. A filter is *denormalized* by applying the following two equations:

$$L' = \left( \frac{R'}{R} \right) \left( \frac{\omega}{\omega'} \right) L \quad (8)$$

$$C' = \left( \frac{R}{R'} \right) \left( \frac{\omega}{\omega'} \right) C \quad (9)$$

where

$L'$ ,  $C'$ ,  $\omega'$  and  $R'$  are the new (desired) values

$L$  and  $C$  are the values found in the filter tables

$R = 1 \Omega$

$\omega = 1$  radian/s.

**Fig 16.12—A 3-pole Butterworth filter designed for a normalized frequency of 1 radian/s.**

**Fig 16.13—A 3-pole Butterworth filter scaled to 3000 Hz.**

The normalized prototype, taken from Fig 16.11B is shown in Fig 16.12. The new (desired) inductor value is:

$$L' = \left( \frac{1000 \Omega}{1 \Omega} \right) \left( \frac{1 \text{ radian/second}}{2\pi(3000)\text{Hz}} \right) 2 \text{ H}$$

or  $L' = 0.106 \text{ H}$ .

**The new (desired) capacitor value is:**

$$C' = \left( \frac{1 \Omega}{1000 \Omega} \right) \left( \frac{1 \text{ radian/second}}{2\pi(3000)\text{Hz}} \right) 1 \text{ F}$$

or  $C' = 0.053 \mu\text{F}$ .

The final denormalized filter is shown in Fig 16.13. The filter response, in the passband, should obey curve  $n = 3$  in Fig 16.14. To use the normalized frequency response curves in Fig 16.14 calculate the frequency ratio  $f/f_c$  where  $f$  is the desired frequency and  $f_c$  is the cutoff frequency. For the filter just designed, the loss at 2000 Hz can be found as follows: When  $f$  is 2000 Hz, the frequency ratio is:

**Fig 16.14—Passband loss of Butterworth low-pass filters. The horizontal axis is normalized frequency (see text).**

$f/f_c = 2000/3000 = 0.67$ . Therefore the predicted loss (from the  $n = 3$  curve) is about 0.37 dB.

When  $f$  is 4000 Hz, the filter is operating in the stop-band (Fig 16.17). The resulting frequency ratio is:  $f/f_c = 4000/3000 = 1.3$ . Therefore the expected loss is about 8 dB. Note that as the number of reactances (poles) increases the filter response approaches the low-pass response of Fig 16.3A.

## BAND-PASS FILTERS—SIMPLIFIED DESIGN

The design of band-pass filters may be directly obtained from the low-pass prototype by a frequency translation. The low-pass filter has a “center frequency” (in the parlance of band-pass filters) of 0 Hz. The frequency translation from 0 Hz to the band-pass filter center frequency,  $f$ , is obtained by replacing in the low-pass prototype all shunt capacitors with parallel tuned circuits and all series inductors with series tuned circuits.

As an example, suppose a band-pass filter is required at the front end of a homebrew 40-m QRP receiver to suppress powerful adjacent broadcast stations. The proposed filter has these characteristics:

- Center frequency,  $f_c = 7.15$  MHz
- 3-dB bandwidth = 360 kHz
- terminating resistors = 50  $\Omega$
- 3-pole Butterworth characteristic.

Start the design for the normalized 3-pole Butterworth low-pass filter (shown in Fig 16.11). First determine the center frequency from the band-pass limits. This frequency,  $f_0$ , is found by determining the geometric mean of the band limits. In this case the band limits are  $7.15 + 0.360/2 = 7.33$  MHz and  $7.15 - 0.360/2 = 6.97$  MHz; then

$$f_0 = \sqrt{f_{lo} \times f_{hi}} = \sqrt{6.97 \times 7.33} = 7.14 \text{ MHz} \quad (10)$$

where

$f_{lo}$  = low frequency end of the band-pass (or band-stop)

$f_{hi}$  = high frequency end of the band-pass (or band-stop)

Fig 16.15—Interim 3-pole Butterworth low-pass filter designed for cutoff at 0.36 MHz.

[Note that in this case there is little difference between 7.15 (bandwidth center) and 7.147 (band-edge geometric mean) because the bandwidth is small. For wide-band filters, however, there can be a significant difference.]

Next, denormalize to a new interim low-pass filter having  $R' = 50 \Omega$  and  $f' = 0.36$  MHz.

$$L' = \left(\frac{50}{1}\right) \left(\frac{1}{2 \times \pi \times 0.36 \times 10^6}\right) 2H = 44.2 \mu H$$

$$C' = \left(\frac{1}{50}\right) \left(\frac{1}{2 \times \pi \times 0.36 \times 10^6}\right) 1F = 0.0088 \mu F$$

This interim low-pass filter, shown in Fig 16.15, has a cutoff frequency  $f_c = 0.36$  MHz and is terminated with 50- $\Omega$  resis-

tors. The desired 7.147-MHz band-pass filter is achieved by parallel resonating the shunt capacitors with inductors and series resonating the series inductor with a series capacitor. All resonators must be tuned to the center frequency. Therefore, variable capacitors or inductors are required for the resonant circuits. Based on the  $L'$  and  $C'$  just calculated the parallel-resonating inductor values are:

$$L1 = L3 = \frac{1}{C'(2 \times \pi f_0)^2} = 0.056 \mu H$$

The series-resonating capacitor value is:

$$C2 = \frac{1}{L'(2 \times \pi f_0)^2} = 11 \text{ pF}$$

The final band-pass filter is shown in Fig 16.16. The filter should have a 3-dB bandwidth of 0.36 MHz. That is, the

Fig 16.16—Final filter design consists of the low-pass filter scaled to a center frequency of 7.15 MHz.

Fig 16.17—Stop-band loss of Butterworth low-pass filters. The almost vertical angle of the lines representing filters with high values of  $n$  (10, 12, 15, 20) show the slope of the filter will be very high (sharp cutoff).

3-dB loss frequencies are 6.97 MHz and 7.33 MHz. The filter's loaded  $Q$  is:  $Q = 7.147/0.36$  or approximately 20.

The filter response, in the passband, falls on the "n = 3" curve in Fig 16.17. To use the normalized frequency response curves, calculate the frequency ratio  $f/f_c$ . For this band-pass case,  $f$  is the difference between the desired attenuation frequency and the center frequency, while  $f_c$  is the upper 3-dB frequency minus the center frequency. As an example the filter loss at 7.5 MHz is found by using the normalized frequency ratio given by:

$$\frac{f}{f_c} = \frac{7.5 - 7.147}{7.33 - 7.147} = 1.928$$

Therefore, from Fig 16.17 the expected loss is about 17 dB.

At 6 MHz the loss may be found by:

$$\frac{f}{f_c} = \frac{7.147 - 6}{7.33 - 7.147} = 6.26$$

The expected loss is approximately 47 dB. Unfortunately, awkward component values occur in this type of band-pass filter. The series resonant circuit has a very large LC ratio and the parallel resonant circuits have very small LC ratios. The situation worsens as the filter loaded  $Q_L$  ( $Q_L = f_0/BW$ ) increases. Thus, this type of band-pass filter is generally used with a loaded  $Q$  less than 10.

Good examples of low- $Q$  band-pass filters of this type are demonstrated by W3NQN's High Performance CW Filter and Passive Audio Filter for SSB in the projects section of this chapter.

[Note: This analysis used the geometric  $f_c$  with the assumption that the filter response is symmetrical about  $f_c$ , which it is not. A more rigorous analysis yields 16.9 dB at 7.5 MHz and 50.7 dB at 6 MHz.—Ed.]

### Q Restrictions—Band-pass Filters

Most filter component value tables as-

**Fig 16.18—Frequency range and maximum loaded  $Q$  of band-pass filters. Crystal filters are shown with the highest  $Q_L$  and LC filters the lowest.**

sume lossless reactances. In practice, there are always resistance losses associated with capacitors and inductors (especially inductors). Lossy reactances in low-pass filters modify the response curve. There is finite loss at zero frequency and the cutoff "knee" at  $f_c$  will not be as sharp as predicted by theoretical response curves.

The situation worsens with band-pass filters. As loaded  $Q$  is increased the midband insertion loss may become intolerable. Therefore, before a band-pass filter design is started, estimate the expected loss.

An approximate estimate of band-pass filter midband response is given by:

$$\frac{P_L}{P_O} = \left(1 - \frac{Q_L}{Q_U}\right)^{2N} \quad (11A)$$

where:

$P_L$  = power delivered to load resistor  $R_L$

$P_O$  = power available from generator:

$$P_O = \frac{e_g^2}{4R_L} \quad (11B)$$

$Q_U$  = unloaded  $Q$  of inductor:

$$Q_U = \frac{2\pi \times f_0 \times L}{R} \quad (11C)$$

$R$  = inductor series resistance

$L$  = inductance

$Q_L$  = filter loaded  $Q$

$$Q_L = \frac{f_0}{BW_3} \quad (11D)$$

$BW_3$  = 3 dB bandwidth

$N$  = number of filter stages.

This equation assumes that all losses are in the inductors. For example, the expected loss of the 7.15-MHz filter shown in Fig 16.16 is found by assuming  $Q_U = 150$ .  $Q_L$  is found by equation 11D to be  $7.147/0.36 = 19.8$  or approximately 20. Since  $N = 3$  then:

$$\frac{P_L}{P_O} = \left(1 - \frac{20}{150}\right)^6$$

from equation (11A), which equals 0.423. Expressed as dB this is equal to  $10 \log(0.423) = -3.73$  dB.

Therefore this filter may not be suitable for some applications. If the insertion loss is to be kept small there are severe restrictions on  $Q_L/Q_U$ . With typical lumped inductors  $Q_U$  seldom exceeds 200. Therefore, LC band-pass filters are usually designed with  $Q_L$  not exceeding 20 as shown in Fig 16.18.

This loss vs bandwidth trade-off is usually why the final intermediate frequency (IF) in older radio receivers was very low. These units used the equivalent of LC filters in their IF coupling. Generally, for SSB reception the desired receiver bandwidth is about 2.5 kHz. Then 50 kHz was often chosen as the final IF since this implies a loaded  $Q_L$  of 20. AM broadcast receivers require a 10-kHz bandwidth and use a 455-kHz IF, which results in  $Q_L = 45$ . FM broadcast receivers require a 200-kHz bandwidth and use a 10.7-MHz IF and  $Q_L = 22$ .

## Filter Design Using Standard Capacitor Values

Practical filters must be designed using commercially available components. Therefore a set of tables, based upon *standard value capacitors* (SVC), has been generated to facilitate this real design process. The procedure presented here uses eight computer-calculated tables of performance parameters and component values for 5- and 7-branch Chebyshev and 5-branch elliptic 50- $\Omega$  filters. The tables permit the quick and easy selection of an equally terminated passive LC filter for applications where the attenuation re-

sponse is of primary interest. All of the capacitors in the Chebyshev designs and the three nonresonating capacitors in the elliptic designs have standard, off-the-shelf values to simplify construction. Although the tables cover only the 1 to 10-MHz frequency range, a simple scaling procedure gives standard-value capacitor (SVC) designs for any impedance level and virtually any cutoff frequency.

The full tables are printed in the **References** chapter of this *Handbook*. Extracts from the tables are reprinted in this sec-

tion to illustrate the design procedure.

The following text by Ed Wetherhold, W3NQN, is adapted from his paper entitled *Simplified Passive LC Filter Design for the EMC Engineer*. It was presented at an IEEE International Symposium on Electromagnetic Compatibility in 1985.

The approach is based upon the fact that for most nonstringent filtering applications, it is not necessary that the actual cutoff frequency exactly match the desired cutoff frequency. A deviation of 5% or so between the actual and desired cutoff

frequencies is acceptable. This permits the use of design tables based on standard capacitor values instead of pass-band ripple attenuation or reflection coefficient.

## STANDARD VALUES IN FILTER DESIGN CALCULATIONS

Capacitors are commercially available in special series of preferred values having designations of E12 (10% tolerance) and E24 (5% tolerance; Ref 22) The reciprocal of the E-number is the power to which 10 is raised to give the step multiplier for that particular series.

First the normalized Chebyshev and elliptic component values are calculated based on many ratios of standard capacitor values. Next, using a 50-Ω impedance level, the parameters of the designs are calculated and tabulated to span the 1-10 MHz decade. Because of the large number of standard-value capacitor (SVC) designs in this decade, the increment in cutoff frequency from one design to the next is sufficiently small so that virtually any cutoff frequency requirement can be satisfied. Using such a table, the selection of an

appropriate design consists of merely scanning the cutoff frequency column to find a design having a cutoff frequency that most closely matches the desired cutoff frequency.

## Chebyshev and Elliptic Filters

Low-pass and high-pass 5- and 7-element Chebyshev and 5-branch elliptic designs were selected for tabulation because they are easy to construct and will satisfy the majority of nonstringent filtering requirements where the amplitude response is of primary interest. The pre-calculated 50-Ω designs are presented in eight tables of five low-pass and three high-pass designs with cutoff frequencies covering the 1-10 MHz decade. The applicable filter configuration and attenuation response curve accompany each table. In addition to the component values, attenuation vs frequency data and SWR are also included in the table. The passband attenuation ripples are so low in amplitude that they are swamped by the filter losses and are not measurable. For this reason, they are not shown in the response curves.

## LOW-PASS TABLES

Fig 16.19 is an extract from the tables for the low-pass 5- and 7-element Chebyshev capacitor input/output configuration in the **References** chapter of this *Handbook*. This filter configuration is generally preferred to the alternate inductor input/output configuration because it requires fewer inductors. Generally, decreasing input impedance with increasing frequency in the stop band presents no problems. Fig 16.20 shows the corresponding information for low-pass applications, but with an inductor input/output configuration. This configuration is useful when the filter input impedance in the stop band must rise with increasing frequency. For example, some RF transistor amplifiers may become unstable when terminated in a low-pass filter having a stop-band response with a decreasing input impedance. In this case, the inductor-input configuration may eliminate the instability. (Ref 23) Because only one capacitor value is required in the designs of Fig 16.20, it was feasible to have the inductor value of L1 and L5 also be a standard value. Fig 16.21 is extracted from the table

for the low-pass 5-branch elliptic filter with the capacitor input/output configuration, in which the nonresonating capacitors (C1, C3 and C5) are standard values. The alternate inductor input/output elliptic configuration is seldom used and therefore it is not included.

## HIGH-PASS TABLES

A high-pass 5-element Chebyshev capacitor input/output configuration is shown in the table extract of **Fig 16.22**. Because the inductor input/output configuration is seldom used, it was not included. High-pass tables for elliptical filters appear in the **References** chapter.

## SCALING TO OTHER FREQUENCIES AND IMPEDANCES

The tables shown are for the 1-10 MHz decade and for a 50-Ω equally terminated

impedance. The designs are easily scaled to other frequency decades and to other equally terminated impedance levels, however, making the tables a universal design aid for these specific filter types.

## Frequency Scaling

To scale the frequency and the component values to the 10-100 or 100-1000 MHz decades, multiply all tabulated frequencies by 10 or 100, respectively. Then divide all C and L values by the same number. The  $A_s$  and SWR data remain unchanged. To scale the filter tables to the 0.1-1 kHz, 1-10 kHz or the 10-100 kHz decades, divide the tabulated frequencies by 1000, 100 or 10, respectively. Next multiply the component values by the same number. By changing the “MHz” frequency headings to “kHz” and the “pF” and “μH” headings to “nF” and

“mH,” the tables are easily changed from the 1-10 MHz decade to the 1-10 kHz decade and the table values read directly. Because the impedance level is still at 50 Ω, the component values may be awkward, but this can be corrected by increasing the impedance level by ten times using the impedance scaling procedure described below.

## Impedance Scaling

All the tabulated designs are easily scaled to impedance levels other than 50 Ω, while keeping the convenience of standard-value capacitors and the “scan mode” of design selection. If the desired new impedance level differs from 50 Ω by a factor of 0.1, 10 or 100, the 50-Ω designs are scaled by shifting the decimal points of the component values. The other data remain unchanged. For example, if the

The schematic for a 5-element capacitor input/output Chebyshev high-pass filter.

impedance level is increased by ten or one hundred times (to 500 or 5000  $\Omega$ ), the decimal point of the capacitor is shifted to the left one or two places and the decimal point of the inductor is shifted to the right one or two places. With increasing impedance the capacitor values become smaller and the inductor values become larger. The opposite is true if the impedance decreases.

When the desired impedance level differs from the standard 50- $\Omega$  value by a factor such as 1.2, 1.5 or 1.86, the following scaling procedure is used:

1. Calculate the impedance scaling ratio:

$$R = \frac{Z_x}{50} \quad (12)$$

where  $Z_x$  is the desired new impedance level, in ohms.

2. Calculate the cutoff frequency ( $f_{50\Omega}$ ) of a "trial" 50- $\Omega$  filter,

$$f_{50\Omega} = R \times f_{x\Omega} \quad (13)$$

where  $R$  is the impedance scaling ratio and  $f_{x\Omega}$  is the desired cutoff frequency of the filter at the new impedance level.

3. From the appropriate SVC table select a design having its cutoff frequency closest to the calculated  $f_{50\Omega}$  value. The tabulated capacitor values of this design are taken directly, but the frequency and inductor values must be scaled to the new impedance level.

4. Calculate the exact  $f_{x\Omega}$  values, where

$$f_{x\Omega} = \frac{f'_{50\Omega}}{R} \quad (14)$$

and  $f'_{50\Omega}$  is the tabulated cutoff frequency of the selected design. Calculate the other frequencies of the design in the same way.

5. Calculate the inductor values for the new filter by multiplying the tabulated inductor values of the selected design by the square of the scaling ratio,  $R$ .

For example, assume a 600- $\Omega$  elliptic low-pass filter is desired with a cutoff frequency of 1.0 kHz. The elliptic low-pass table is frequency scaled to the 1-10 kHz decade by changing the table headings to kHz, nF and mH. A suitable design is then selected for scaling to 60  $\Omega$ . The 60- $\Omega$  design is then scaled to 600  $\Omega$  by shifting the decimal point to complete the scaling procedure. The calculations for this example follow, using the five steps outlined above and using the

table extract in Fig 16.21:

$$1. R = \frac{Z_x}{50} = \frac{60}{50} = 1.2$$

$$2. f_{50\Omega} = 1.2 \times 1.0 \text{ kHz} = 1.2 \text{ kHz}$$

3. From the elliptic low-pass table (Fig 16.21), designs 5 and 10 have cutoff frequencies closest to the  $f_{50\Omega}$  of 1.2 kHz. Either design is suitable and design 5 is chosen because of its better selectivity. The tabulated capacitor values of 2200 nF, 3900 nF, 1800 nF, 271 nF and 779 nF are copied directly.

4. All frequencies of the final design are calculated by dividing the tabulated frequencies (in kHz) of design 5 by the impedance scaling ratio, 1.2:

$$f_{co} = \frac{1.27}{1.2} = 1.06$$

$$f_{3dB} = \frac{1.45}{1.2} = 1.21$$

$$f_{AS} = \frac{2.17}{1.2} = 1.88$$

Note that a cutoff frequency of 1.0 kHz was desired, but a 1.06-kHz cutoff frequency will be accepted in exchange for the convenience of using an SVC design.

5. The L2 and L4 inductor values of design 5 are scaled to 60  $\Omega$  by multiplying them by the square of the impedance ratio, where  $R = 1.2$  and  $R^2 = 1.44$ :

$$L2 = 1.44 \times 7.85 \text{ mH} = 11.3 \text{ mH}$$

$$L4 = 1.44 \times 6.39 \text{ mH} = 9.20 \text{ mH}$$

The 60- $\Omega$  design is now impedance scaled to 600  $\Omega$  by shifting the decimal points of the capacitor values to the left and the decimal points of the inductor values to the right. The final scaled component values for the 600- $\Omega$  filter are:

$$C1 = 0.22 \mu\text{F}$$

$$C3 = 0.39 \mu\text{F}$$

$$C5 = 0.18 \mu\text{F}$$

$$C2 = 27.1 \text{ nF}$$

$$C4 = 77.9 \text{ nF}$$

$$L2 = 113 \text{ mH}$$

$$L4 = 92.0 \text{ mH}$$

### How to Use the Filter Tables

1. 50- $\Omega$  impedance level: Before selecting a filter design, the important parameters of the filter must be known, such as type (low-pass or high-pass), cutoff frequency, impedance level, preferred input

element (for low-pass only) and an approximation of the required stop band attenuation. It is obvious which tables to use for low-pass or high-pass applications, but it is not so obvious which one design of the many possible choices is optimum for the intended application.

Generally, the Chebyshev will be preferred over the elliptic because the Chebyshev does not require tuning of the inductors. If the relatively gradual attenuation rise of the Chebyshev is not satisfactory, however, then the elliptic should be considered. For audio filtering, the elliptic designs with high values of SWR are preferred because these designs have a much more abrupt attenuation rise than the Chebyshev. For RF applications, SWR values less than 1.2 are recommended to minimize undesired reflections. Low SWR is also important when cascading high-pass and low-pass filters to achieve a band-pass response more than two octaves wide. Each filter will operate as expected if it is correctly terminated, but this will occur only if both designs have the relatively constant terminal impedance that is associated with low SWR.

Once you know the filter type and response needed, select the table of designs most appropriate for the application on a trial basis. From the chosen table, scale the 1-10 MHz data to the desired frequency decade and search the cutoff frequency column for a value nearest the desired cutoff frequency. After finding a possible design, check the stop-band attenuation levels to see if they are satisfactory. Then check the SWR to see if it is appropriate for the application. Finally, check the component values to see if they are convenient. For example, in the audio-frequency range, the capacitor values probably will be in the microfarad range and capacitors in this size are available only in the E12 series of standard values. Then connect the components in accordance with the diagram shown in the table from which the design was selected.

2. Impedance levels other than 50  $\Omega$ : First calculate a "trial" filter design using the impedance scaling procedure previously explained. Then search the appropriate table for the best match to the trial filter and scale the selected design to the desired impedance level. In this way, the convenient scan mode of filter selection is used regardless of the desired impedance level.

# Chebyshev Filter Design (Normalized Tables)

The figures and tables in this section provide the tools needed to design Chebyshev filters including those filters for which the previously published *standard value capacitor* (SVC) designs might not be suitable. **Table 16.2** lists normalized low-pass designs that, in addition to low-pass filters, can also be used to calculate high-pass, band-pass and band-stop filters in either the inductor or capacitor input/output configurations for equal impedance terminations. **Table 16.3** provides the attenuation for the resultant filter.

This material was prepared by Ed Wetherhold, W3NQN, who has been the author of a number of articles and papers on the design of LC filters. It is a complete revision of his previously published filter

design material and provides both insight to the design and actual designs in just a few minutes.

For a given number of elements (N), increasing the filter reflection coefficient (RC or  $\rho$ ) causes the attenuation slope to increase with a corresponding increase in both the passband ripple amplitude ( $a_p$ ) and SWR and with a decrease in the filter return loss. All of these parameters are mathematically related to each other. If one is known, the others may be calculated. Filter designs having a low RC are preferred because they are less sensitive to component and termination impedance variations than are designs having a higher RC. The RC percentage is used as the independent variable in Table 16.2 because

it is used as the defining parameter in the more frequently used tables, such as those by Zverev and Saal (see Refs 17 and 18).

The return loss is tabulated instead of passband ripple amplitude ( $a_p$ ) because it is easy to measure using a return loss bridge. In comparison, ripple amplitudes less than 0.1 dB are difficult to measure accurately. The resulting values of attenuation are contained in Table 16.3 and corresponding values of  $a_p$  and SWR may be found by referring to the Equivalent Values of Reflection Coefficient, Attenuation, SWR and Return Loss table in the **References** chapter. The filter used (low pass, high-pass, band-pass and so on) will depend on the application and the stop-band attenuation needed.

**Table 16.2**

**Element values of Chebyshev low-pass filters normalized for a ripple cutoff frequency ( $F_{ap}$ ) of one radian/sec ( $1/2\pi$  Hz) and 1- $\Omega$  terminations.**

Use the top column headings for the low-pass C-in/out configuration and the bottom column headings for the low-pass L-in/out configuration. Fig 16.23 shows the filter schematics.

**Fig 16.23—The schematic diagrams shown are low-pass and high-pass Chebyshev filters with the C-in/out and L-in/out configurations. For all normalized values see Table 16.2.**

**A:** C-in/out low-pass configuration. Use the C and L values associated with the top column headings of the Table.

**B:** L-in/out low-pass configuration. For normalized values, use the L and C values associated with the bottom column headings of the Table.

**C:** L-in/out high-pass configuration is derived by transforming the C-in/out low-pass filter in A into an L-in/out high-pass by replacing all Cs with Ls and all Ls with Cs. The reciprocals of the lowpass component values become the highpass component values. For example, when  $n = 3$ ,  $RC = 1.00\%$  and  $C1 = 0.3524 \text{ F}$ ,  $L1$  and  $L3$  in C become  $2.838 \text{ H}$ .

**D:** The C-in/out high-pass configuration is derived by transforming the L-in/out low-pass in B into a C-in/out high-pass by replacing all Ls with Cs and all Cs with Ls. The reciprocals of the low-pass component values become the high-pass component values. For example, when  $n = 3$ ,  $RC = 1.00\%$  and  $L1 = 0.3524 \text{ H}$ ,  $C1$  and  $C3$  in D become  $2.838 \text{ F}$ .

The filter schematic diagrams shown in **Fig 16.23** are for low-pass and high-pass versions of the Chebyshev designs listed in Table 16.2. Both low-pass and high-pass equally terminated configurations and component values of the C-in/out or L-in/out filters can be derived from this single table. By using a simple procedure, the low-pass and high-pass designs can be transformed into corresponding band-pass and band-stop filters. The normalized element values of the low-pass C-in/out and L-in/out designs, Fig 16.23A and B, are read directly from the table using the values associated with either the top or bottom column headings, respectively.

The first four columns of Table 16.2 list  $N$  (the number of filter elements),  $RC$  (reflection coefficient percentage), *return loss* and the ratio of the 3-dB-to- $F_{ap}$  frequencies. The passband maximum ripple amplitude ( $a_p$ ) is not listed because it is difficult to measure. If necessary it can be calculated from the reflection coefficient. The  $F3/F_{ap}$  ratio varies with  $N$  and  $RC$ ; if both of these parameters are known, the  $F3/F_{ap}$  ratio may be calculated. The remaining columns list the normalized Chebyshev element values for equally terminated filters for  $N$ s from 3 to 9 in increments of 2.

The Chebyshev passband ends when the passband attenuation first exceeds the maximum ripple amplitude,  $a_p$ . This frequency is called the “ripple cutoff frequency,  $F_{ap}$ ” and it has a normalized value of unity. All Chebyshev designs in Table 16.2 are based on the ripple cutoff frequency instead of the more familiar 3-dB frequency of the Butterworth response. However, the 3-dB frequency of a Chebyshev design may be obtained by multiplying the ripple cutoff frequency by the  $F3/F_{ap}$  ratio listed in the fourth column.

The element values are normalized to a ripple cutoff frequency of  $0.15915 \text{ Hz}$  (one radian/sec) and  $1\text{-}\Omega$  terminations, so that the low-pass values can be transformed directly into high-pass values. This is done by replacing all Cs and Ls in the low-pass configuration with Ls and Cs and by replacing all the low-pass element values with their reciprocals. The normalized values are then multiplied by the appropriate C and L scaling factors to obtain the final values based on the desired ripple cutoff frequency and impedance level. The listed C and L element values are in farads and henries and become more reasonable after the values are scaled to the desired cutoff frequency and impedance level.

The normalized designs presented are a mixture: Some have integral values of *reflection coefficient (RC)* (1% and 10%) while others have “integral” values of

Table 16.3

Normalized Frequencies at Listed Attenuation Levels for Chebyshev Low-Pass Filters with N = 3, 5, 7 and 9.

passband ripple amplitude (0.001, 0.01 and 0.1 dB). These ripple amplitudes correspond to reflection coefficients of 1.517, 4.796 and 15.087%, respectively. By having tabulated designs based on integral values of both reflection coefficient and passband ripple amplitude, the correctness of the normalized component values may be checked against those same values published in filter handbooks whichever parameter, RC or  $a_p$ , is used.

In addition to the customary normalized design listings based on integral values of reflection coefficient or ripple amplitude, Table 16.2 also includes unique designs having special element ratios that make them more useful than previously published tables. For example, for N = 5 and RC = 6.302, the ratio of C3/C1 is 2.000. This ratio allows 5-element low-pass filters to be realized with only one capacitor value because C3 may be obtained by using parallel-connected capacitors each having the same value as C1 and C5.

In a similar way, for N = 7 and RC = 8.101, C3/C1 and C5/C1 are also 2.000. Another useful N = 7 design is that for RC = 1.427%. Here the L4/L2 ratio is 1.25, which is identical to 110/88. This means a seventh-order C-in/out low-pass audio filter can be realized with four surplus 88-mH inductors. Both L2 and L6 can be 88 mH while L4 is made up of a series connection of 22 mH and 88 mH. The

22-mH value is obtained by connecting the two windings of one of the four surplus inductors in parallel. Other useful ratios also appear in the N = 9 listing for both C3/C1 and L4/L2.

Except for the first two N = 5 designs, all designs were calculated for a reflection coefficient range from 1% to about 15%. The first two N = 5 designs were included because of their useful L3/L1 ratios. Designs with an RC of less than 1% are not normally used because of their poor selectivity. Designs with RC greater than 15% yield increasingly high SWR values with correspondingly increased objectionable reflective losses and sensitivity to termination impedance and component value variations.

Low-pass and high-pass filters may be realized in either a C-input/output or an L-input/output configuration. The C-input/output configuration is usually preferred because fewer inductors are required, compared to the L-input/output configuration. Inductors are usually more lossy, bulky and expensive than capacitors. The selection of the filter order or number of filter elements, N, is determined by the desired stop-band attenuation rate of increase and the tolerable reflection coefficient or SWR. A steeper attenuation slope requires either a design having a higher reflection coefficient or more circuit elements. Consequently, to

select an optimum design, the builder must determine the amount of attenuation required in the stop band and the permissible maximum amount of reflection coefficient or SWR.

Table 16.3 shows the theoretical normalized frequencies (relative to the ripple cutoff frequency) for the listed attenuation levels and reflection coefficient percentages for Chebyshev low-pass filters of 3, 5, 7 and 9 elements. For example, for N = 5 and RC = 15.087%, an attenuation of 40 dB is reached at 2.22 times the ripple cutoff frequency (slightly more than one octave). The tabulated data are also applicable to high-pass filters by simply taking the reciprocal of the listed frequency. For example, for the same previous N and RC values, a high-pass filter attenuation will reach 40 dB at  $1/2.22 = 0.450$  times the ripple cutoff frequency (slightly less than one octave).

The attenuation levels are theoretical and assume perfect components, no coupling between filter sections and no signal leakage around the filter. A working model should follow these values to the 60 or 70-dB level. Beyond this point, the actual response will likely degrade somewhat from the theoretical.

Fig 16.24 shows four plotted attenuation vs normalized frequency curves for N = 5 corresponding to the normalized frequencies in Table 16.3 At two octaves

**Fig 16.24**—The graph shows attenuation vs frequency for four 5-element low-pass filters designed with the information obtained from Table 16.2. This graph demonstrates how reflection coefficient percentage (RC), maximum passband ripple amplitude ( $a_p$ ), SWR, return loss and attenuation rolloff are all related. The exact frequency at a specified attenuation level can be obtained from Table 16.3.

above the ripple cutoff frequency,  $f_c$ , the attenuation slope gradually becomes 6 dB per octave per filter element.

## LOW-PASS AND HIGH-PASS FILTERS

### Low-Pass Filter

Let's look at the procedure used to calculate the capacitor and inductor values of low-pass and high-pass filters by using two examples. Assume a 50- $\Omega$  low-pass filter is needed to give more than 40 dB of attenuation at  $2f_c$  or one octave above the ripple-cutoff frequency of 4.0 MHz. Referring to Table 16.3, we see from the 40-dB column that a filter with 7 elements ( $N = 7$ ) and a RC of 4.796% will reach 40 dB at 1.80 times the cutoff frequency or  $1.8 \times 4 = 7.2$  MHz. Since this design has a reasonably low reflection coefficient and will satisfy the attenuation requirement, it is a good choice. Note that no 5-element filters are suitable for this application because 40 dB of attenuation is not achieved one octave above the cutoff frequency.

From Table 16.2, the normalized component values corresponding to  $N = 7$  and RC = 4.796% for the C-in/out configuration are:  $C_1, C_7 = 0.7970$  F,  $L_2, L_6 = 1.392$  H,  $C_3, C_5 = 1.748$  F and

$L_4 = 1.633$  H. See Fig 16.23A for the corresponding configuration. The C and L normalized values will be scaled from a ripple cutoff frequency of one radian/sec and an impedance level of 1  $\Omega$  to a cutoff frequency of 4.0 MHz and an impedance level of 50  $\Omega$ . The  $C_s$  and  $L_s$  scaling factors are calculated:

$$C_s = \frac{1}{2\pi R f} \quad (15)$$

$$L_s = \frac{R}{2\pi f} \quad (16)$$

where:

$R$  = impedance level  
 $f$  = cutoff frequency.

In this example:

$$C_s = \frac{1}{2\pi R f} = \frac{1}{2\pi \times 50 \times 4 \times 10^6} = 795.8 \times 10^{-12}$$

$$L_s = \frac{R}{2\pi f} = \frac{50}{2\pi \times 4 \times 10^6} = 1.989 \times 10^{-6}$$

Using these scaling factors, the capacitor and inductor normalized values are scaled to the desired cutoff frequency and impedance level:

$$C_1, C_7 = 0.797 \times 795.8 \text{ pF} = 634 \text{ pF}$$

$$C_3, C_5 = 1.748 \times 795.8 \text{ pF} = 1391 \text{ pF}$$

$$L_2, L_6 = 1.392 \times 1.989 \mu\text{H} = 2.77 \mu\text{H}$$

$$L_4 = 1.633 \times 1.989 \mu\text{H} = 3.25 \mu\text{H}$$

### High-Pass Filter

The procedure for calculating a high-pass filter is similar to that for a low-pass filter, except a low-pass-to-high-pass transformation must first be performed. Assume a 50- $\Omega$  high-pass filter is needed to give more than 40 dB of attenuation one octave below ( $f_c/2$ ) a ripple cutoff frequency of 4.0 MHz. Referring to Table 16.3, we see from the 40-dB column that a 7-element low-pass filter with RC of 4.796% will give 40 dB of attenuation at  $1.8f_c$ . If this filter is transformed into a high-pass filter, the 40-dB level is reached at  $f_c/1.80$  or at  $0.556f_c = 2.22$  MHz. Since the 40-dB level is reached before one octave from the 4-MHz cutoff frequency, this design will be satisfactory.

From Fig 16.23, we choose the low-pass L-in/out configuration in B and transform it into a high-pass filter by replacing all inductors with capacitors and all capacitors with inductors. Fig 16.23D is the filter configuration after the transformation. The reciprocals of the low-pass values become the high-pass values to complete the transformation. The high-pass values of the filter shown in Fig 16.23D are:

$$C_1, C_7 = \frac{1}{0.7970} = 1.255 \text{ F}$$

$$L_2, L_6 = \frac{1}{1.392} = 0.7184 \text{ H}$$

$$C_3, C_5 = \frac{1}{1.748} = 0.5721 \text{ F}$$

and

$$L_4 = \frac{1}{1.633} = 0.6124 \text{ H}$$

Using the previously calculated C and L scaling factors, the high-pass component values are calculated the same way as before:

$$C_1, C_7 = 1.255 \times 795.8 \text{ pF} = 999 \text{ pF}$$

$$C_3, C_5 = 0.5721 \times 795.8 \text{ pF} = 455 \text{ pF}$$

$$L_2, L_6 = 0.7184 \times 1.989 \mu\text{H} = 1.43 \mu\text{H}$$

$$L_4 = 0.6124 \times 1.989 \mu\text{H} = 1.22 \mu\text{H}$$

### BAND-PASS FILTERS

Band-pass filters may be classified as either narrowband or broadband. If the ratio of the upper ripple cutoff frequency to the lower cutoff frequency is greater than two, we have a wideband filter. For wideband filters, the band-pass filter (BPF) requirement may be realized by simply cascading separate high-pass and low-pass filters having the same design

impedance. (The assumption is that the filters maintain their individual responses even though they are cascaded.) *For this to be true, it is important that both filters have a relatively low reflection coefficient percentage (less than 5%) so the SWR variations in the passband will be small.*

For narrowband BPFs, where the separation between the upper and lower cutoff frequencies is less than two, it is necessary to transform an appropriate low-pass filter into a BPF. That is, we use the low-pass normalized tables to design narrowband BPFs.

We do this by first calculating a low-pass filter (LPF) with a cutoff frequency equal to the desired bandwidth of the BPF. The LPF is then transformed into the desired BPF by resonating the low-pass components at the geometric center frequency of the BPF.

For example, assume we want a 50- $\Omega$  BPF to pass the 75/80-m band and attenuate all signals outside the band. Based on the passband ripple cutoff frequencies of 3.5 and 4.0 MHz, the geometric center frequency =  $(3.5 \times 4.0)^{0.5} = (14)^{0.5} = 3.741657$  or 3.7417 MHz. Let's slightly extend the lower and upper ripple cutoff frequencies to 3.45 and 4.058 MHz to account for possible component tolerance variations and to maintain the same center frequency. We'll evaluate a low-pass 3-element prototype with a cutoff frequency equal to the BPF passband of (4.058–3.45) MHz = 0.608 MHz as a possible choice for transformation.

Further, assume it is desired to attenuate the second harmonic of 3.5 MHz by at least 40 dB. The following calculations show how to design an  $N = 3$  filter to provide the desired 40-dB attenuation at 7 MHz and above.

The bandwidth (BW) between 7 MHz on the upper attenuation slope (call it "f+") of the BPF and the corresponding frequency at the same attenuation level on the lower slope (call it "f-") can be calculated based on  $(f+)(f-) = (f_c)^2$  or

$$f- = \frac{14}{7} = 2 \text{ MHz}$$

Therefore, the bandwidth at this unknown attenuation level for 2 and 7 MHz is 5 MHz. This 5-MHz BW is normalized to the ripple cutoff BW by dividing 5.0 MHz by 0.608 MHz:

$$\frac{5.0}{0.608} = 8.22$$

We now can go to Table 16.3 and search for the corresponding normalized frequency that is closest to the desired normalized BW of 8.22. The low-pass design of  $N = 3$  and  $RC = 4.796\%$  gives 40 dB for

a normalized BW of 8.08 and 50 dB for 11.83. Therefore, a design of  $N = 3$  and  $RC = 4.796\%$  with a normalized BW of 8.22 is at an attenuation level somewhere between 40 and 50 dB. Consequently, a low-pass design based on 3 elements and a 4.796% RC will give slightly more than the desired 40 dB attenuation above 7 MHz. The next step is to calculate the C and L values of the low-pass filter using the normalized component values in Table 16.2.

From this table and for  $N = 3$  and  $RC = 4.796\%$ ,  $C1, C3 = 0.6292 \text{ F}$  and  $L2 = 0.9703 \text{ H}$ . We calculate the scaling factors as before and use 0.608 MHz as the ripple cutoff frequency:

$$C_s = \frac{1}{2\pi R f} = \frac{1}{2\pi \times 50 \times 0.608 \times 10^6} = 5235 \times 10^{-12}$$

$$L_s = \frac{R}{2\pi f} = \frac{50}{2\pi \times 0.608 \times 10^6} = 13.09 \times 10^{-6}$$

$$C1, C3 = 0.6292 \times 5235 \text{ pF} = 3294 \text{ pF} \text{ and } L2 = 0.9703 \times 13.09 \text{ } \mu\text{H} = 12.70 \text{ } \mu\text{H}$$

The LPF (in a pi configuration) is transformed into a BPF with 3.7417-MHz center frequency by resonating the low-pass elements at the center frequency. The resonating components will take the same identification numbers as the components they are resonating.

$$L1, L3 = \frac{25330}{(F_c^2 \times C1)} = \frac{25330}{(14 \times 3294)} = 0.5493 \text{ } \mu\text{H}$$

$$C2 = \frac{25330}{(F_c^2 \times L2)} = \frac{25330}{(14 \times 12.7)} = 142.5 \text{ pF}$$

where L, C and f are in  $\mu\text{H}$ , pF and MHz, respectively.

The BPF circuit after transformation (for  $N = 3$ ,  $RC = 4.796\%$ ) is shown in Fig 16.25.

The component-value spread is

$$\frac{12.7}{0.549} = 23$$

and the reactance of L1 is about  $13 \Omega$  at the center frequency. For better BPF performance, the component spread should be reduced and the reactance of L1 and L3 should be raised to make it easier to achieve the maximum possible Q for these two inductors. This can be easily done by designing the BPF for an impedance level of 200  $\Omega$  and then using the center taps on L1 and L3 to obtain the desired 50- $\Omega$  terminations. The result of this approach

is shown in Fig 16.26.

The component spread is now a more reasonable

$$\frac{12.7}{2.20} = 5.77$$

and the L1, L3 reactance is 51.6  $\Omega$ . This higher reactance gives a better chance to achieve a satisfactory Q for L1 and L3 with a corresponding improvement in the BPF performance.

As a general rule, keep reactance values between 5  $\Omega$  and 500  $\Omega$  in a 50- $\Omega$  circuit. When the value falls below 5  $\Omega$ , either the equivalent series resistance of the inductor or the series inductance of the capacitor degrades the circuit Q. When the inductive reactance is greater than 500  $\Omega$ , the inductor is approaching self-resonance and circuit Q is again degraded. In practice, both L1 and L3 should be bifilar wound on a powdered-iron toroidal core to assure that optimum coupling is obtained between turns over the entire winding. The junction of the bifilar winding serves as a center tap.

**Fig 16.25—After transformation of the band-pass filter, all parallel elements become parallel LCs and all series elements become series LCs.**

**Fig 16.26—A filter designed for 200- $\Omega$  source and load provides better values. By tapping the inductors, we can use a 200- $\Omega$  filter design in a 50- $\Omega$  system.**

## Side-Slope Attenuation Calculations

The following equations allow the calculation of the frequencies on the upper and lower sides of a BPF response curve at any given attenuation level if the bandwidth at that attenuation level and the geometric center frequency of the BPF are known:

$$f_{lo} = -X + \sqrt{f_c^2 + X^2} \quad (17)$$

$$f_{hi} = f_{lo} + BW \quad (18)$$

where

BW = bandwidth at the given attenuation level,

$f_c$  = geometric center frequency

$$X = \frac{BW}{2}$$

For example, if  $f = 3.74166$  MHz and BW = 5 MHz, then

$$\frac{BW}{2} = X = 2.5$$

and:

$$f_{lo} = -2.5 + \sqrt{3.74166^2 + 2.5^2} = 2.00 \text{ MHz}$$

$$f_{hi} = f_{lo} + BW = 2 + 5 = 7 \text{ MHz}$$

## BAND-STOP FILTERS

Band-stop filters may be classified as either narrowband or broadband. If the ratio of the upper ripple cutoff frequency to the lower cutoff frequency is greater than two, the filter is considered wideband. A wideband band-stop filter (BSF) requirement may be realized by simply paralleling the inputs and outputs of separate low-pass and high-pass filters having the same design impedance and with the low-pass filter having its cutoff frequency one octave or more below the high-pass cutoff frequency.

In order to parallel the low-pass and high-pass filter inputs and outputs without one affecting the other, it is essential that each filter have a high impedance in that portion of its stop band which lies in the passband of the other. *This means that each of the two filters must begin and end in series branches.* In the low-pass filter, the input/output series branches must con-

sist of inductors and in the high-pass filter, the input/output series branches must consist of capacitors.

When the ratio of the upper to lower cutoff frequencies is less than two, the BSF is considered to be narrowband, and a calculation procedure similar to that of the narrowband BPF design procedure is used. However, in the case of the BSF, the design process starts with the design of a high-pass filter having the desired impedance level of the BSF and a ripple cutoff frequency the same as that of the desired ripple bandwidth of the BSF. After the HPF design is completed, every high-pass element is resonated to the center frequency of the BSF in the same manner as if it were a BPF, except that all shunt branches of the BSF will consist of series-tuned circuits, and all series branches will consist of parallel-tuned circuits—just the opposite of the resonant circuits in the BPF. The reason for this becomes obvious when the impedance characteristics of the series and parallel circuits at resonance are considered relative to the intended purpose of the filter, that is, whether it is for a band-pass or a band-stop application.

## Quartz Crystal Filters

Practical inductor Q values effectively set the minimum achievable bandwidth limits for LC band-pass filters. Higher-Q circuit elements must be employed to extend these limits. These high-Q resonators include PZT ceramic, mechanical and coaxial devices. However, the quartz crystal provides the highest Q and best stability with temperature and time of all available resonators. Quartz crystals suitable for filter use are fabricated over a frequency range from audio to VHF.

The quartz resonator has the equivalent circuit shown in Fig 16.31.  $L_s$ ,  $C_s$  and  $R_s$  represent the *motional* reactances and loss resistance.  $C_p$  is the parallel plate capacitance formed by the two metal electrodes separated by the quartz dielectric. Quartz has a dielectric constant of 3.78. Table 16.4 shows parameter values for typical moderate-cost quartz resonators.  $Q_U$  is the resonator unloaded Q.

$$Q_U = 2\pi f_s r_s \quad (19)$$

$Q_U$  is very high, usually exceeding 25,000. Thus the quartz resonator is an ideal component for the synthesis of a high-Q band-pass filter.

A quartz resonator connected between

**Fig 16.34—A half-lattice crystal filter.** No phasing capacitor is needed in this circuit.

**Fig 16.33—The practical one-stage crystal filter in A has the response shown in B.** The phasing capacitor is adjusted for best response (see text).

**Fig 16.35—A four-stage crystal ladder filter.** The crystals must be chosen properly for best response.

generator and load, as shown in Fig 16.32A, produces the frequency response of Fig 16.32B. There is a relatively low loss at the series resonant frequency  $f_s$  and high loss at the parallel resonant frequency  $f_p$ . The test circuit of Fig 16.32A is useful for determining the parameters of a quartz resonator, but yields a poor filter.

A crystal filter developed in the 1930s is shown in Fig 16.33A. The disturbing effect of  $C_p$  (which produces  $f_p$ ) is canceled by the phasing capacitor,  $C1$ . The voltage

reversing transformer  $T1$  usually consists of a bifilar winding on a ferrite core. Voltages  $V_a$  and  $V_b$  have equal magnitude but  $180^\circ$  phase difference. When  $C1 = C_p$ , the effect of  $C_p$  will disappear and a well-behaved single resonance will occur as shown in Fig 16.33B. The band-pass filter will exhibit a loaded  $Q$  given by:

$$Q_L = \frac{2\pi f_s L_s}{R_L} \quad (20)$$

This single-stage "crystal filter," oper-

ating at 455 kHz, was present in almost all high-quality amateur communications receivers up through the 1960s. When the filter was switched into the receiver IF amplifier the bandwidth was reduced to a few hundred Hz for Morse code reception.

The half-lattice filter shown in **Fig 16.34** is an improvement in crystal filter design. The quartz resonator parallel-plate capacitors,  $C_p$ , cancel each other. Remaining series resonant circuits, if prop-

erly offset in frequency, will produce an approximate 2-pole Butterworth or Chebyshev response. Crystals A and B are usually chosen so that the parallel resonant frequency ( $f_p$ ) of one is the same as the series resonant frequency ( $f_s$ ) of the other.

Half-lattice filter sections can be cascaded to produce a composite filter with many poles. Until recently, most vendor-supplied commercial filters were lattice types. Ref 11 discusses the computer de-

sign of half-lattice filters.

Many quartz crystal filters produced today use the ladder network design shown in **Fig 16.35**. In this configuration, all resonators have the same series resonant frequency  $f_s$ . Interresonator coupling is provided by shunt capacitors such as C12 and C23. Refs 12 and 13 provide good ladder filter design information. A test set for evaluating crystal filters is presented in the **Projects** section of this chapter.

## Monolithic Crystal Filters

A monolithic (Greek: one-stone) crystal filter has two sets of electrodes deposited on the same quartz plate, as shown in **Fig 16.36**. This forms two resonators with acoustic (mechanical) coupling between them. If the acoustic coupling is correct, a 2-pole Butterworth or Chebyshev response will be achieved. More than two resonators can be fabricated on the same plate yielding a multipole response. Monolithic crystal filter technology is popular because it produces a low parts count, single-unit filter at lower cost than

a lumped-element equivalent. Monolithic crystal filters are typically manufactured in the range from 5 to 30 MHz for the fundamental mode and up to 90 MHz for the third-overtone mode.  $Q_L$  ranges from 200 to 10,000.

**Fig 16.36—Typical two-pole monolithic crystal filter. This single small ( $1/2$  to  $3/4$ -inch) unit can replace 6 to 12, or more, discrete components.**

# SAW Filters

The resonators in a monolithic crystal filter are coupled together by bulk acoustic waves. These acoustic waves are generated and propagated in the interior of a quartz plate. It is also possible to launch, by an appropriate transducer, acoustic waves which propagate only along the surface of the quartz plate. These are called "surface-acoustic-waves" because they do not appreciably penetrate the interior of the plate.

A surface-acoustic-wave (SAW) filter consists of thin aluminum electrodes, or fingers, deposited on the surface of a piezoelectric substrate as shown in Fig 16.37. Lithium Niobate ( $\text{LiNbO}_3$ ) is usually favored over quartz because it yields less insertion loss. The electrodes

make up the filter's transducers. RF voltage is applied to the input transducer and generates electric fields between the fingers. The piezoelectric material vibrates launching an acoustic wave along the surface. When the wave reaches the output transducer it produces an electric field between the fingers. This field generates a voltage across the load resistor.

Since both input and output transducers are not entirely unidirectional, some acoustic power is lost in the acoustic absorbers located behind each transducer. This lost acoustic power produces a midband electrical insertion loss typically greater than 10 dB. The SAW filter frequency response is determined by the choice of substrate material and finger

pattern. The finger spacing, (usually one-quarter wavelength) determines the filter center frequency. Center frequencies are available from 20 to 1000 MHz. The number and length of fingers determines the filter loaded Q and shape factor.

Loaded Qs are available from 2 to 100, with a shape factor of 1.5 (equivalent to a dozen poles). Thus the SAW filter can be made broadband much like the LC filters that it replaces. The advantage is substantially reduced volume and possibly lower cost. SAW filter research was driven by military needs for exotic amplitude-response and time-delay requirements. Low-cost SAW filters are presently found in television IF amplifiers where high midband loss can be tolerated.

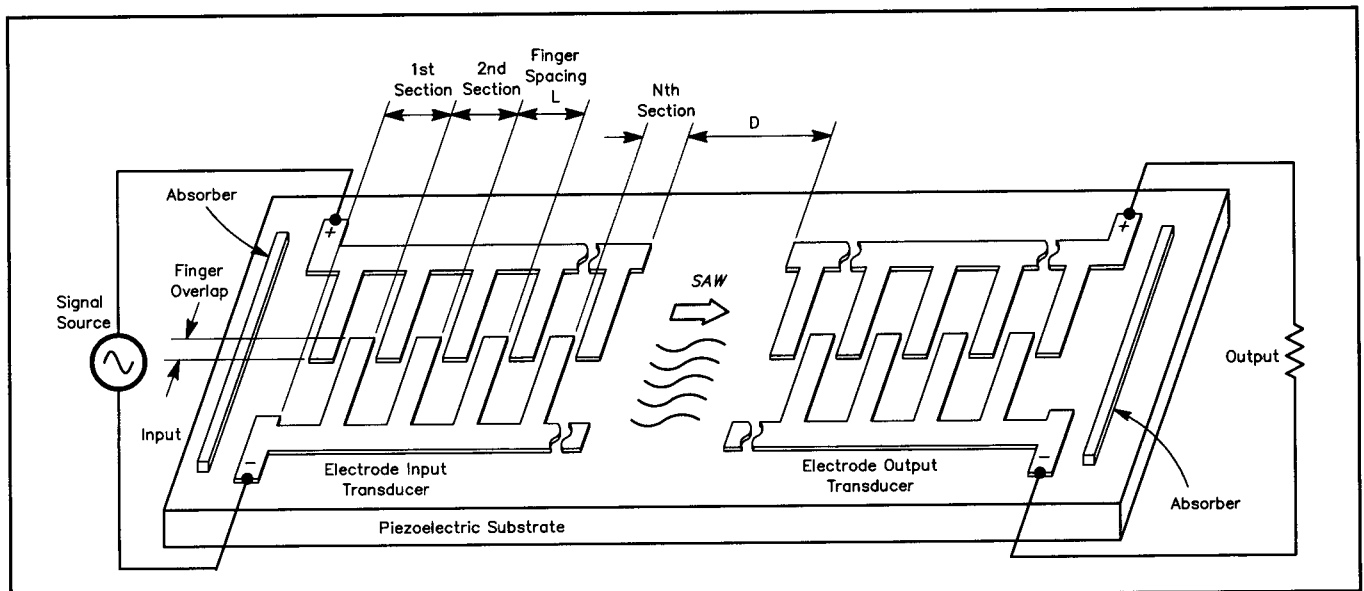

Fig 16.37—The *interdigitated* transducer, on the left, launches SAW energy to a similar transducer on the right (see text).

# Transmission-Line Filters

LC filter calculations are based on the assumption that the reactances are *lumped*—the physical dimensions of the components are considerably less than the operating wavelength. Therefore the unavoidable interturn capacitance associated with inductors and the unavoidable series inductance associated with capacitors are neglected as secondary effects. If careful attention is paid to circuit layout and miniature components are used, lumped LC filter technology can be used up to perhaps 1 GHz.

Transmission-line filters predominate from 500 MHz to 10 GHz. In addition they are often used down to 50 MHz when narrowband ( $Q_L > 10$ ) band-pass filtering is required. In this application they exhibit considerably less loss than their LC counterparts.

Replacing lumped reactances with selected short sections of TEM transmission lines results in transmission-line filters. In TEM, or *Transverse Electromagnetic Mode*, the electric and magnetic fields associated with a transmission line are at right angles (transverse) to the direction of wave propagation. Coaxial cable, stripline and microstrip are examples of TEM components. Waveguides and waveguide resonators are not TEM components.

## Transmission Lines for Filters

Fig 16.38 shows three popular transmission lines used in transmission-line filters. The circular coaxial transmission line (coax) shown in Fig 16.38A consists of two concentric metal cylinders separated by dielectric (insulating) material. Coaxial transmission line possesses a characteristic impedance given by:

$$Z_0 = \frac{138}{\sqrt{\epsilon}} \log \left( \frac{D}{d} \right) \quad (21)$$

A plot of  $Z_0$  vs  $D/d$  is shown in

Fig 16.39. At RF,  $Z_0$  is an almost pure resistance. If the distant end of a section of coax is terminated in  $Z_0$ , then the impedance seen looking into the input end is also  $Z_0$  at all frequencies. A terminated section of coax is shown in Fig 16.40A. If the distant end is not terminated in  $Z_0$ , the input impedance will be some other value. In Fig 16.40B the distant end is short circuited and the length is less than  $1/4 \lambda$ . The input impedance is an inductive reactance as seen by the notation  $+j$  in the equation in part B of the figure.

$X_L$  vs  $\ell$  for the short-circuit case is tabulated in Fig 16.41. A length of  $1/4 \lambda$  as propagating in the coax is denoted  $\lambda_g$ .

The input impedance for the case of the open-circuit distant end, is shown in Fig 16.40C. This case results in a capacitive reactance ( $-j$ ). Thus, short sections of coaxial line (stubs) can replace the inductors and capacitors in an LC filter. Coax line inductive stubs usually have lower loss than their lumped counterparts.

There is an optimum value of  $Z_0$  that yields lowest loss, given by

Fig 16.38—Transmission lines.  
A: Coaxial line. B: Coupled stripline, which has two ground planes.  
C: Microstripline, which has only one ground plane.

Fig 16.39—Coaxial-line impedance varies with the ratio of the inner- and outer-conductor diameters. The dielectric constant,  $\epsilon$ , is 1.0 for air and 2.32 for polyethylene.

**Fig 16.40—Transmission line stubs.**  
**A:** A line terminated in its characteristic impedance. **B:** A shorted line less than  $\frac{1}{4}\lambda$  long is an *inductive* stub. **C:** An open line less than  $\frac{1}{4}\lambda$  long is a *capacitive* stub.

	Shorted Stub	Open Stub
$\frac{\ell}{\lambda_g}$	$X_L$ $\Omega$	$X_C$ $\Omega$
0	0	$\infty$
0.05	16.2	154
0.10	36.3	68.8
0.125	50	50
0.15	68.8	36.3
0.20	154	16.2
0.25	$\infty$	0

**Fig 16.41—Stub reactance for various lengths of transmission line. Values are for  $Z_0 = 50 \Omega$ . For  $Z_0 = 100 \Omega$ , double the tabulated values.**

$$Z_0 = \frac{75}{\sqrt{\epsilon}} \quad (22)$$

If the dielectric is air,  $Z_0 = 75 \Omega$ . If the dielectric is polyethylene ( $\epsilon = 2.32$ )  $Z_0 = 50 \Omega$ . This is the reason why polyethylene dielectric flexible coaxial cable is usually manufactured with a 50- $\Omega$  characteristic impedance.

The first transmission-line filters were built from sections of coaxial line. Their mechanical fabrication is expensive and it

**Fig 16.42—The  $Z_0$  of stripline varies with  $w$ ,  $b$  and  $t$  (conductor thickness). See Fig 16.38B. The conductor thickness is  $t$  and the plots are normalized in terms of  $t/b$ .**

is difficult to provide electrical coupling between line sections. Fabrication difficulties are reduced by the use of shielded strip transmission line (stripline) shown in Fig 16.38B. The outer conductor of stripline consists of two flat parallel metal plates (ground planes) and the inner conductor is a thin metal strip. Sometimes the inner conductor is a round metal rod. The dielectric between ground planes and strip can be air or a low-loss plastic such as polyethylene. The outer conductors (ground planes or shields) are separated from each other by distance  $b$ .

Striplines can be easily coupled together by locating the strips near each other as shown in Fig 16.38B. Stripline  $Z_0$  vs width ( $w$ ) is plotted in Fig 16.42. Air-dielectric stripline technology is best for low bandwidth ( $Q_L > 20$ ) band-pass filters.

The most popular transmission line is microstrip (unshielded stripline), shown in Fig 16.38C. It can be fabricated with standard printed-circuit processes and is the least expensive configuration. Unfortunately, microstrip is the most lossy of the three lines, therefore it is not suitable for narrow band-pass filters. In microstrip the outer conductor is a single flat metal ground-plane. The inner conductor is a thin metal strip separated from the ground-plane by a solid dielectric substrate. Typical substrates are 0.062-inch G-10 fiber-

glass ( $\epsilon = 4.5$ ) for the 50 MHz to 1-GHz frequency range and 0.031-inch Teflon ( $\epsilon = 2.3$ ) for frequencies above 1 GHz.

Conductor separation must be minimized or free-space radiation and unwanted coupling to adjacent circuits may become problems. Microstrip characteristic impedance and the effective dielectric constant ( $\epsilon_e$ ) are shown in Fig 16.43. Unlike coax and stripline, the effective dielectric constant is less than that of the substrate since a portion of the electromagnetic wave propagating along the microstrip "sees" the air above the substrate.

$Z_0 \Omega$	$\epsilon=1$ (AIR) $w/h$	$\epsilon=2.3$ (RT/Duroid)		$\epsilon=4.5$ (G-10)	
		$w/h$	$\sqrt{\epsilon_e}$	$w/h$	$\sqrt{\epsilon_e}$
25	12.5	7.6	1.4	4.9	2.0
50	5.0	3.1	1.36	1.8	1.85
75	2.7	1.6	1.35	0.78	1.8
100	1.7	0.84	1.35	0.39	1.75
	$\sqrt{\epsilon}=1$				

**Fig 16.43—Microstrip parameters (after H. Wheeler, *IEEE Transactions on MTT*, March 1965, p 132).**

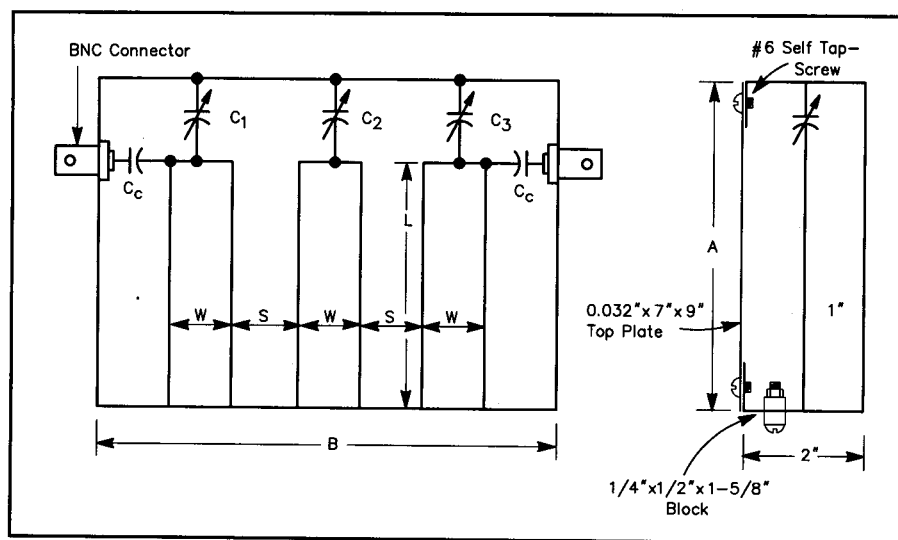

**Fig 16.44**—This 146-MHz stripline band-pass filter has been measured to have a  $Q_L$  of 63 and a loss of approximately 1 dB.

The least-loss characteristic impedance for stripline and microstrip-lines is not  $75 \Omega$  as it is for coax. Loss decreases as line width increases, which leads to clumsy, large structures. Therefore, to conserve space, filter sections are often constructed from  $50\text{-}\Omega$  stripline or microstrip stubs.

### Transmission-Line Band-Pass Filters

Band-pass filters can also be constructed from transmission-line stubs. At VHF the stubs can be considerably shorter than a quarter wavelength yielding a compact filter structure with less midband loss than its LC counterpart. The single-stage 146-MHz stripline band-pass filter shown in **Fig 16.44** is an example. This filter consists of a single inductive  $50\text{-}\Omega$  stripline stub mounted into a  $2 \times 5 \times 7$ -inch aluminum box. The stub is resonated at 146 MHz with the “APC” variable capacitor,

**Fig 16.45**—This Butterworth filter is constructed in combine. It was originally discussed by R. Fisher in December 1968 *QST*.

Dimension	52 MHz	146 MHz	222 MHz
A	9"	7"	7"
B	7"	9"	9"
L	$7\frac{3}{8}$ "	6"	6"
S	1"	$1\frac{1}{16}$ "	$1\frac{3}{8}$ "
W	1"	$1\frac{5}{8}$ "	$1\frac{5}{8}$ "

### Capacitance (pF)

C1	110	22	12
C2	135	30	15
C3	110	22	12
$C_c$	35	6.5	2.8
$Q_L$	10	29	36

### Performance

BW3 (MHz)	5.0	5.0	6.0
Loss (dB)	0.6	0.7	—

C1. Coupling to the  $50\text{-}\Omega$  generator and load is provided by the coupling capacitors  $C_c$ . The measured performance of this filter is:  $f_0 = 146 \text{ MHz}$ ,  $BW = 2.3 \text{ MHz}$  ( $Q_L = 63$ ) and midband loss = 1 dB.

Single-stage stripline filters can be coupled together to yield multistage filters. One method uses the capacitor coupled band-pass filter synthesis technique to design a 3-pole filter. Another method allows closely spaced inductive stubs to magnetically couple to each other. When the coupled stubs are grounded on the same side of the filter housing, the structure is called a “combine filter.” Three examples of combine band-pass filters are shown in **Fig 16.45**. These filters are constructed in  $2 \times 7 \times 9$ -inch chassis boxes.

### Quarter-Wave Transmission-Line Filters

**Fig 16.41** shows that when  $\ell = 0.25 \lambda_g$ , the shorted-stub reactance becomes infi-

nite. Thus, a  $\frac{1}{4}\lambda$  shorted stub behaves like a parallel-resonant LC circuit. Proper input and output coupling to a  $\frac{1}{4}\lambda$  resonator yields a practical band-pass filter. Closely spaced  $\frac{1}{4}\lambda$  resonators will couple together to form a multistage band-pass filter. When the resonators are grounded on opposite walls of the filter housing, the structure is called an “interdigital filter” because the resonators look like interlaced fingers. Two examples of 3-pole UHF interdigital filters are shown in **Fig 16.46**. Design graphs for round-rod interdigital filters are given in Ref 16. The  $\frac{1}{4}\lambda$  resonators may be tuned by physically changing their lengths or by tuning the screw opposite each rod.

If the short-circuited ends of two  $\frac{1}{4}\lambda$  resonators are connected to each other, the resulting  $\frac{1}{2}\lambda$  stub will remain in resonance, even when the connection to ground-plane is removed. Such a floating  $\frac{1}{2}\lambda$  microstrip line, when bent into a

U-shape, is called a "hairpin" resonator. Closely coupled hairpin resonators can be arranged to form multistage band-pass filters. Microstrip hairpin band-pass filters are popular above 1 GHz because they can be easily fabricated using photo-etching techniques. No connection to the ground-plane is required.

### Transmission-Line Filters Emulating LC Filters

Low-pass and high-pass transmission-line filters are usually built from short sections of transmission lines (stubs) that emulate lumped LC reactances. Sometimes low-loss lumped capacitors are mixed with transmission-line inductors to form a hybrid component filter. For example, consider the 720-MHz 3-pole microstrip low-pass filter shown in Fig 16.47A that emulates the LC filter shown in Fig 16.47B. C1 and C3 are replaced with 50- $\Omega$  open-circuit shunt stubs  $\ell_C$  long. L2 is replaced with a short section of 100- $\Omega$  line  $\ell_L$  long. The LC filter, Fig 16.47B, was designed for  $f_c = 720$  MHz. Such a filter could be connected between a 432-MHz transmitter and antenna to reduce harmonic and spurious emissions. A reactance chart shows that  $X_C$  is 50  $\Omega$ , and the inductor reactance is 100  $\Omega$  at  $f_c$ . The microstrip version is constructed on G-10 fiberglass 0.062-inch thick, with  $\epsilon = 4.5$ . Then, from Fig 16.43,  $w$  is 0.11 inch and  $\ell_C = 0.25 \lambda_g$  for the 50- $\Omega$  capacitive stubs. Also, from Fig 16.43,  $w$  is 0.024 inch and  $\ell_L$  is  $0.25 \lambda_g$  for the 100- $\Omega$  inductive line. The inductive line length is approximate because the far end is not a short circuit.  $\lambda_g$  is  $300/(720)(1.75) = 0.238$  m, or 9.37 inches. Thus  $\ell_C$  is 1.1 inch and  $\ell_L$  is 1.1 inch.

**Fig 16.46—**These 3-pole Butterworth filters (upper: 432 MHz, 8.6 MHz bandwidth, 1.4 dB pass-band loss; lower: 1296 MHz, 110 MHz bandwidth, 0.4 dB pass-band loss) are constructed as interdigitated filters. The material is from R. E. Fisher, March 1968 QST.

**Fig 16.47—A microstrip 3-pole Butterworth low-pass filter with a cutoff frequency of 720 MHz.**  
**A:** Microstrip version built with G-10 fiberglass board ( $\epsilon = 4.5$ ,  $h = 0.062$  inches). **B:** Lumped LC version of the same filter. To construct this filter with lumped elements very small values of  $L$  and  $C$  must be used and stray capacitance and inductance reduced to a tiny fraction of the component values.

## Helical Resonators

Ever-increasing occupancy of the radio spectrum brings with it a parade of receiver overload and spurious responses. Overload problems can be minimized by using high-dynamic-range receiving techniques, but spurious responses (such as the image frequency) must be filtered out before mixing occurs. Conventional tuned circuits cannot provide the selectivity necessary to eliminate the plethora of signals found in most urban and many suburban neighborhoods. Other filtering techniques must be used.

Helical resonators are usually a better choice than  $1/4\lambda$  cavities on 50, 144 and 222 MHz to eliminate these unwanted inputs. They are smaller and easier to build. In the frequency range from 30 to 100 MHz it is difficult to build high- $Q$  inductors and coaxial cavities are very large. In this frequency range the helical resonator is an excellent choice. At 50 MHz for example, a capacitively tuned,  $1/4\lambda$  coaxial

cavity with an unloaded  $Q$  of 3000 would be about 4 inches in diameter and nearly 5 ft long. On the other hand, a helical resonator with the same unloaded  $Q$  is about 8.5 inches in diameter and 11.3 inches long. Even at 432 MHz, where coaxial cavities are common, the use of helical resonators results in substantial size reductions.

The helical resonator was described by W1HR in a *QST* article as a coil surrounded by a shield, but it is actually a shielded, resonant section of helically wound transmission line with relatively high characteristic impedance and low axial propagation velocity. The electrical length is about 94% of an axial  $1/4\lambda$  or  $84.6^\circ$ . One lead of the helical winding is connected directly to the shield and the other end is open circuited as shown in **Fig 16.48**. Although the shield may be any shape, only round and square shields will be considered here.

### Design

The unloaded  $Q$  of a helical resonator is determined primarily by the size of the shield. For a round resonator with a copper coil on a low-loss form, mounted in a copper shield, the unloaded  $Q$  is given by

$$Q_U = 50D\sqrt{f_0} \quad (23)$$

where

$D$  = inside diameter of the shield, in inches

$f_0$  = frequency, in MHz.

$D$  is assumed to be 1.2 times the width of one side for square shield cans. This formula includes the effects of losses and imperfections in practical materials. It yields values of unloaded  $Q$  that are easily attained in practice. Silver plating the shield and coil increases the unloaded  $Q$  by about 3% over that predicted by the equation. At VHF and UHF, however, it is

**Fig 16.48—Dimensions of round and square helical resonators. The diameter, D (or side, S) is determined by the desired unloaded Q. Other dimensions are expressed in terms of D or S (see text).**

more practical to increase the shield size slightly (that is, increase the selected  $Q_U$  by about 3% before making the calculation). The fringing capacitance at the open-circuit end of the helix is about 0.15 D pF (that is, approximately 0.3 pF for a shield 2 inches in diameter). Once the required shield size has been determined, the total number of turns, N, winding pitch, P and characteristic impedance,  $Z_0$ ,

for round and square helical resonators with air dielectric between the helix and shield, are given by:

$$N = \frac{1908}{f_0 D} \quad (24A)$$

$$P = \frac{f_0 D^2}{2312} \quad (24B)$$

$$Z_0 = \frac{99,000}{f_0 D} \quad (24C)$$

$$N = \frac{1590}{f_0 S} \quad (24D)$$

$$P = \frac{f_0 S^2}{1606} \quad (24E)$$

$$Z_0 = \frac{82,500}{f_0 S} \quad (24F)$$

In these equations, dimensions D and S are in inches and  $f_0$  is in megahertz. The design nomograph for round helical resonators in Fig 16.49 is based on these formulas.

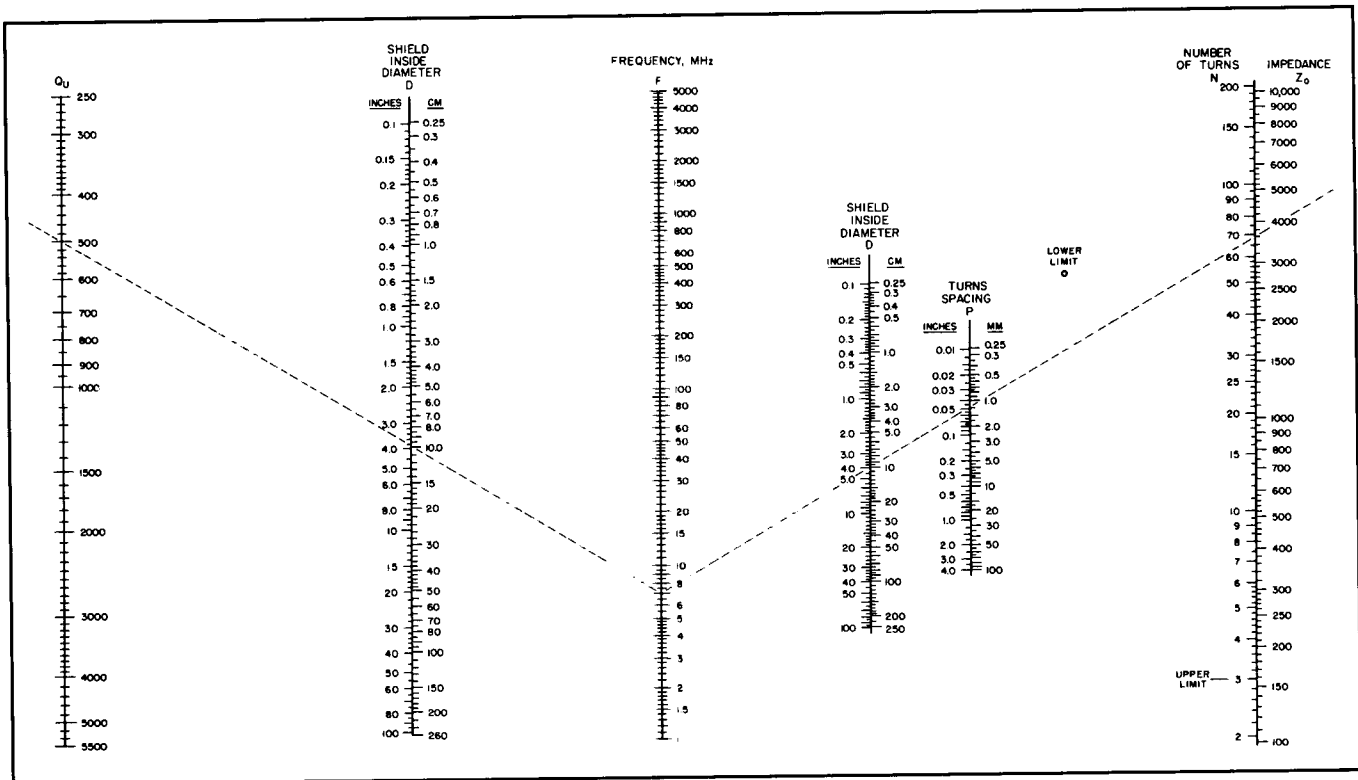

Although there are many variables to consider when designing helical resonators, certain ratios of shield size to length and coil diameter to length, provide optimum results. For helix diameter,  $d = 0.55$

D or  $d = 0.66 S$ . For helix length,  $b = 0.825D$  or  $b = 0.99S$ . For shield length,  $B = 1.325 D$  and  $H = 1.60 S$ .

**Fig 16.50** simplifies calculation of these dimensions. Note that these ratios result in a helix with a length 1.5 times its diameter, the condition for maximum Q. The shield is about 60% longer than the helix—although it can be made longer—to completely contain the electric field at the top of the helix and the magnetic field at the bottom.

The winding pitch, P, is used primarily to determine the required conductor size. Adjust the length of the coil to that given by the equations during construction. Conductor size ranges from 0.4 P to 0.6 P for both round and square resonators and are plotted graphically in Fig 16.51.

Obviously, an area exists (in terms of frequency and unloaded Q) where the designer must make a choice between a conventional cavity (or lumped LC circuit) and a helical resonator. The choice is affected by physical shape at higher frequencies. Cavities are long and relatively small in diameter, while the length of a helical resonator is not much greater than its diameter. A second consideration is that point where the winding pitch, P, is less than the radius of the helix (otherwise the

**Fig 16.49—The design nomograph for round helical resonators starts by selecting  $Q_U$  and the required shield diameter. A line is drawn connecting these two values and extended to the frequency scale (example here is for a shield of about 3.8 inches and  $Q_U$  of 500 at 7 MHz). Finally the number of turns, N, winding pitch, P, and characteristic impedance,  $Z_0$ , are determined by drawing a line from the frequency scale through selected shield diameter (but this time to the scale on the right-hand side. For the example shown, the dashed line shows  $P \approx 0.047$  inch,  $N = 70$  turns, and  $Z_n = 3600 \Omega$ ).**

**Fig 16.50**—The helical resonator is scaled from this design nomograph. Starting with the shield diameter, the helix diameter,  $d$ , helix length,  $b$ , and shield length,  $B$ , can be determined with this graph. The example shown has a shield diameter of 3.8 inches. This requires a helix mean diameter of 2.1 inches, helix length of 3.1 inches, and shield length of 5 inches.

**Fig 16.51**—This chart provides the design information of helix conductor size vs winding pitch,  $P$ . For example, a winding pitch of 0.047 inch results in a conductor diameter between 0.019 and 0.028 inch (#22 or #24 AWG).

structure tends to be nonhelical). This condition occurs when the helix has fewer than three turns (the "upper limit" on the design nomograph of Fig 16.49).

### Construction

The shield should not have any seams parallel to the helix axis to obtain as high an unloaded  $Q$  as possible. This is usually not a problem with round resonators because large-diameter copper tubing is used for the shield, but square resonators require at least one seam and usually more. The effect on unloaded  $Q$  is minimum if the seam is silver soldered carefully from one end to the other.

Results are best when little or no dielectric is used inside the shield. This is usually no problem at VHF and UHF because the conductors are large enough that a supporting coil form is not required. The lower end of the helix should be soldered to the nearest point on the inside of the shield.

Although the external field is minimized by the use of top and bottom shield covers, the top and bottom of the shield may be left open with negligible effect on frequency or unloaded  $Q$ . Covers, if provided, should make electrical contact with the shield. In those resonators where the helix is connected to the bottom cover, that cover must be soldered solidly to the shield to minimize losses.

### Tuning

A carefully built helical resonator designed from the nomograph of Fig 16.49 will resonate very close to the design frequency. Slightly compress or expand the helix to adjust resonance over a small range. If the helix is made slightly longer than that called for in Fig 16.50, the resonator can be tuned by pruning the open end of the coil. However, neither of these methods is recommended for wide frequency excursions because any major deviation in helix length will degrade the unloaded  $Q$  of the resonator.

Most helical resonators are tuned by means of a brass tuning screw or high-quality air-variable capacitor across the open end of the helix. Piston capacitors also work well, but the  $Q$  of the tuning capacitor should ideally be several times the unloaded  $Q$  of the resonator. Varactor diodes have sometimes been used where remote tuning is required, but varactors can generate unwanted harmonics and other spurious signals if they are excited by strong, nearby signals.

When a helical resonator is to be tuned by a variable capacitor, the shield size is based on the chosen unloaded  $Q$  at the operating frequency. Then the number of turns,  $N$  and the winding pitch,  $P$ , are based on resonance at  $1.5 f_0$ . Tune the resonator to the desired operating frequency,  $f_0$ .

### Insertion Loss

The insertion loss (dissipation loss),  $I_L$ , in decibels, of all single-resonator circuits is given by

$$I_L = 20 \log_{10} \left( \frac{1}{1 - \frac{Q_L}{Q_U}} \right) \quad (25)$$

where

$Q_L$  = loaded  $Q$

$Q_U$  = unloaded  $Q$

This is plotted in Fig 16.52. For the most

practical cases ( $Q_L > 5$ ), this can be closely approximated by  $I_L \approx 9.0 (Q_L/Q_U)$  dB. The selection of  $Q_L$  for a tuned circuit is dictated primarily by the required selectivity of the circuit. However, to keep dissipation loss to 0.5 dB or less (as is the case for low-noise VHF receivers), the unloaded  $Q$  must be at least 18 times the  $Q_L$ .

### Coupling

Signals are coupled into and out of helical resonators with inductive loops at the bottom of the helix, direct taps on the coil or a combination of both. Although the correct tap point can be calculated easily, coupling by loops and probes must be determined experimentally.

The input and output coupling is often provided by probes when only one resonator is used. The probes are positioned on opposite sides of the resonator for maximum isolation. When coupling loops are used, the plane of the loop should be perpendicular to the axis of the helix and separated a small distance from the bottom of the coil. For resonators with only a few turns, the plane of the loop can be tilted slightly so it is parallel with the slope of the adjacent conductor.

Helical resonators with inductive coupling (loops) exhibit more attenuation to signals above the resonant frequency (as compared to attenuation below resonance), whereas resonators with capacitive coupling (probes) exhibit more attenuation below the passband, as shown for a typical 432-MHz resonator in Fig 16.53. Consider this characteristic when choosing a coupling method. The passband can be made more symmetrical by using a combination of coupling methods (inductive input and capacitive output, for example).

If more than one helical resonator is required to obtain a desired band-pass characteristic, adjacent resonators may be coupled through apertures in the shield

**Fig 16.52**—The ratio of loaded ( $Q_L$ ) to unloaded ( $Q_U$ )  $Q$  determines the insertion loss of a tuned resonant circuit.

**Fig 16.53—This response curve for a single-resonator 432-MHz filter shows the effects of capacitive and inductive input/output coupling. The response curve can be made symmetrical on each side of resonance by combining the two methods (inductive input and capacitive output, or vice versa).**

wall between the two resonators. Unfortunately, the size and location of the aperture must be found empirically, so this method of coupling is not very practical unless you're building a large number of identical units.

Since the loaded  $Q$  of a resonator is determined by the external loading, this must be considered when selecting a tap (or position of a loop or probe). The ratio of this external loading,  $R_b$ , to the characteristic impedance,  $Z_0$ , for a  $1/4$ - $\lambda$  resonator is calculated from:

$$K = \frac{R_b}{Z_0} = 0.785 \left( \frac{1}{Q_L} - \frac{1}{Q_U} \right) \quad (26)$$

Even when filters are designed and built properly, they may be rendered totally ineffective if not installed properly. Leakage around a filter can be quite high at VHF and UHF, where wave-

lengths are short. Proper attention to shielding and good grounding is mandatory for minimum leakage. Poor coaxial cable shield connection into and out of the filter is one of the greatest offenders with regard to filter leakage. Proper dc-lead bypassing throughout the receiving system is good practice, especially at VHF and above. Ferrite beads placed over the dc leads may help to reduce leakage. Proper filter termination is required to minimize loss.

Most VHF RF amplifiers optimized for noise figure do not have a 50- $\Omega$  input impedance. As a result, any filter attached to the input of an RF amplifier optimized for noise figure will not be properly terminated and filter loss may rise substantially. As this loss is directly added to the RF amplifier noise figure, carefully choose and place filters in the receiver.

## Active Filters

(A)

### LOW-PASS FILTER

$$C_1 \leq \frac{[a^2 + 4b(K-1)]C_2}{4b}$$

$$R_1 = \frac{2}{[aC_2 + \sqrt{[a^2 + 4b(K-1)]C_2^2 - 4bC_1C_2}] \omega_c}$$

$$R_2 = \frac{1}{bC_1C_2R_1\omega_c^2}$$

$$R_3 = \frac{K(R_1 + R_2)}{K-1} \quad (K > 1)$$

$$R_4 = K(R_1 + R_2)$$

where

$K$  = gain

$f_c$  = -3 dB cutoff point

$\omega_c = 2\pi f_c$

$a = 0.765367$  (see table)

$b = 1$

$C_2$  = a standard value near  $10/f_c \mu F$

Note: For unity gain, short  $R_4$  and omit  $R_3$ .

Example:

$K = 2$

$f = 4000$  Hz

$\omega_c = 25,132.74$

$C_2 \approx 0.0025 \mu F$

$C_1 \leq 0.003 \mu F$

$R_1 = 19,254 \Omega$  (use 20 k $\Omega$ )

$R_2 = 11,278 \Omega$  (use 11 k $\Omega$ )

$R_3 = 61,066 \Omega$  (use 62 k $\Omega$ )

$R_4 = 61,066 \Omega$  (use 62 k $\Omega$ )

(B)

### HIGH-PASS FILTER

$$R_1 = \frac{4b}{[a + \sqrt{a^2 + 8b(K-1)}] \omega_c C}$$

$$R_2 = \frac{b}{\omega_c^2 C^2 R_1}$$

$$R_3 = \frac{KR_1}{K-1} \quad (K > 1)$$

$$R_4 = KR_1$$

where

$K$  = gain

$f_c$  = -3 dB cutoff point

$\omega_c = 2\pi f_c$

$a = 0.765367$  (see table)

$b = 1$

$C$  = a standard value near  $10/f_c \mu F$

Note: For unity gain, short  $R_4$  and omit  $R_3$ .

Example:

$K = 4$

$f = 250$  Hz

$\omega_c = 1570.8$

$C \approx 0.04 \mu F$  (use 0.039  $\mu F$ )

$R_1 = 11,407 \Omega$  (use 11 k $\Omega$ )

$R_2 = 23,358 \Omega$  (use 24 k $\Omega$ )

$R_3 = 15,210 \Omega$  (use 15 k $\Omega$ )

$R_4 = 45,630 \Omega$  (use 47 k $\Omega$ )

(C)

### BAND-PASS FILTER

Pick  $K$ ,  $Q$ ,  $\omega_0 = 2\pi f_c$   
where  $f_c$  = center freq.  
Choose  $C$

$$\text{Then } R_1 = \frac{Q}{K_0 \omega_0 C}$$

$$R_2 = \frac{Q}{(2Q^2 - K_0) \omega_0 C}$$

$$R_3 = \frac{2Q}{\omega_0 C}$$

Example:

$K = 2$ ,  $f_0 = 800$  Hz,  $Q = 5$  and

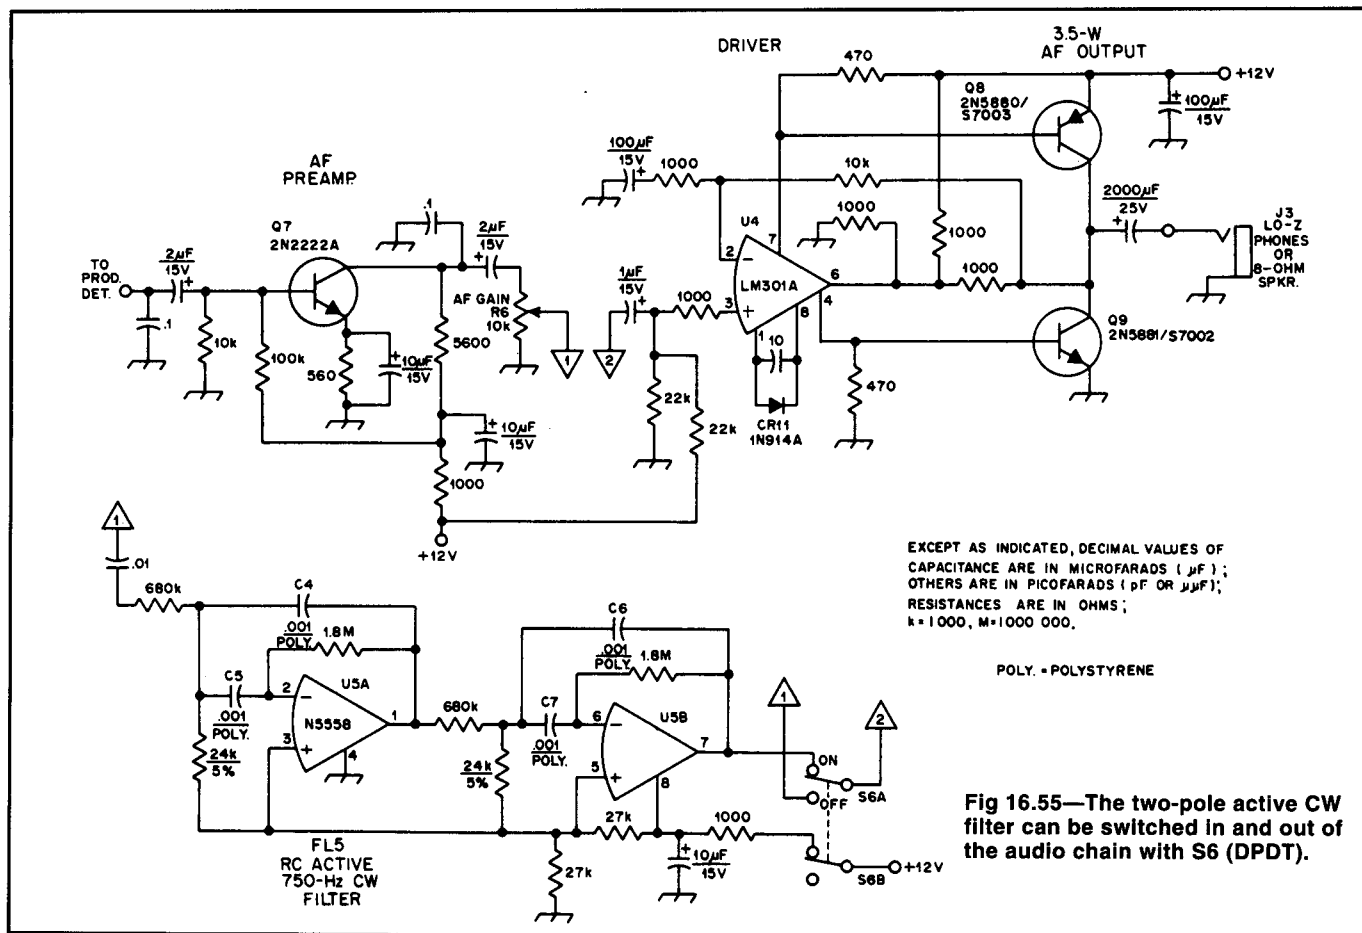

$C = 0.022 \mu F$

$R_1 = 22.6$  k $\Omega$  (use 22 k $\Omega$ )

$R_2 = 942 \Omega$  (use 1000  $\Omega$ )

$R_3 = 90.4$  k $\Omega$  (use 91 k $\Omega$  or 100 k $\Omega$ )

**Fig 16.54—Equations for designing a low-pass RC active audio filter are given at A. B, C and D show design information for high-pass, band-pass and band-reject filters, respectively. All of these filters will exhibit a Butterworth response.**

#### BAND-REJECT FILTER

$$f_o = \frac{1}{2\pi R_1 C_2}$$

where

$$R_2 = R_3 = \frac{R_1}{2}$$

$$C_1 = 2C_2$$

$$C_2 = C_3$$

Example:

$$f_o = 500\ \text{Hz}$$

$$R_1 = 150\ \text{k}\Omega$$

Then

$$R_2 = R_3 = 75\ \text{k}\Omega$$

$$C_2 = 2122\ \text{pF} \text{ (choose } 2000\ \text{pF or } 2200\ \text{pF)}$$

$$C_3 = 4244\ \text{pF} \text{ (choose } 4300\ \text{pF)}$$

HF passive filters are constructed with inductors and capacitors. Inductors are often undesirable at low frequency ranges because of their size. Consequently there has been a trend toward replacing inductors with active devices that simulate them. This trend has accelerated with the availability of op amps as the active devices. Advantages include lower cost than filters with inductances and simplified tuning (by adjusting only resistors). Active band-pass filters can be made with variable Q and variable center frequency.

Active filters have a few disadvantages: Upper frequency is limited to a few hundred kilohertz, if low-cost op amps are used. Active filters have a limited dynamic range, which means that the active device

output voltage swing must be less than the dc supply voltage. Strong out-of-band input signals may unknowingly overload the active device and distort the desired signal.

The design equations for various active filters at audio frequencies are given in Fig 16.54. A program (ACTFIL.EXE) to design 1-4 stage filters is on the disk accompanying this book. Fig 16.55 contains the schematic and installation information of a two-pole RC active filter that uses a dual op amp. A typical receiver audio channel is shown with S1 switching the filter into and out of the audio chain. A two-stage cascade filter provides the minimum acceptable performance on CW. Three or four stages would be needed for weak-signal work in heavy QRM or high noise.

#### Factor "a" for Low- and High-Pass Filters

No. of Stages	Stage 1	Stage 2	Stage 3	Stage 4
1	1.413	-	-	-
2	0.7649	1.847	-	-
3	0.5174	1.931	1.414	-
4	0.3901	1.662	1.961	1.111

## Switched Capacitor Filters

The *switched capacitor filter*, or SCF, uses an IC to synthesize a high-pass, low-pass, band-pass or notch filter. The performance of multiple-pole filters is available, with Q and bandwidth set by external resistors. An external clock frequency sets

the filter center frequency, so this frequency may be easily changed or digitally controlled. Dynamic range of 80 dB, Q of 50, 5-pole equivalent design and maximum usable frequency of 250 kHz are available for such uses as audio CW and

**RTTY filters.** In addition, all kinds of digital tone signaling such as DTMF and modem encoding and decoding are being designed with these circuits. An example SCF appears in the Project portion of this chapter.

## CRYSTAL-FILTER EVALUATION

Crystal filters, such as those described earlier in this chapter, are often constructed of surplus crystals or crystals whose characteristics are not exactly known. Randy Henderson, W15W, developed a swept frequency generator for testing these filters. It was first described in March 1994 *QEX*. This test instrument adds to the ease and success in quickly building filters from inexpensive microprocessor crystals.

A package of additional information is available from the ARRL Technical Secretary. Enclose an SASE and request the Crystal Filter Evaluation Project template.

## An Overview

The basic setup is shown in **Fig 16.56A**.

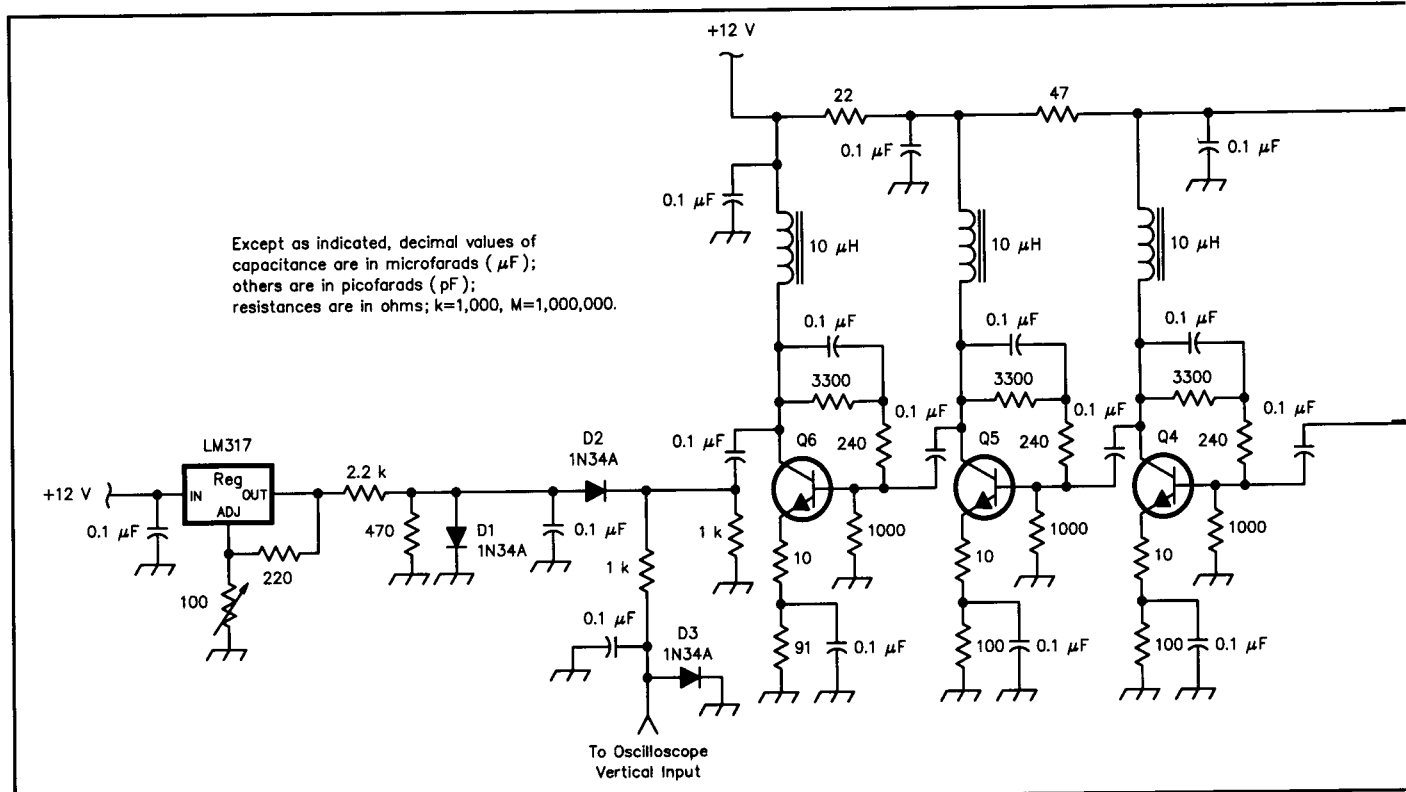

The VCO is primarily a conventional LC-tuned Hartley oscillator with its frequency tuned over a small range by a varactor diode (MV2104 in part B of the figure). Other varactors may be used as long as the capacitance specifications aren't too different. Change the 5-pF coupling capacitor to expand the sweep width if desired.

The VCO signal goes through a buffer amplifier to the filter under test. The filter is followed by a wide-bandwidth amplifier and then a detector. The output of the detector is a rectified and filtered signal. This varying dc voltage drives the vertical input of an oscilloscope. At any particular time, the deflection and sweep circuitry commands the VCO to "run at this frequency." The same deflection voltage causes the oscilloscope beam to deflect

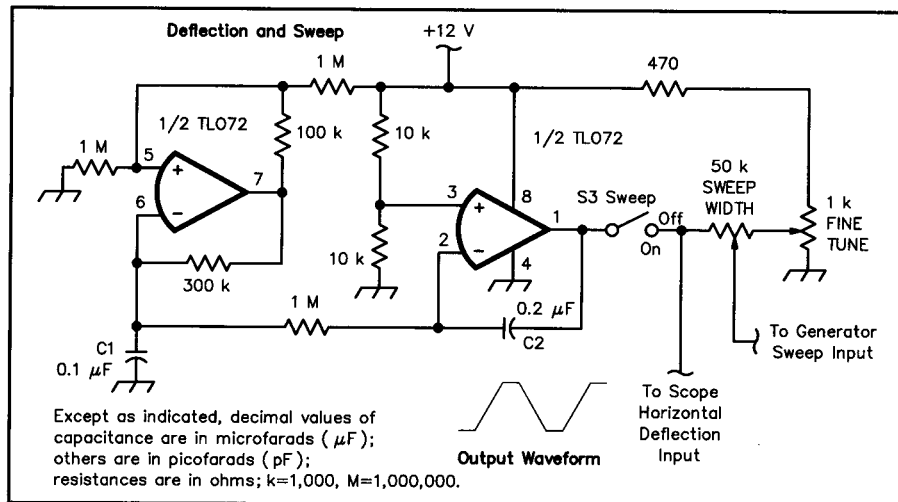

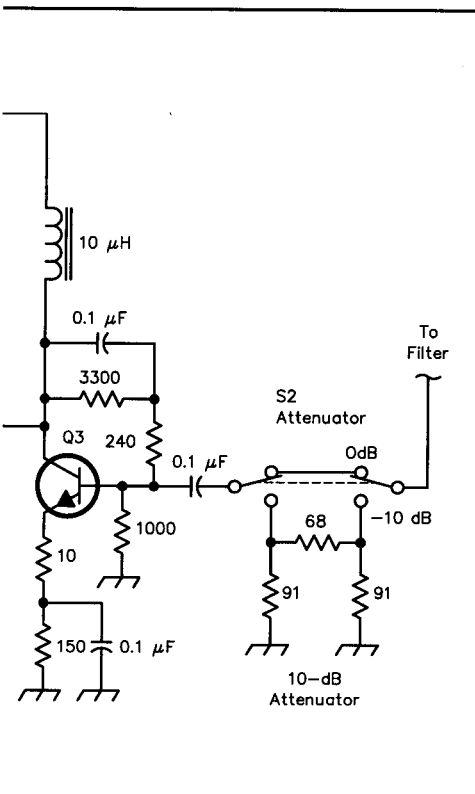

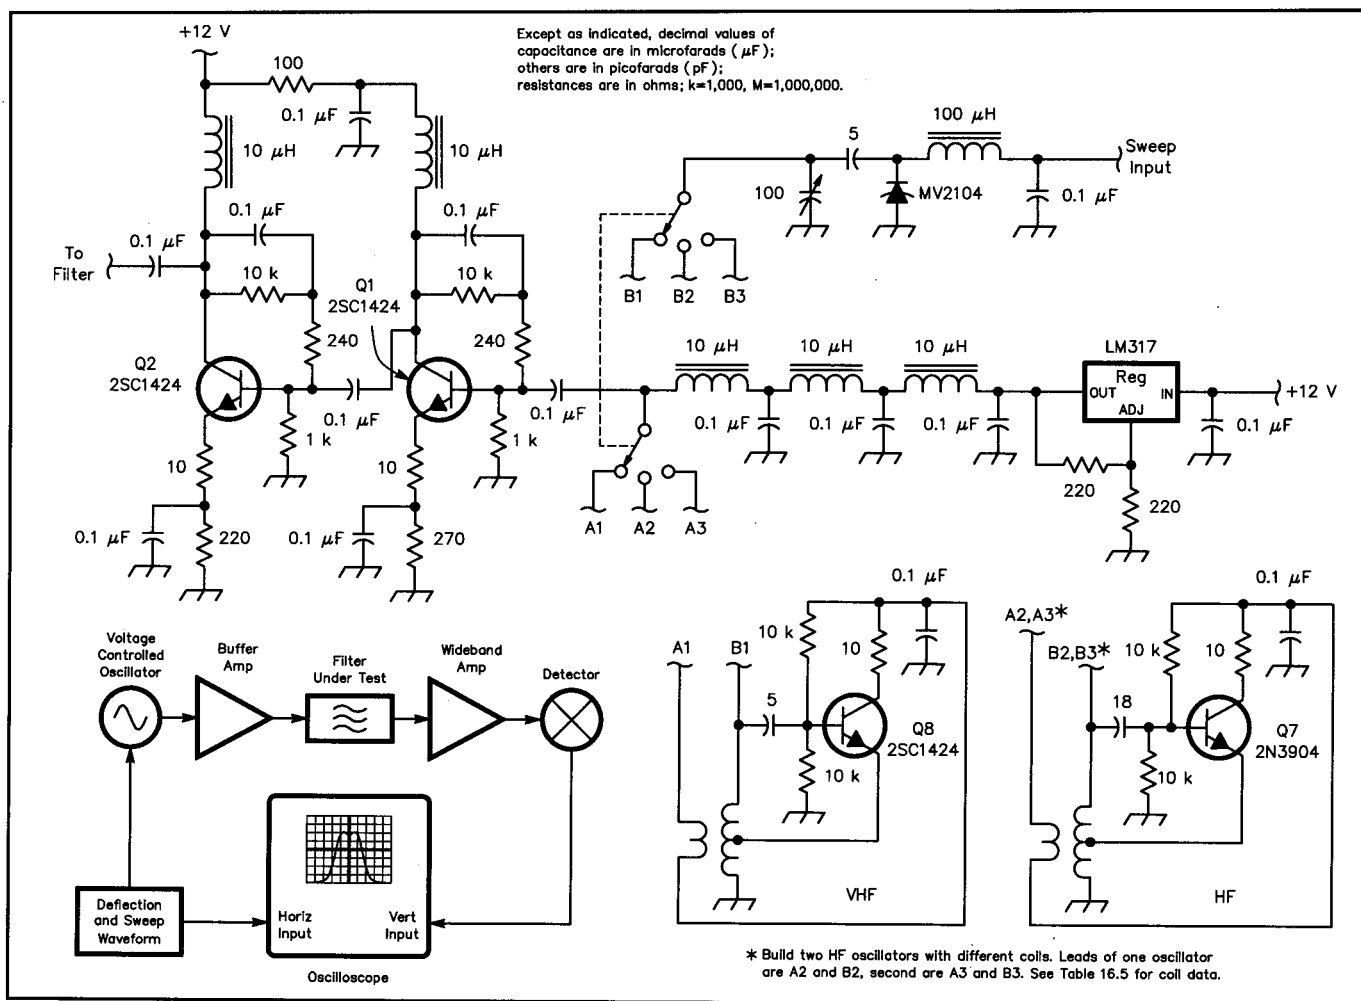

left or right to a position corresponding to the frequency.

Any or all of these circuits may be eliminated by the use of appropriate commercial test equipment. For example, a commercial sweep generator would eliminate the need for everything but the wide-band amplifier and detector. Motorola, Mini-Circuits Labs and many others sell devices suitable for the wide-band amplifiers and detector.

The generator/detector system covers approximately 6 to 74 MHz in three ranges. Each tuning range uses a separate RF oscillator module selected by switch S1. The VCO output and power-supply input are multiplexed on the “A” lead to each oscillator. The tuning capacitance for each VCO is switched into the appropriate

circuit by a second set of contacts on S1.  $C_T$  is the coarse tuning adjustment for each oscillator module.

Two oscillator coils are wound on PVC plastic pipe. The third, for the highest frequency range, is self supporting #14 copper wire. Although PVC forms with Super Glue dope may not be "state of the art" technology, frequency stability is completely adequate for this instrument.

The oscillator and buffer stage operate at low power levels to minimize frequency drift caused by component heating. Crystal filters cause large load changes as the frequency is swept in and out of the passband. These large changes in impedance tend to "pull" the oscillator frequency and cause inaccuracies in the passband shape depicted by the oscilloscope. Therefore a buffer amplifier is a necessity. The wide-band amplifier in **Fig 16.57** is derived from one in ARRL's *Solid State Design for the Radio Amateur*.

S2 selects a 50- $\Omega$  10-dB attenuator in the input line. When the attenuator is in the line, it provides a better output match for the filter under test. The detector uses some forward bias for D2. A simple unbiased diode detector would offer about 50 dB of dynamic range. Some dc bias increases the dynamic range to almost 70 dB. D3, across the detector output (the scope input), increases the vertical-amplifier sensitivity while compressing or limiting the response to high-level signals. With this arrangement, high levels of attenuation (low-level signals) are easier to observe and low attenuation levels are still visible on the CRT. The diode only

**Table 16.5**

**VCO Coils**

Coil	Inside Diameter (inches)	Length (inches)	Turns, Wire	Inductance ( $\mu H$ )
large	0.85	1.1	18 t, #28	5.32
medium	0.85	0.55	7 t, #22	1.35
small	0.5	0.75	5 t, #14	0.27

The two larger coils are wound on  $3/4$ -inch PVC pipe and the smaller one on a  $1/2$ -inch drill bit. Tuning coverage for each oscillator is obtained by squeezing or spreading the turns before gluing them in place. The output windings connected to A1, A2 and A3 are each single turns of #14 wire spaced off the end of the tapped coils.

kicks in to provide limiting at higher signal levels.

The horizontal-deflection sweep circuit uses a dual op-amp IC (see **Fig 16.58**). One section is an oscillator; the other is an integrator. The integrator output changes linearly with time, giving a uniform brightness level as the trace is moved from side to side. Increasing C1 decreases the sweep rate. Increasing C2 decreases the slope of the output waveform ramp.

**Operation**

The CRT is swept in both directions, left to right and right to left. The displayed curve is a result of changes in frequency, not time. Therefore it is unnecessary to incorporate the usual right-to-left, snap-back and retrace blanking used in oscilloscopes.

S3 in Fig 16.58 disables the automatic sweep function when opened. This permits manual operation. Use a frequency counter to measure the VCO output, from which bandwidth can be calculated. Turn

the fine-tune control to position the CRT beam at selected points of the passband curve. The difference in frequency readings is the bandwidth at that particular point or level of attenuation.

Substitution of a calibrated attenuator for the filter under test can provide reference readings. These reference readings may be used to calibrate an otherwise uncalibrated scope vertical display in dB.

The buffer amplifier shown here is set up to drive a 50- $\Omega$  load and the wide-bandwidth amplifier input impedance is about 50  $\Omega$ . If the filter is not a 50- $\Omega$  unit, however, various methods can be used to accommodate the difference.

## BAND-PASS FILTERS FOR 144 OR 222 MHz

Spectral purity is necessary during transmitting. Tight filtering in a receiving system ensures the rejection of out-of-band signals. Unwanted signals that lead to receiver overload and increased intermodulation-distortion (IMD) products result in annoying in-band "birdies." One solution is the double-tuned band-pass filters shown in Fig 16.64. They were designed by Paul Drexler, WB3JYO. Each includes a resonant trap coupled between

the resonators to provide increased rejection of undesired frequencies.

Many popular VHF conversion schemes use a 28-MHz intermediate frequency (IF), yet proper filtering of the image frequency is often overlooked in amateur designs. The low-side injection frequency used in 144-MHz mixing schemes is 116 MHz and the image frequency, 88 MHz, falls in TV channel 6. Inadequate rejection of a broadcast carrier at this frequency results in a strong, wideband signal at the low end of the 2-m band. A similar problem on the transmit side can cause TVI. These band-pass filters have effectively suppressed undesired mixing products. See Fig 16.65 and 16.66.

The circuit is constructed on a double-sided copper-clad circuit board. Minimize

component lead lengths to eliminate resistive losses and unwanted stray coupling. Mount the piston trimmers through the board with the coils soldered to the opposite end, parallel to the board. The shield between L1 and L3 decreases mutual coupling and improves the frequency response. Peak C1 and C3 for optimum response.

L1, C1, L3 and C3 form the tank circuits that resonate at the desired frequency. C2 and L2 reject the undesired energy while allowing the desired signal to pass. The tap points on L1 and L3 provide 50- $\Omega$  matching; they may be adjusted for optimum energy transfer. Several filters have been constructed using a miniature variable capacitor in place of C2 so that the notch frequency could be varied.

## A TUNABLE SWITCHED-CAPACITOR AUDIO FILTER

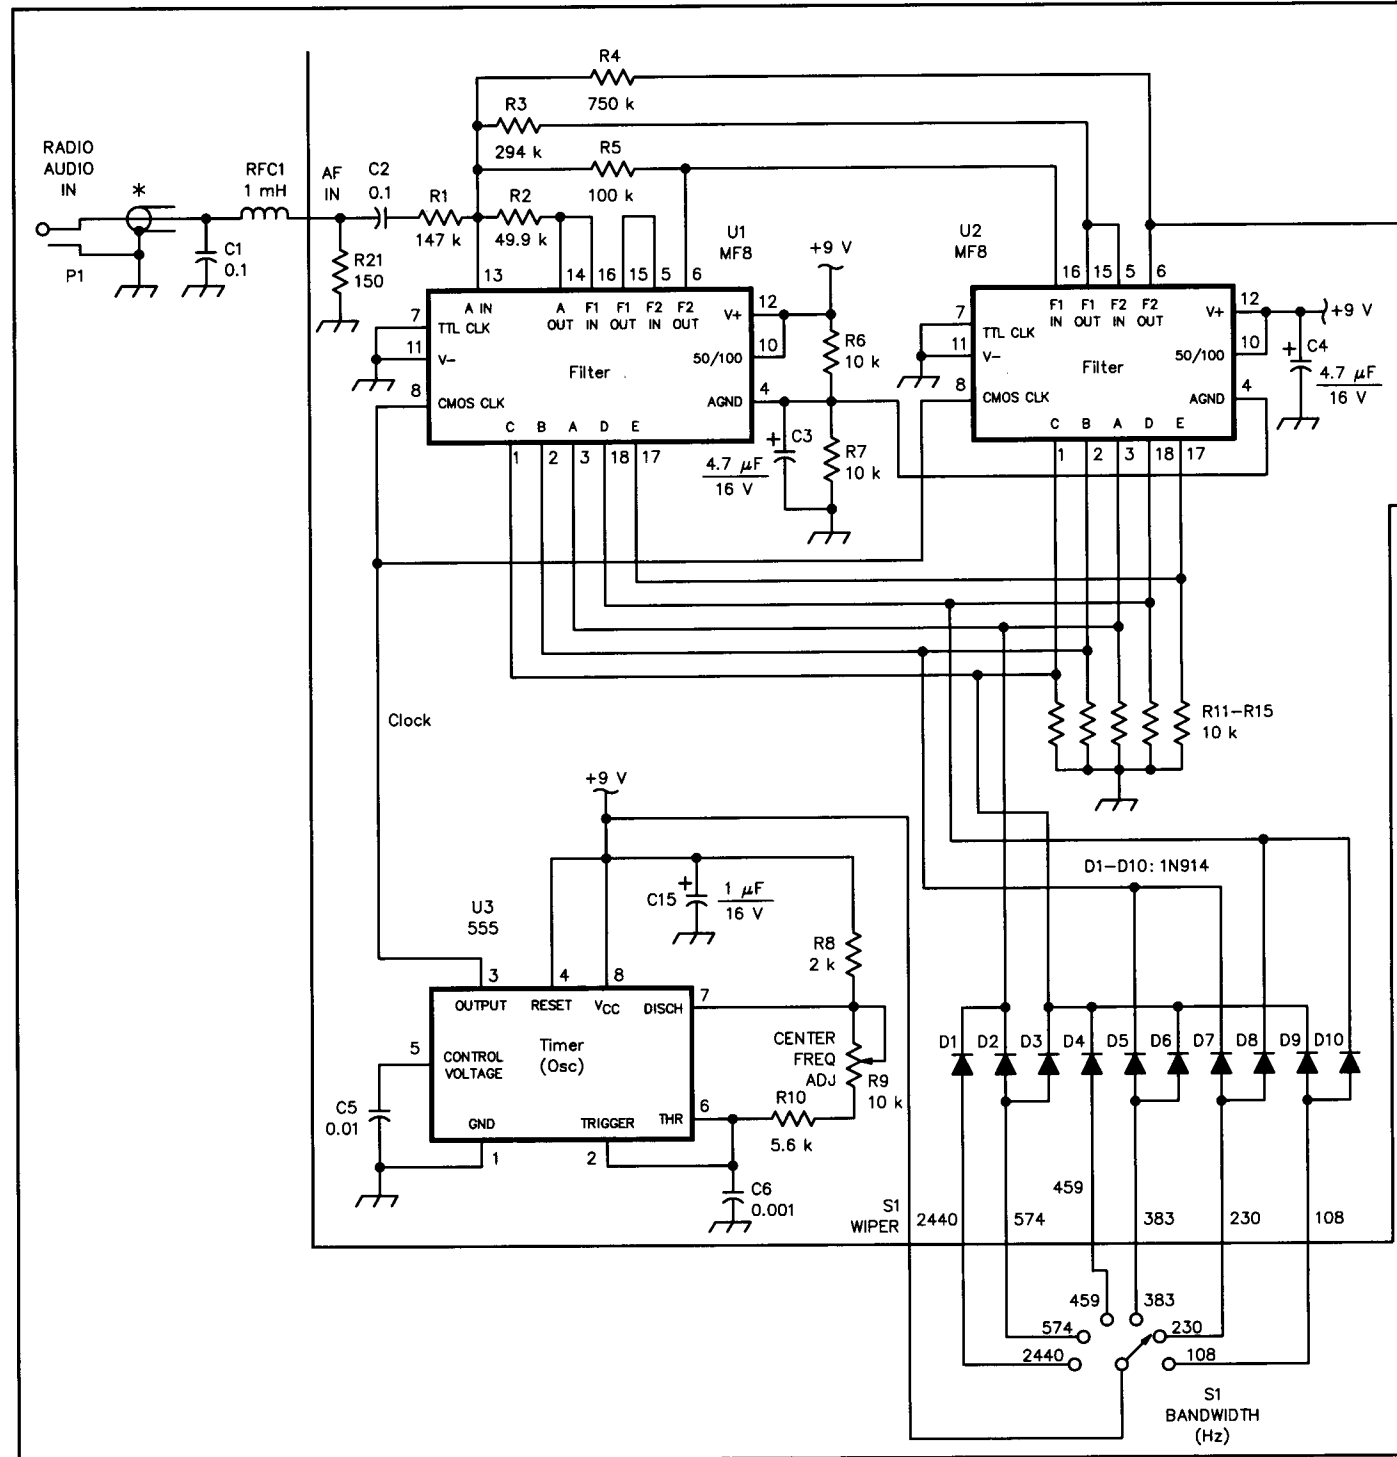

This active audio filter, designed by Samuel Ulbing, N4UAU, uses a low-cost MF8 IC as a switched-capacitor audio filter. One potentiometer sets its center frequency, and its 3-dB bandwidth readily adjusted from about 0.13 to 3 times its center frequency. (With a center frequency of 750 Hz, for example, its calculated 3-dB bandwidths span the range from 108 to 2440 Hz.)

It cuts off very sharply, with attenuation rising to 30 dB just 150 Hz outside its passband. Using all new parts, it probably can be built for under \$50 (1992 prices), including a PC board. PC-board templates and part overlays for this project are available free of charge. Write, phone or email the Technical Department Secretary at ARRL HQ and request the N4UAU Audio Filter PC Board Template Package.

Etched, solder-coated and drilled PC boards for this project are available from FAR Circuits (see the Address List in the **References** chapter). A full description of the circuit appears in October 1992 *QST*.

### The Filter Circuit

**Fig 16.67** (on the following two pages) shows the circuit, which includes the MF8s (U1 and U2), a 555 clock oscillator

(U3) and the LM386N audio-amplifier stage for headphone drive. U5, a 78L09 regulator, serves to isolate U1 and U2 from power supply effects.

Filter bandwidth is selected by the S1 (BANDWIDTH (HZ)). A Diode matrix (D1-D10) selects filter Qs that correspond to calculated 3-dB bandwidths of 2440 (Q = 0.47), 574 (2), 459 (2.5), 383 (3), 230 (5) and 108 Hz (10.6) at the chosen center frequency (750 Hz).

The value C6 is critical. It sets the clock

frequency (about 75 kHz) in conjunction with R8-R10. Use a 2%-tolerance polypropylene capacitor for this component. R9, CENTER FREQ ADJ, sets the clock frequency. It must be adjusted for maximum audio output when listening to the transceiver sidetone oscillator with the BANDWIDTH (HZ) switch set to minimum (108 Hz).

The LC filter (C1-RFC1) on the audio-input line keeps RF out of the MF8. On the output side of the LM386, C12, RFC2 and

R20 help eliminate RFI. R20 also reduces the LM386 idling hiss, which is audible in sensitive headphones.

### Construction and Operation

The filter is built on a Radio Shack universal PC board (#276-168). The filter board is mounted in an enclosure such as Radio Shack 270-253 metal box. J1, S1 and S2, the optional POWER switch, mount on the box front panel; BP1 and BP2 mount on the back.

This filter works for both CW and SSB. Its narrowest bandwidth is handy for zero-beating incoming signals. At its widest bandwidth (2440 Hz), it is useful for SSB listening. For general CW reception, bandwidths from 230 to 459 Hz work best, depending on interference.

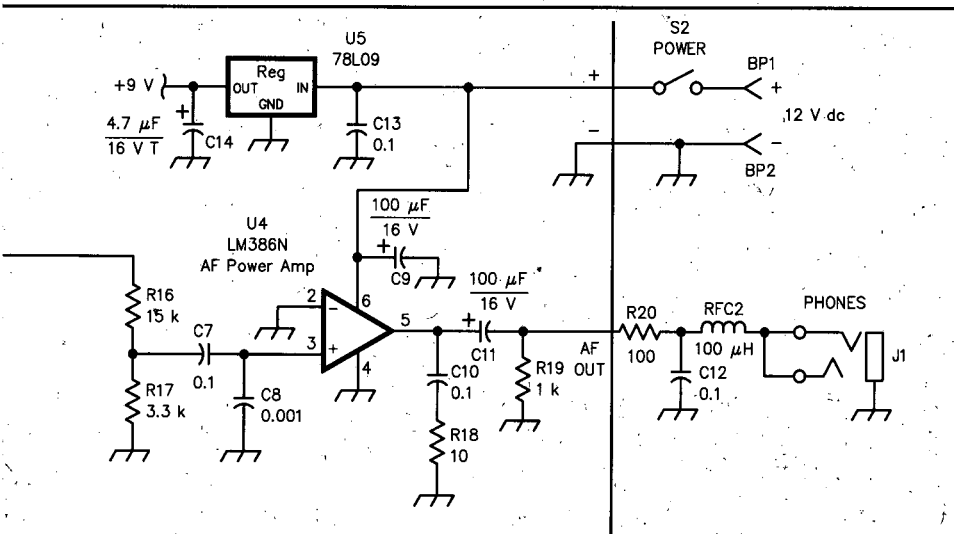

### Filter RFI?

Under some conditions, RF from a station transmitter may affect this filter, or the filter may produce interference in a receiver. Here's what to do if either of these situations occur.

RF can get into the filter via the RADIO AUDIO IN, POWER and PHONES lines. It may be heard as humming, buzzing, thumping, blasting or other noises during transmission. Poor station grounding can worsen such effects. So can using unshielded cable and connectors for the filter's external audio and power wiring. C1 and RFC1 in the RADIO AUDIO IN line and R20, C12 and RFC2 in the PHONES line, are there to suppress interference. It is possible to omit some or all of these components at some stations; at other locations the filter may require additional bypass capacitors and/or RFC chokes/ferrite beads.

Weak harmonics of the filter clock oscillator may be heard, especially if the antenna is very close to the filter. This problem is similar to those encountered with computers or any other digital circuitry in a ham shack. The clock operates at about 100 times the filter center frequency—75 kHz for a center frequency of 750 Hz, for example. Harmonics of its clock may appear every 75 kHz or so across the receiver dial.

Shielded audio and power cables can help. One other approach is to use a CMOS '555 timer IC instead of a bipolar '555. (Generally, CMOS '555s—the Harris ICM7555 or National LMC555CN, for instance—generate waveforms with slower rise and fall times and hence with less harmonic content, than bipolar '555s). Running the filter and a receiver may be asking for interference unless heavy decoupling and bypassing are used on the power bus they share.

Except as indicated, decimal values of capacitance are in microfarads ( $\mu\text{F}$ ); others are in picofarads (pF); resistances are in ohms; k=1,000.

## A BC-BAND ENERGY-REJECTION FILTER

Inadequate front-end selectivity or poorly performing RF amplifier and mixer stages often result in unwanted cross-talk and overloading from adjacent commercial or amateur stations. The filter shown is inserted between the antenna and receiver. It attenuates the out-of-band signals from broadcast stations but passes signals of interest (1.8 to 30 MHz) with little or no attenuation.

The high signal strength of local broadcast stations requires that the stop-band attenuation of the high-pass filter also be high. This filter provides about 60 dB of stop-band attenuation with less than 1 dB of attenuation above 1.8 MHz. The filter input and output ports match 50  $\Omega$  with a maximum SWR of 1.353:1 (reflection coefficient = 0.15). A 10-element filter yields adequate stop-band attenuation and a reasonable rate of attenuation rise.

The design uses only standard-value capacitors.

### Building the Filter

The filter parts layout, schematic diagram, response curve and component values are shown in Fig 16.68. The standard capacitor values listed are within 2.8% of the design values. If the attenuation peaks ( $f_2$ ,  $f_4$  and  $f_6$ ) do not fall at 0.677, 1.293 and 1.111 MHz, tune the series-resonant circuits by slightly squeezing or separating the inductor windings.

Construction of the filter is shown in Fig 16.69. Use Panasonic NP0 ceramic disk capacitors (ECC series, class 1) or equivalent for values between 10 and 270 pF. For values between 330 pF and 0.033  $\mu$ F, use Panasonic P-series polypropylene (type ECQ-P) capacitors. These capacitors are available through Digi-Key

(see the Address List in the **References** chapter) and other suppliers. The powdered-iron T-50-2 toroidal cores are available through Amidon, Palomar Engineers and others.

For a 3.4-MHz cutoff frequency, divide the L and C values by 2. (This effectively doubles the frequency-label values in Fig 16.68.) For the 80-m version, L2 through L6 should be 20 to 25 turns each, wound on T-50-6 cores. The actual turns required may vary one or two from the calculated values. Parallel-connect capacitors as needed to achieve the non-standard capacitor values required for this filter.

### Filter Performance

The measured filter performance is shown in Fig 16.68. The stop-band attenuation is more than 58 dB. The measured cutoff frequency (less than 1 dB attenuation) is under 1.8 MHz. The measured passband loss is less than 0.8 dB from 1.8 to 10 MHz. Between 10 and 100 MHz, the insertion loss of the filter gradually increases to 2 dB. Input impedance was measured between 1.7 and 4.2 MHz. Over the range tested, the input impedance of the filter remained within the 37 to 67.7  $\Omega$  input-impedance window (equivalent to a maximum SWR of 1.353:1).

Fig 16.68—Schematic, layout and response curve of the broadcast band rejection filter.

Fig 16.69—The filter fits easily in a 2x5-inch enclosure. The version in the photo was built on a piece of perfboard.

## A DIGITAL SIGNAL PROCESSOR

This digital signal processor (see Fig 16.70) was designed by Dave Hershberger, W9GR. It is a modern filter that uses digital technology. The programmable digital signal processor (DSP) replaces inductors, capacitors and op amps. It connects between a receiver's audio output and a speaker. A total of 18 functions are selectable. It features an LED display and 13 bit analog-to-digital conversion for a wide dynamic range.

Parts, including the preprogrammed chip and PC boards, are available in kit form. The **Digital Signal Processing** chapter discusses DSP techniques in more detail and points to other information sources.

### HARDWARE DESCRIPTION

All DSP filters for analog signals begin with an analog-to-digital converter or A/D. Often an integrated circuit known as a *CODEC*—a COder/DECoder consisting of

an A/D, a D/A and filtering—is used. This DSP unit is drawn in block form in Fig 16.71 and its schematic is in Fig 16.72. The input at J2 is connected to a 13 bit CODEC, IC2. A 13 bit conversion is theoretically equivalent to an 80 dB dynamic range, which makes it easier to set the input audio levels. It also improves CW filtering, because a wide dynamic range is necessary to select a weak CW signal amidst much stronger signals. In voice applications, the signal to noise ratio of a relatively strong SSB signal might be 30 dB; there is 50 dB of S/N "headroom" left with 13 bits! With such a margin, 13 bits is more than adequate for amateur applications.

IC2 uses switched capacitor antialias low-pass filter. (See the DSP chapter for an explanation of aliasing.) The low-pass filter cuts off at about 3.2 kHz. IC2 accepts analog input at pin 18 and outputs a serial digital audio bit stream at pin 13.

Shift registers IC3 and IC4 convert the serial output from IC2 to a parallel word,

Fig 16.70—The PC board is mounted in a steel case to minimize radiation from the digital circuits. All controls are on the front panel except S4.

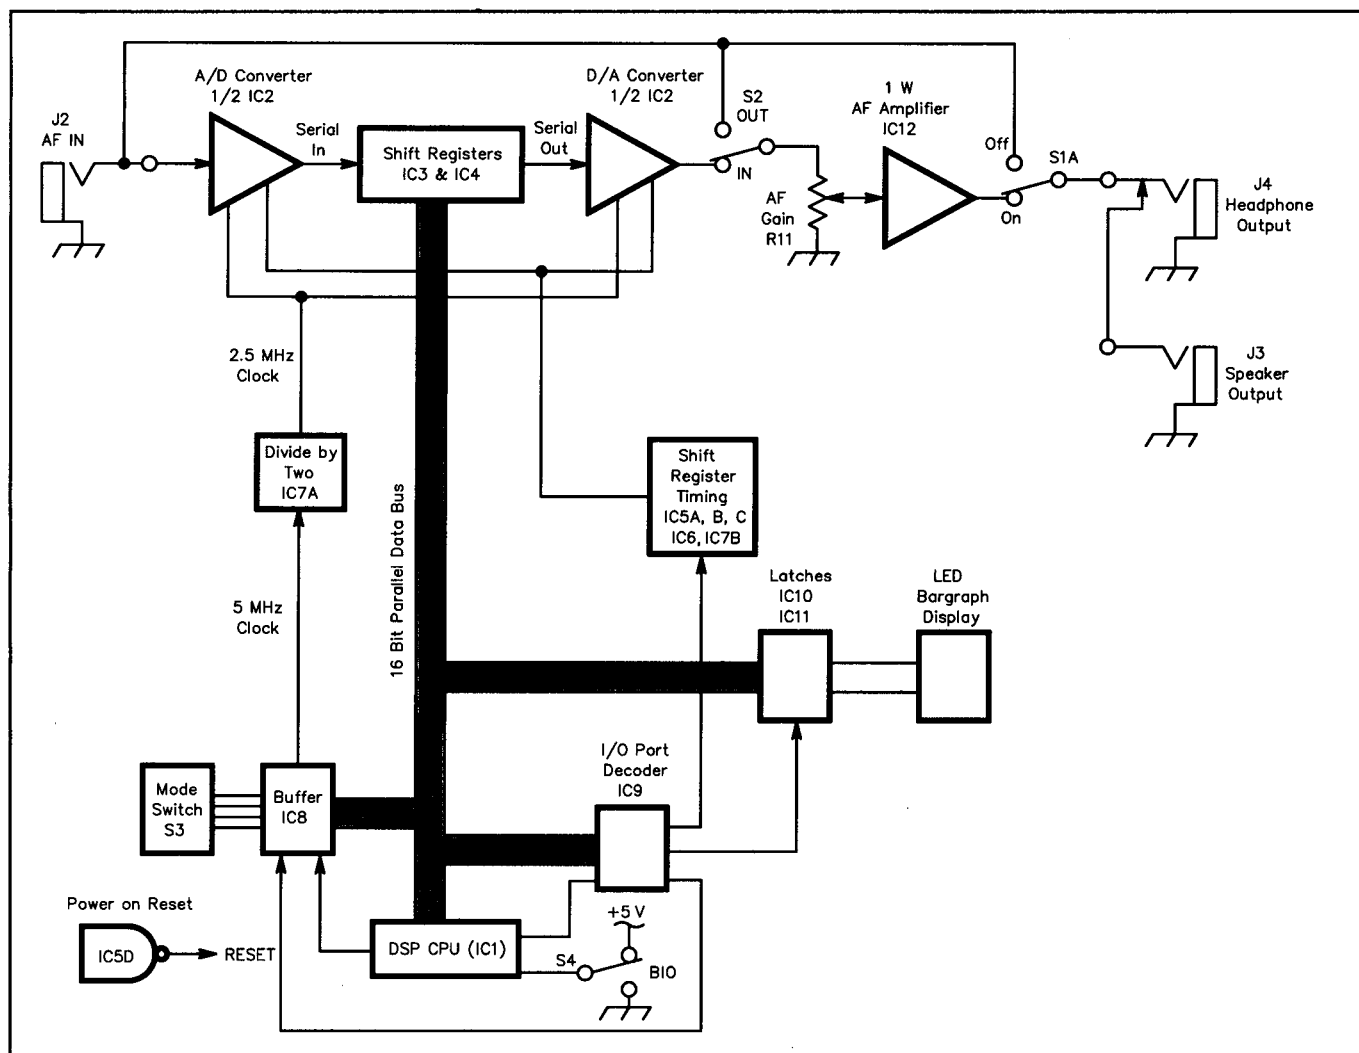

Fig 16.71—The DSP uses a 16-bit parallel data bus to connect the CPU (IC1) to the input/output shift register (IC3 and IC4). The CODEC is IC2 (see text).

for the CPU chip, IC1. The sampling rate is approximately 7700 Hz.

IC1 is a 16 bit DSP CPU with a 32 bit accumulator. This processor executes instructions at a rate of 5 MIPS (million instructions per second). It contains 8 kbytes of OTP (one time programmable; not erasable) PROM memory that holds the DSP firmware.

For special applications, the CPU can be replaced with another, such as a TMS320C10 or TMS320C15. These processors require external program memory, such as 57C43 high speed EPROMs at IC13 and IC14. These ICs are not shown in Fig 16.71, but their connections are shown in Fig 16.72. This capability is provided for advanced experimenters, who want to do their own DSP software development.

Modes are selected by a rotary encoder switch, S3. It generates a 4 bit binary code, which is periodically read by the CPU via the tristate buffer IC8. The setting of S3 determines which DSP function is executed by IC1.

IC5D is connected as an inverter that goes low for a fraction of a second when the power is turned on. This short pulse initializes the CPU (IC1), the shift registers (IC3 and IC4) and some of the various remaining flip-flops.

IC7A accepts the 5-MHz clock output from IC1 via IC8 and produces the 2.5-MHz clock for IC2. Chips IC5A, IC5B, IC5C, IC7B and IC6 all work to

produce the proper timing signals to interface IC2 and shift registers to the CPU.

IC9 is a port decoder, which produces active-low outputs to read the binary encoder mode switch S3. It also reads the A/D converter's output from the shift registers, writes parallel digital audio words to the shift registers, and writes data to the LED bargraph display.

When the CPU writes to the LED display, the data word controlling the individual LEDs is written to IC10 and IC11. IC10 holds the left-most 8 bits of the LED display, and IC11 holds the right-most 2 bits. A logic 0 at any output turns the corresponding LED on; 1 turns it off.

After the CPU performs the desired filtering operation on the input audio, it outputs parallel audio words to shift register chips IC3 and IC4. These shift registers are bidirectional. In addition to converting the serial A/D data to parallel, they also convert the parallel data back to serial again, so that it can be sent to the D/A in IC2.

The processed serial digital audio data enters IC2 at pin 8. Within IC2, it is converted back to analog again. IC2 also includes a switched capacitor low-pass filter for analog reconstruction and  $\sin(x)/x$  correction. The filtered analog output is connected from pin 2 through R11, the AF GAIN control, to the audio amplifier, IC12. This amplifier provides about 1 W of audio output power to J3 and J4.

The 12-V dc power supply is connected to the audio power amplifier IC12. VR1 drops 12 V to 5 V for IC2 and the digital circuitry.

## BUILDING THE DSP

This DSP may be built with PC board, wire-wrap, or point-to-point hand-wiring techniques. A PC board (double sided, with plated-through holes) and parts kit are available from Quantics.<sup>1,2</sup> Fig 16.70 shows the inside of the case. The digital pulses in the DSP are capable of generating strong interference. Therefore, enclose the unit in a case that provides good shielding. A steel enclosure works very well.

If you do not want the headphone jack to mute speaker audio when you plug in a pair of headphones, install a jumper wire at JP3.

R16 prevents the grounded sleeve on mono audio plugs from shorting the audio output circuit. If you intend to use only stereo headphones, install a jumper wire in place of R16. If stereo headphones are used with R16 installed, there will be a slight level imbalance between the left and right channels.

S1 is the power switch. Switch S4 (BIO, for binary I/O) is wired to pin 9 of IC1 (Fig 16.72). It controls the processor mode selection in conjunction with

## You may be surprised

All filters have side effects. A very good, very narrow crystal filter may ring and surround the signal you are trying to copy with an annoying echo. Modern, state-of-the-art digital filters also have their side effects, and if you are not prepared they may surprise you. The W9GR filter in the 50 or 100 Hz position does a fine job on a single CW signal. But try to use it in a round table—or when listening to two stations—and you may only hear one station unless both are within 50 or 100 Hz in frequency.

The filter also has a limited amount of intelligence. In the notch position it will select the interfering heterodyne by itself. At the same time, tests of this mode in the lab showed some distortion, since there was no background noise to limit the AGC level. When used on the air, this distortion was not evident, because there is always noise or slight QRM present.

The performance of the filter is primarily software controlled. The chip supplied by Quantics includes the latest version of the software. As more and more experience is gained with this software, changes are made in the program to incorporate improvements based on the experience of hams using this filter. For further information on the software version, contact Quantics at the address given in the **References** chapter—Paul Danzer, N11I, ARRL Staff

<sup>1</sup> The TMS320P15 CPU chip, preprogrammed with the firmware for this project, is available exclusively from Quantics (see the Address List in the **References** chapter). Contact Quantics for current pricing and firmware features. A PC board and a complete parts kit are also available from Quantics.

<sup>2</sup> A package of additional descriptive technical information is available from the ARRL Technical Secretary. Enclose a 10×13-inch self addressed envelope and request the '96 *Handbook* DSP-3 template.

S3. Power and ground connections are shown in **Table 16.6**.

## TESTING THE DSP

To test the DSP, you will need the following:

1. A source of audio, which may be taken from a receiver.
2. A speaker.
3. A 12 V, 0.5 A dc power supply.

Before applying power, make sure that the ON/OFF switch is off, which is the *out* position. Apply audio (from any source that is capable of driving a speaker) to connector J2 (AF IN) or to pad E3 on the PC board. Similarly, connect a speaker to connector J3 (AF OUT). This should produce unprocessed audio at the speaker. Next, set the MODE switch to the 12 o'clock position (knob pointer straight up or flat on shaft straight down).

If you use the coaxial dc power connector at J1, make sure that the center pin is positive, and apply power. Turn the power on by pushing S1 in. When you first apply power, the LEDs should light up and then a pattern quickly sweeps back and forth across the bar graph. Then some LEDs should light in response to the input audio. Increase and decrease the audio to see how the bar graph responds. If you push S2 in, you will hear processed audio.

With S2 out, the DSP is bypassed; the signal passes through only the AF GAIN control and analog audio amplifier stage. Finally, with the IN/OUT switch S2 in, rotate the MODE switch through its various positions, and you will be able to hear the effect of the various DSP modes.

## CONTROLS AND OPERATION

The DSP normally connects between a receiver and speaker. For FSK or SSTV, the DSP goes between a receiver and terminal unit, TNC, or SSTV demodulator. The DSP requires 12 V dc to operate. The front panel controls are:

**ON/OFF switch (S1)**—When S1 is pushed in, power is on; when S1 is out, power is off. When the power is off, the audio input is connected to the audio output, bypassing the DSP.

**IN/OUT switch (S2)**—This switch enables or bypasses the digital signal processing function. When S2 is pushed in, processing is on; when S2 is out, the signal passes through the analog amplifier only.

**AF GAIN control (R11)**—This controls the audio output level.

**LED bar graph**—The DSP includes a 10 segment LED bar graph display. In most of the operating modes, the bar graph displays peak audio level. Each LED represents a 3-dB change in audio level. The maximum input level (without clipping) is 5 V peak to peak, about 1.8 V RMS.

Although the hardware and software have been designed to accept and process audio across a wide range of input levels, it is best to set the receiver audio gain so that the strongest signals light most or all of the LEDs occasionally. Once the receiver gain is properly adjusted, use only the AF GAIN control on the processor to adjust speaker volume. This procedure maximizes A/D and D/A precision, and minimizes quantization noise. Most modern receivers have good AGC characteristics that produce consistent audio level for both strong and weak signals. If receiver audio level varies, it may occasionally overload the DSP and produce clipping distortion. If this happens, simply turn down the audio input.

**Rear panel BIO switch**—The BIO

switch (S4) selects DSP configuration options and activates special functions. It may be thought of as an auxiliary mode switch. BIO stands for *binary I/O*.

**MODE switch (S3)**—This 16 position rotary switch selects the DSP operating mode. Here are the DSP functions, beginning with no. 1 at the 12 noon position, and numbered clockwise. The 16 positions and the 18 DSP functions are as follows:

1. *Combined automatic notch and denoiser*—This mode automatically notches carriers and simultaneously reduces noise. It is recommended for most HF SSB operation. When the BIO switch is set to 1 (up) in this mode, audio AGC is enabled. (More on AGC operation later.)

The noise reducer mode is most effective against hiss and thermal noise, but it also reduces impulse noise and static crashes. Noise reduction reduces listener fatigue, and it is recommended for long-term monitoring. The automatic notch function eliminates multiple carriers within a few milliseconds. CW interference, carriers and other forms of undesired audio tones are quickly eliminated. If a carrier comes on your frequency, you will only hear a subtle click as the automatic notch acquires it.

2. *Denoiser*—This mode reduces noise with greater effectiveness than in Mode 1. Use Mode 2 for weak voice signals, such as SSB, VHF SSB and FM. When the BIO

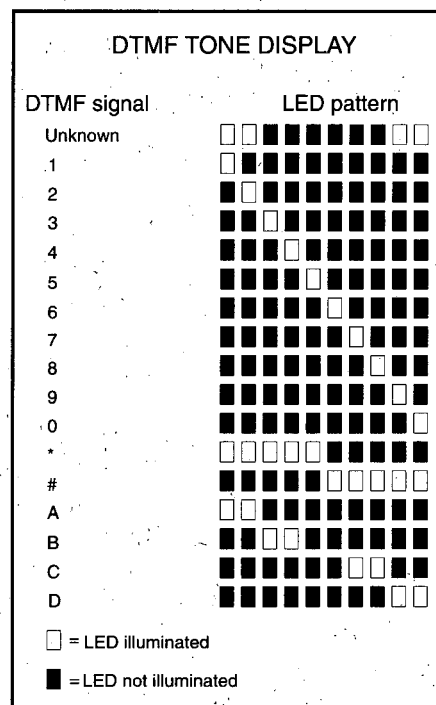

Fig 16.73—The DSP will decode and identify DTMF tones. The LED pattern indicates which tone was transmitted.

Fig 16.72—(see next two pages) DC power input, audio input and audio output connections are at the bottom of the schematic. IC13 and IC14 are only used for custom programming (see text). An LM380 (IC12) is the audio output amplifier. Any of the 74XX series TTL parts (marked with a \*) may be used in any of the following variations: 74XX, 74LSXX, 74SXX, 74FXX, 74ALSXX, 74HCXX, 74HCTXX, 74AHCTXX, 74HCTLSXX and so on. For IC5, a HCMOS type is recommended (for example HCT, HCTLS and so on) to minimize the effects of gate input current on the power-on reset circuit. When mixing logic family types, bipolar devices (LS and such) must always drive devices that accept bipolar input levels (such as HCT, HCTLS and so on). Unless otherwise specified, all resistors are 1/4 W, 5% and capacitors are 10% tolerance. All capacitors less than 1.0  $\mu$ F are ceramic; 1.0  $\mu$ F and above are electrolytic, 16-V or greater.

D1, D2—1N4001 silicon diode (diodes with higher voltage ratings such as 1N4002, 1N4003, 1N4004 and so on may also be used).

IC1—TMS320P15 DSP CPU programmed with firmware (see Note 1).

IC2—TCM320AC39 audio CODEC (TCM320AC38 may be substituted).

IC3, IC4—74299 shift register (\*).

IC5—7400 quad NAND gate (HCMOS recommended) (\*).

IC6, IC7, IC11—7474 dual flip-flop (\*).

IC8—74368 hex inverter (\*).

IC9—74139 decoder (\*).

IC10—74374 octal flip-flop (\*).

IC12—LM380 audio power amplifier.

IC13, IC14—WaferScale 57C43 EPROM (see text—only used for user developed firmware).

JP1, 2, 3—Connectors used on the Quantics PC board.

J1—Coaxial dc power jack.

J2, J3—1/8-inch audio jack.

J4—1/8-inch stereo headphone jack.

L1, L2—10  $\mu$ H RF chokes.

LED1—10 segment LED bar graph, Radio Shack 276-081B or equivalent.

R11—100 k  $\Omega$  potentiometer.

S1, S2—DPDT push-push switch. Switch caps for S1 and S2 (1 red; 1 gray).

S3—16 position binary rotary encoder switch.

(Noble SDB161 PH 20F-1-4-16-16PC-B).

S4—SPDT toggle switch (for bio function).

VR1—7805 or LM340T-5 TO-220 voltage regulator.

X1—20 MHz fundamental crystal.

Hardware:

(1) TO-220 heat sink.

(5) 14 pin IC socket.

(2) 16 pin IC socket.

(4) 20 pin IC socket.

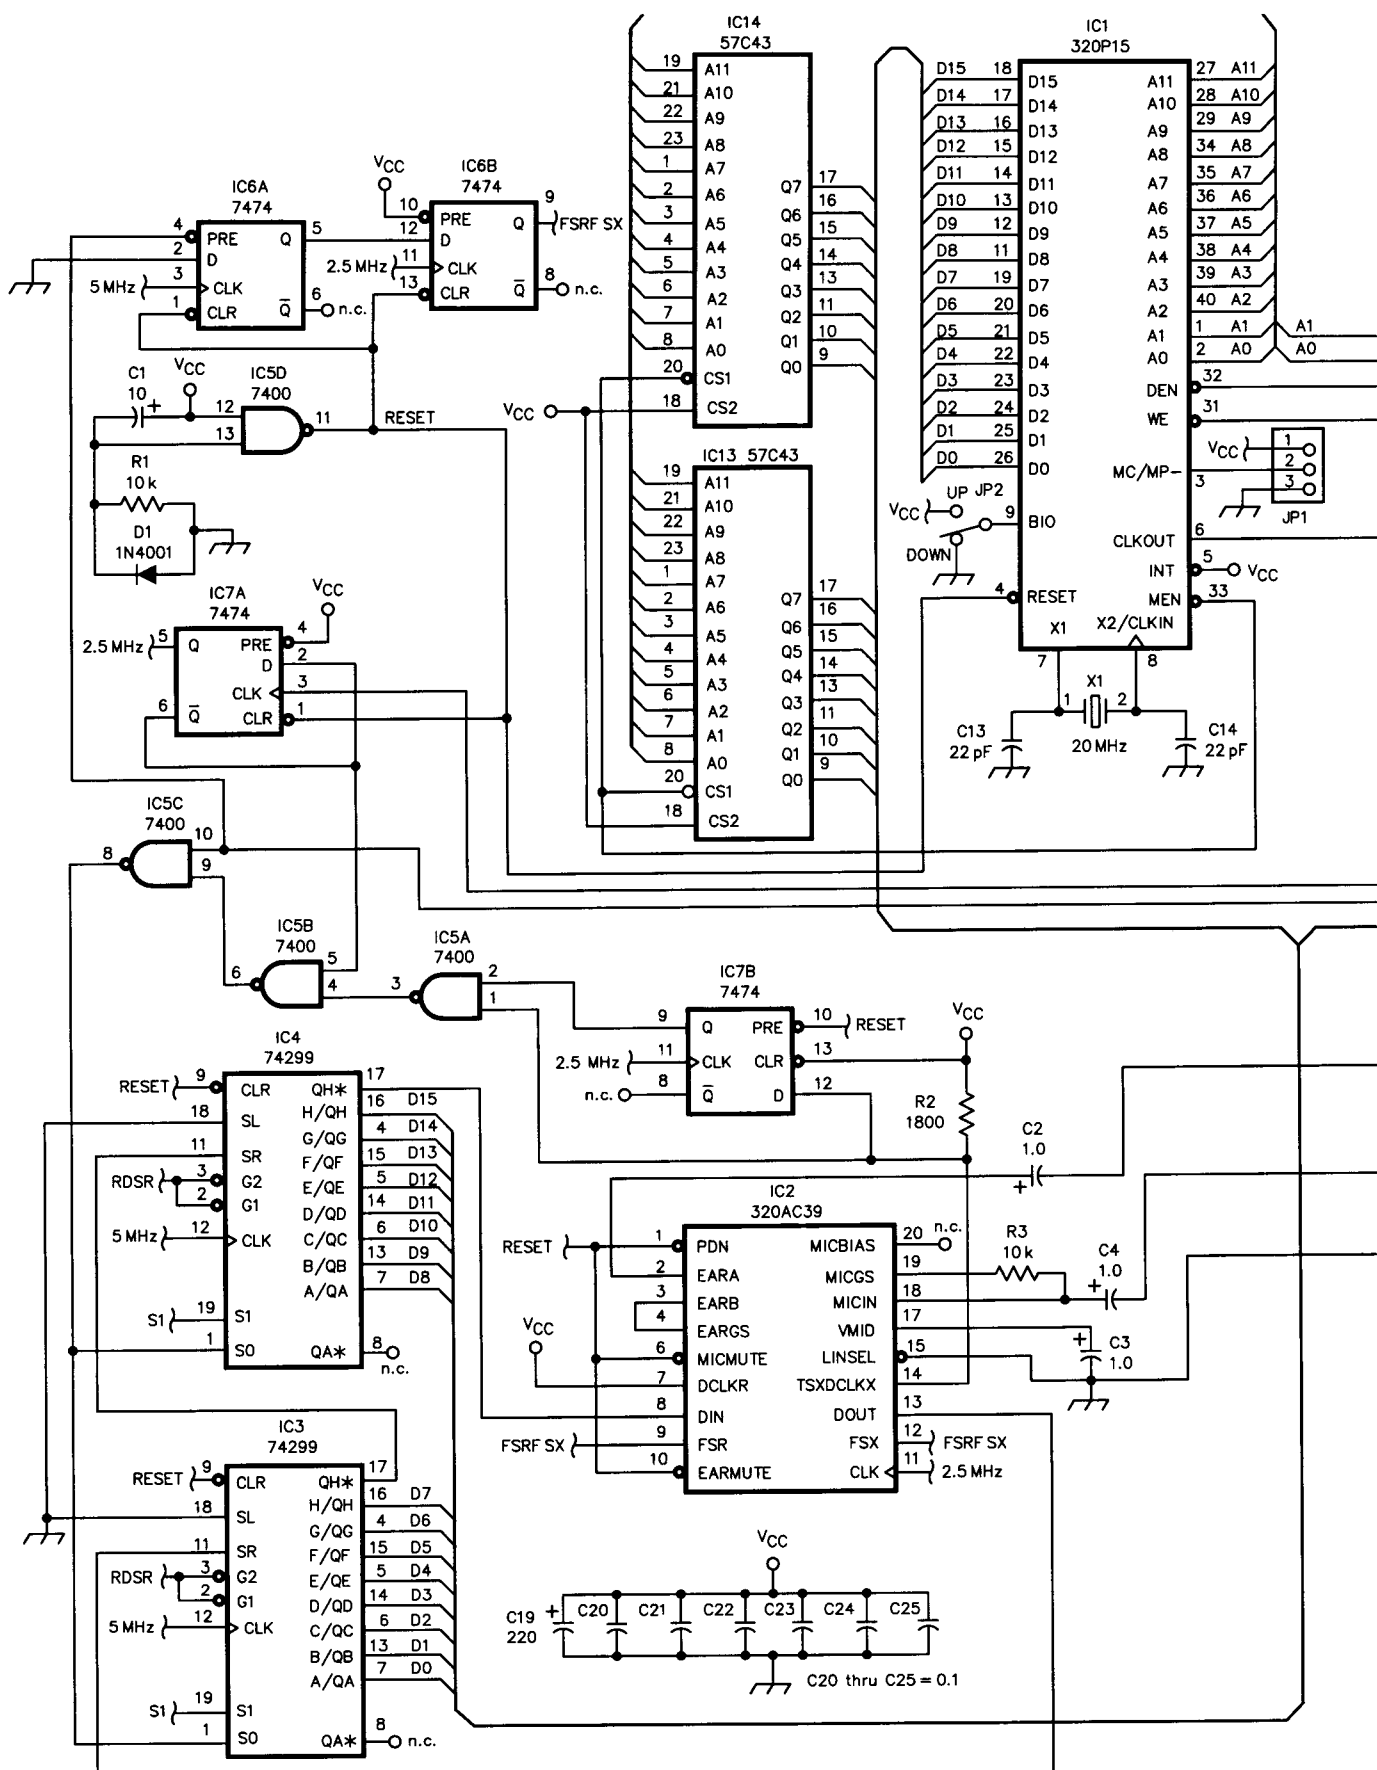

(1) 40 pin IC socket.

(1) 20 pin right angle socket (for LED bar graph).

(2) Knob.

(1) PC board.

(1) Set of # 4 hardware for VR1 and heat sink.

**Fig 16.74—When decoding CTCSS (subaudible) tones the LED pattern again identifies the particular tone detected.**

switch is set to 1 in this mode, AGC is enabled.

**3. Automatic Notch**—This mode automatically notches carriers with greater effectiveness than Mode 1. Use Mode 3 for HF SSB operation where interfering carriers are the most objectionable problem. When the BIO switch is set to 1, AGC is enabled.

**4. Narrow (2.1 kHz) Voice Filter**—This mode is a fixed 100th order narrowband voice FIR (finite impulse response) filter, intended for rejecting adjacent overlapping SSB signals. There is no adaptive noise reduction or automatic notching in this mode. The filter passband is 300-2100

Hz. Outside the passband, the attenuation is >50 to 70 dB.

**5. Narrow (1.8 kHz) Voice Filter**—This mode is identical to the previous mode with the passband narrowed to 300-1800 Hz.

**6. RTTY filter**—This is a 100th order linear phase band-pass filter. This mode is intended for 170 Hz shift FSK signals such as Baudot and AMTOR. When BIO is set to 0 (down), North American RTTY tones are selected (2125/2295 Hz). When BIO is 1, European RTTY tones are selected (1275/1445 Hz). Attenuation out of the passband is >60 dB.

**7. HF packet filter or SSTV filter**—This is a 100th order linear phase band-pass filter. Mode 7 is intended for 200 Hz shift, 1200 baud HF packet FSK signals or SSTV signals. When BIO is 0, the HF packet mode is selected (1600/1800 Hz). When BIO is 1, Mode 7 is a SSTV filter (1200-2300 Hz). The passband for HF packet is 1550-1850 Hz. Attenuation outside this band is >65 dB.

**8. DTMF Decoder**—Mode 8 decodes DTMF signals, using the LED bar graph to indicate the decoded tone pairs. Use this mode to test DTMF encoders, troubleshoot autopatches and monitor repeater autopatch access. The bar graph (Fig 16.73) displays the tone detected.

**9. CTCSS Decoder and Squelch**—Mode 9 is useful for decoding subaudible CTCSS tones. This mode will decode any of the 38 subaudible tones used for repeater access, tone squelch and selective calling. Use it to test your own CTCSS transmissions. Fig 16.74 shows the bar graph patterns for CTCSS frequencies.

**IMPORTANT NOTE: This mode will not work if the receiver cuts off frequencies below 300 Hz! [As many do!—Ed.]**

**10-16. CW Filters**—Modes 10 through 16 are a set of CW filters with center frequencies ranging from 400 to 1000 Hz, and bandwidths of 50 to 200 Hz. Out of band rejection is >50 dB for the 50-Hz filters and >60 dB for the wider filters. A short dit is sent at the filter center frequency (to confirm the frequency selection) when a filter is selected.

To adjust the center frequency of any CW filter, perform the following steps:

1. Turn the power off.
2. Set the BIO switch, S4, to 1.
3. Set the MODE switch, S3, to the CW filter position you want to tune.
4. Turn on the power. The DSP will produce a slowly declining audio tone at the center of the CW filter band pass. When the audio tone reaches the frequency you want, turn the MODE switch to any other position. The filter is now tuned to the note last heard. If the MODE selector is

not moved during the declining tone, tuning will terminate at 30% below the original center frequency.

This process adjusts all of the CW filters by the same percentage. As an example, if a 1000-Hz filter is tuned to 900 Hz (-10%), the 750-Hz filter becomes 675 Hz, 600 Hz becomes 540 Hz and so on. When you select one of the CW filters, the dit sent will be at the new center frequency of the filter. Such adjustments remain in effect until you turn the power off.

This process does not affect the other (RTTY, SSTV or narrow SSB) filters.

**Digital AGC**—When the digital AGC function is selected (BIO = 1 in modes 1, 2 and 3), the AGC range is limited to 30 dB, so that noise and hum are not increased to full output amplitude in the absence of a signal. Therefore, if you use AGC in modes 1, 2 or 3, as long as at least one LED is lit, the audio output level will be brought up to full amplitude.

The AGC function is entirely DSP based, and it exists in software. There is no separate analog AGC chip. The recovery time constant is very slow, about 30 s to adapt to a new (lower) signal level. The time constant was made deliberately slow to avoid “pumping” and “breathing” artifacts. Attack time is fast, virtually instantaneous. If the input level suddenly drops and you do not want to wait for the AGC to adapt, you can reinitialize it by turning the MODE switch away and then back. The AGC will instantly reinitialize to the new signal level, and the output of the DSP will be at full amplitude.

Hershberger, D., “Low Cost Digital Signal Processing for the Radio Amateur,” Sept 1992 *QST*. Contains an explanation of the algorithms used in a digital signal processor and a description of the hardware.

Reyer, S., and D. Hershberger, “Using the LMS Algorithm for QRM and QRN Reduction,” Sept 1992 *QEX*. A thorough mathematical treatment of the firmware noise reduction and autonotcher algorithm.

## OTHER FILTER PROJECTS

Filters for specific applications may be found in other chapters of this *Handbook*. Receiver input filters, transmitter filters, interstage filters and others can be separated from the various projects and built for other applications. Since filters are a first line of defense against *electromagnetic interference* (EMI) problems, the

following filter projects appear in the EMI chapter:

- Differential-mode high-pass filter for 75- $\Omega$  coax (for TV reception)
- Brute-force ac-line filter
- Loudspeaker common-mode choke
- LC filter for speaker leads
- Audio equipment input filter

# Receivers, Transmitters, Transceivers and Projects

## 17

**T**his chapter, by William E. Sabin, WØIYH, discusses the “system design” of Amateur Radio receivers, transmitters and transceivers. “A Single-Stage Building Block” reviews briefly a few of the basic properties of the various individual building block circuits, described in detail in other chapters, and the methods that are used to combine and interconnect them in order to meet the requirements of the completed equipment. “The Amateur Radio Communication Channel” describes the relationships between the equipment system design and the electromagnetic medium that conveys radio signals from transmitter to receiver. This understanding helps to put the radio equipment mission and design requirements into perspective. Then we discuss receiver, transmitter, transceiver and transverter design techniques in general terms. At the end of the theory discussion is a list of references for further study on the various topics. The projects section contains several hardware descriptions that are suitable for amateur construction and use on the ham bands. They have been selected to illustrate system-design methods. The emphasis in this chapter is on analog design. Those functions that can be implemented using digital signal processing (DSP) can be explored in other

chapters, but an initial basic appreciation of analog methods and general system design is very valuable.

### A SINGLE-STAGE BUILDING BLOCK

We start at the very beginning with **Fig 17.1**, a generic single-stage module that would typically be part of a system of many stages.

A signal source having an “open-circuit” voltage  $V_{gen}$  causes a current  $I_{gen}$  to flow through  $Z_{gen}$ , the impedance of the generator, and  $Z_{in}$ , the input impedance of the stage. This input current is responsible for an open-circuit output voltage  $V_d$  (measured with a high-impedance voltmeter) that is proportional to  $I_{gen}$ .  $V_d$  produces a current  $I_{out}$  and a voltage drop across  $Z_{out}$ , the output impedance of the stage and  $Z_{load}$ , the load impedance of the stage. Observe that the various  $Z$ s may contain reactance and resistance in various combinations. Let’s first look at the different types of gain and power relationships that can be used to describe this stage.

#### Actual Power Gain

Current  $I_{gen}$  produces a power dissipation  $P_{in}$  in the resistive component of  $Z_{in}$  that is equal to  $I_{gen}^2 R_{in}$ . The current  $I_{out}$  produces a power dissipation  $P_{load}$  in the

resistive component of  $Z_{load}$  that is equal to  $I_{out}^2 R_{load}$ . The actual power gain in dB is  $10 \log (P_{load} / P_{in})$ . This is the conventional usage of dB, to describe a power ratio.

#### Voltage Gain

The current  $I_{gen}$  produces a voltage drop across  $Z_{in}$ .  $V_d$  produces a current  $I_{out}$  and a voltage drop  $V_{out}$  across  $Z_{load}$ . The voltage gain is the ratio

$$V_{out} / V_{in} \quad (1)$$

In decibels (dB) it is

$$20 \log (V_{out} / V_{in}) \quad (2)$$

This aberrant usage of dB, to describe a voltage ratio, is common practice. It is *different* from the power gain mentioned in the previous section because it does *not* take into account the power ratio or the resistance values involved. It is a voltage ratio only. It is used in troubleshooting and other instances where a rough indication of operation is needed, but precise measurement is unimportant. Voltage gain is often used in high-impedance circuits such as pentode vacuum tubes and is also sometimes convenient in solid-state circuits. Its improper usage often creates errors in radio circuit design because many calculations, for correct answers, require power ratios rather than voltage ratios. We will see several examples of this throughout this chapter.

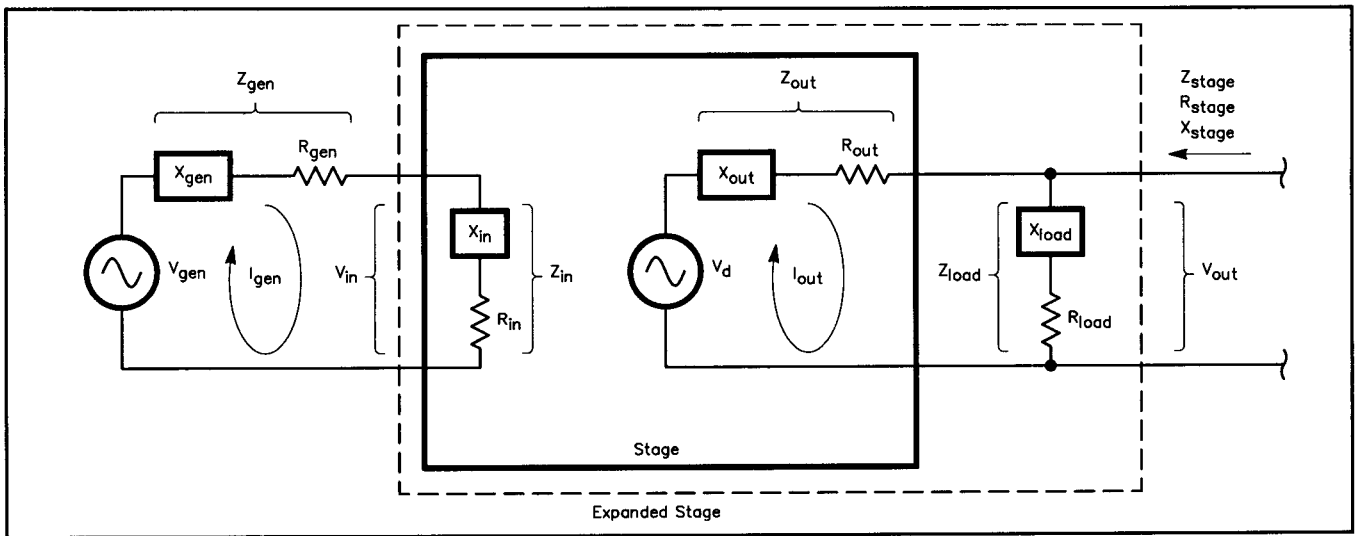

Fig 17.1—A single-stage building-block signal processor. The properties of this stage are discussed in the text.

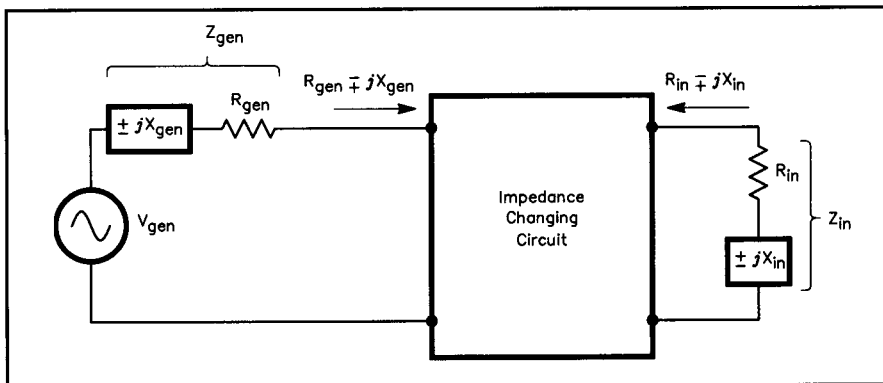

Fig 17.2—The conjugate impedance match of a generator to a stage input. The network input impedance is  $R_{gen} \mp jX_{gen}$  and its output impedance is  $R_{in} \mp jX_{in}$  (where either R term may represent a dynamic impedance). Therefore the generator and the stage input are both impedance matched for maximum power transfer.

### Available Power

The maximum power, in watts, that can be obtained from the generator is  $V_{gen}^2 / (4 R_{gen})$ . To see this, suppose temporarily that  $X_{gen}$  and  $X_{in}$  are both zero. Then let  $R_{in}$  increase from zero to some large value. The maximum power in  $R_{in}$  occurs when  $R_{in} = R_{gen}$  and the power in  $R_{in}$  then has the value mentioned above (plot a graph of power in  $R_{in}$  vs  $R_{in}$  to verify this, letting  $V_{gen} = 1$  V and  $R_{gen} = 50 \Omega$ ). This is called the “available power” (we’re assuming sine wave signals). If  $X_{gen}$  is an inductive (or capacitive) reactance and if  $X_{in}$  is an equal value of capacitive (or inductive) reactance, the net series reactance is nullified and the above discussion holds true. If the net reactance is not zero the current  $I_{gen}$  is reduced and the power in  $R_{in}$  is less than maximum. The process of tuning out the reactance and then transforming the resistance of  $R_{in}$  is called “conjugate

matching.” A common method for doing this conjugate matching is to put an impedance transforming circuit of some kind, such as a transformer or a tuned circuit, between the generator and the stage input that “transforms”  $R_{in}$  to the value  $R_{gen}$  (as seen by the generator) and at the same time nullifies the reactance. Fig 17.2 illustrates this idea and later discussion gives more details about these interstage networks. A small amount of power is lost within any lossy elements of the matching network.

This same technique can be used between the output of the stage in Fig 17.1 and the load impedance  $Z_{load}$ . In this case, the stage delivers the maximum amount of power to the load resistance. If both input and output are processed in this way, the stage utilizes the generator signal to the maximum extent possible. It is very important to note, however, that in many situations we do not want this maximum uti-

lization. We deliberately “mismatch” in order to achieve certain goals that will be discussed later (Ref 1).

### The dBm Unit of Power

In low-level radio circuitry, the watt (W) is inconveniently large. Instead, the milliwatt (mW) is commonly used as a reference level of power. The dB with respect to 1 mW is defined as

$$\text{dBm} = 10 \log (P_W / 0.001) \quad (3)$$

where

dBm = Power level in dB with respect to 1 mW

$P_W$  = Power level, watts.

For example, 1 W is equivalent to 30 dBm. Also

$$P_W = 0.001 \times 10^{\text{dBm}/10} \quad (4)$$

### Maximum Available Power Gain

The ratio of the power that is available from the stage,  $V_d^2 / (4 R_{out})$ , to the power that is available from the generator,  $V_{gen}^2 / (4 R_{gen})$ , is called the maximum available power gain. In some cases the circuit is adjusted to achieve this value, using the conjugate-match method described above. In many cases, as mentioned before, less than maximum gain is acceptable, perhaps more desirable.

### Available Power Gain

Consider that in Fig 17.1 the stage and its output load  $Z_{load}$  constitute an “expanded” stage as defined by the dotted box. The power available from this new stage is determined by  $V_{out}$  and by  $R_{stage}$ , the resistive part of  $Z_{stage}$ . The available power gain is then  $V_{out}^2 / (4 R_{stage})$  divided by  $V_{gen}^2 / (4 R_{gen})$ . This value of gain is used in a number of design proce-

dures. Note that  $Z_{load}$  can be a physical network of some kind, or it may be partly or entirely the input impedance of the stage following the one shown in Fig 17.1. In the latter case it is sometimes convenient to “detach” this input impedance from the next stage and make it part of the expanded first stage, as shown in Fig 17.1, but we note that  $Z_{out}$  is still the generator (source) impedance that the input of the next stage “sees.”

### Transducer Power Gain

The transducer gain is defined as the ratio of the power actually delivered to  $R_{load}$  in Fig 17.1 to the power that is available from the generator  $V_{gen}$  and  $R_{gen}$ . In other words, how much more power does the stage deliver to the load than the generator could deliver if the generator were impedance matched to the load? We will discuss how to use this kind of gain later.

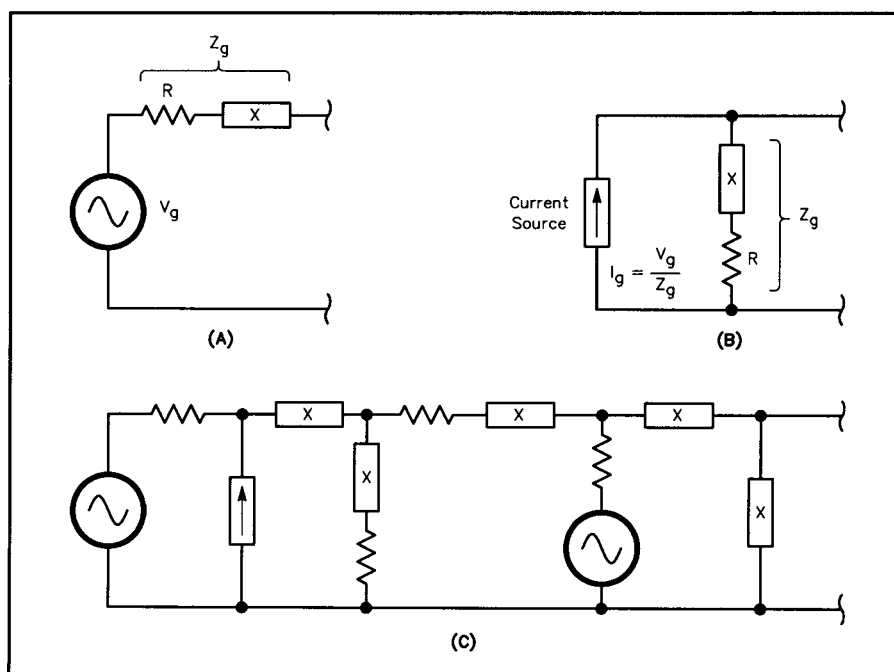

### Transformation Methods

Let’s digress briefly to discuss two valuable techniques that are often used in designing radio circuits. **Fig 17.3A** shows a voltage generator in series with an impedance. **Fig 17.3B** shows how to represent **Fig 17.3A** as a current generator in parallel with the same value of impedance. We can also see how to move from **3B** to **3A**. **Fig 17.3C** shows a complicated network consisting of generators, resistors, capacitors and inductors. At any single frequency, this network can be replaced with a single generator and a single impedance as shown in **Fig 17.3**. The methods for doing this may be learned from a study of ac circuit analysis, and a personal computer math-equation-solving program that handles complex numbers and matrices is a valuable tool for quickly performing these operations over a range of frequencies and plotting the results. There are also simulation programs such as SPICE (which is available under many different brand names and versions) that are very effective and easy to learn and use. Student radio circuit designers should learn these techniques.

### Feedback (Undesired)

One of the most important properties of the single-stage building block in Fig 17.1 is that changes in the load impedance  $Z_{load}$  cause changes in the input impedance  $Z_{in}$ . Changes in  $Z_{gen}$  also affect  $Z_{out}$ . These effects are due to reverse coupling, within the stage, from output to input. For many kinds of circuits (such as networks, filters, attenuators, transformers and so on) these effects cause no unexpected problems.

But, as the chapter on **Amplifiers** explains in detail, in active circuits such as

**Fig 17.3—Transformations of networks that are useful in radio circuit design.**

amplifiers this reverse coupling within one stage can have a major impact not only on that stage but also on other stages that follow and precede. It is the effect on system performance that we discuss here. In particular, if a stage is expected to have certain gain, noise factor and distortion specifications, all of these can be changed either by reverse coupling (undesired feedback) within the stage or adjacent stages. For example, internal feedback can cause the input impedance of a certain stage “A” (**Fig 17.1**) to become very large. If this impedance is the load impedance for the preceding stage, the gain of the preceding stage can become excessive, creating problems in both stages. This same feedback can cause the gain of stage “A” to become greater, thereby causing the next stage to be driven into heavy distortion. A very common event is that stage “A” goes into oscillation. All of these occurrences are common in poorly designed radio equipment. Changes in temperature and variations in component tolerances are major contributors to these problems.

One particular example is shown in **Fig 17.4**, a transistor amplifier, shown in skeleton form, with sharply tuned resonators at input and output.

Because of reverse coupling, the two tuned circuits interact, making adjustments difficult or even impossible. The likelihood of oscillation is very high. There are two solutions: drastically reduce the gain of the amplifier, or use an amplifier circuit that has very little reverse coupling. Usually, both methods are used si-

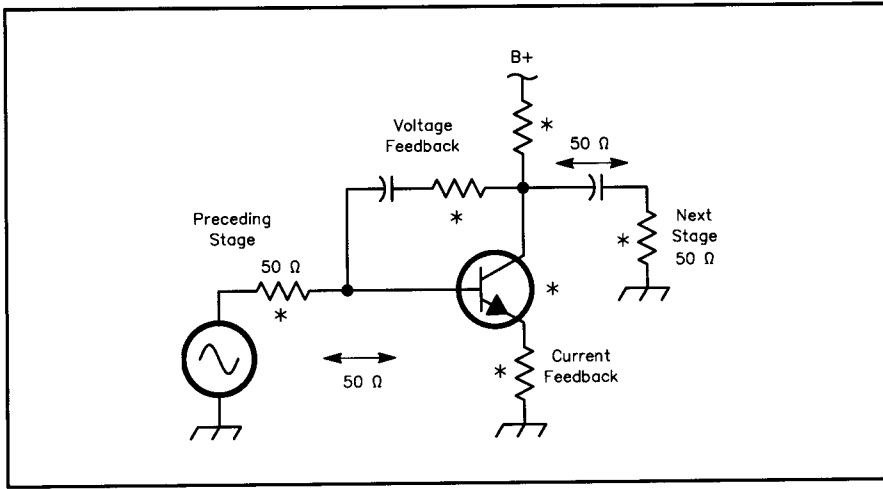

**Fig 17.4—A double tuned transistor amplifier circuit that may be untunable and may oscillate due to excessive amplification and reverse coupling.**

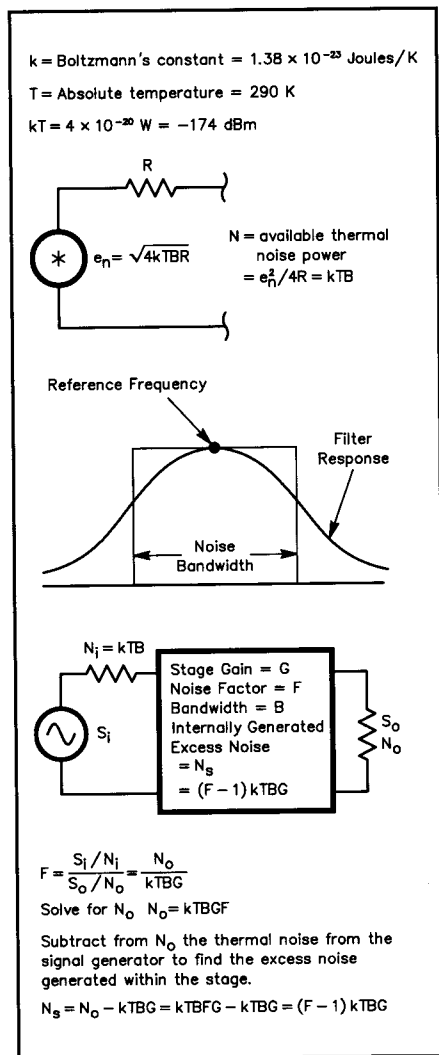

multaneously (in the right amount) in order to get predictable performance. The object lesson for the system designer is that a combination of reduced gain and low reverse coupling is the safe way to go when designing a radio system. More stages may be required, but the price is well worthwhile. The cascode amplifier, grounded-gate amplifier, dual-gate FET and many types of IC amplifiers are examples of circuits that have little reverse coupling and good stability. “Neutralization” methods are used to cancel reverse coupling that causes instability. All such circuits are said to be “unilateral,” which means “in one direction” and both input and output can be independently tuned as in **Fig 17.4** if the gain is not too high.

### Feedback (Desired)

The **Amplifiers** chapter explains how

**Fig 17.5—A cascable amplifier using feedback. The feedback and therefore the amplifier performance depends on the load and driving-stage impedances.**

**Fig 17.6—Diagram and equations that explain  $F$ , the noise factor of a single stage. The excess noise generated within the stage is also indicated. The definition of noise bandwidth is included.**

formers instead of resistors or lossy networks that introduce thermal noise into a system.

## Noise Factor and Noise Figure

The output resistance of the signal generator that drives a typical signal processing block such as shown in Fig 17.5 is a source of thermal noise power, which is a natural phenomenon occurring in the resistive component of any impedance. It is caused by random motion of electrons within a conducting (or semiconducting) material. Note that the reactive part of an impedance is not a source of thermal noise power because the voltage across a pure reactance and the current through the reactance are in phase quadrature ( $90^\circ$ ) at any one frequency. The average value of the product of these two (the power) is zero. If this is true at any frequency, then it is true at all frequencies. Also, a purely “dynamic resistance” such as  $R_e$ , the dynamic resistance ( $\Delta V / \Delta I$ ) of a perfect forward conducting PN junction, is also not a source of thermal noise. However, the junction is a source of “shot noise” power that, by the way, is only 50% as great as the thermal noise that  $R_e$  would have if it were an actual resistor (Ref 2).

Each “\*” in Fig 17.5 indicates a noise source. Passive elements generate thermal noise. Active components such as transistors generate thermal noise and other types, such as shot noise and flicker ( $1/f$ ) noise, internally. These “excess” noises are all superimposed on the signal from the generator. Therefore the noise factor of a single stage is a measure of how much the signal to noise ratio is degraded as signal passes through that stage.

Refer now to the diagram and equations in Fig 17.6.  $F$  is noise factor and  $S_i / N_i$  is the input signal to noise ratio from the signal generator.  $S_o / N_o$  is signal to noise ratio at the output and  $kTB$  is the thermal noise power that is available from any value of resistance ( $kT = -174 \text{ dBm}$  in a 1-Hz bandwidth at room temperature).  $G$  is  $S_o / S_i$ , the available power gain of the stage and  $B$  is the noise bandwidth at the output of the stage, assumed to be not wider than the noise bandwidth at the input. The case where the output noise bandwidth is wider will be considered in a later section.

Noise bandwidth is defined in Fig 17.6. An ideal rectangular frequency response has a maximum value that is defined at the reference frequency. The area under the rectangle is the same as the area under the actual filter response, therefore the noise within the rectangle and within the actual filter response are equal. The width of the rectangle is called the noise bandwidth. Various kinds of filters have certain ratios of signal bandwidth to noise bandwidth

negative feedback (good feedback) can be used to stabilize a circuit and make it much more predictable over a range of temperature and component tolerances. Here we wish to point out some system implications of negative feedback. One is that the gain, noise-figure and distortion performances within a stage are made much more constant and predictable. Therefore a system designer can put building blocks together with more confidence and less guesswork.

There are some problems, though. In some circuits the amount of feedback depends on both the output impedance of the driving circuit and the input impedance of the next stage. A classic example is the cascable amplifier shown in Fig 17.5.

In this circuit, if the output load impedance becomes very low the amplifier input impedance becomes high, and vice versa (a “teeter-totter” effect). Other amplifier properties also can change. With amplifiers of this type it is important to maintain the correct impedances at the input and output interfaces. Any building block should be examined for effects of this kind. Data sheets frequently specify the reverse transfer values as well as those for forward transfer. Often, lab measurements are needed. Apply a signal to the output and measure the reverse coupling to the input. Where varying load and source impedances are involved, look for a circuit that is less vulnerable (that is, has less reverse coupling).

Another problem is that feedback networks often add thermal noise sources to a circuit and so degrade its noise figure. In systems where this is a consideration, use so-called “loss-less feedback” circuits. These circuits use very efficient trans-

that can be measured or calculated.

Part of the output noise is amplified thermal noise from the signal generator. To find the noise that is generated within the stage, we must subtract the amplified signal generator noise from the total output noise. Fig 17.6 shows the equation that performs this operation and the quantity (F-1)kTBG is the excess noise that the stage contributes.

In general, the excess noise of a stage is the output noise minus the amplified noise from the previous stage. A thorough understanding of this concept is very important for any one who designs radio systems that employ low-level signals. Finally, noise figure, NF, is 10 times the logarithm of F, the noise factor (Ref 3).

### Noise Factor of a Passive Device

Often the stage in Fig 17.6 is a filter, an attenuator or some other passive device (no amplification) that contains only thermal noise sources. In a device of this kind, the output noise is thermal noise of the same magnitude as the thermal noise of the generator alone. That is, using the method of Fig 17.3, all the thermal noise sources inside the device and also the generator resistance can be combined into a single resistor whose available noise power is kTB, the same as that of the generator alone. Therefore no additional noise is added by the device. But the available signal power is reduced by the attenuation (loss of signal) of the device. Therefore, using the equation for noise factor in Fig 17.6, the noise factor F of the device is numerically equal to its attenuation. For example, a 3-dB attenuator has a 3-dB noise figure, or a noise factor of 2. This important fact is very useful in radio design. It applies only when there is no amplification and no shot noise or 1/f noise sources within the device. This discussion assumes that all components and the generator are at the same temperature. If not, a slightly more complicated procedure involving Equivalent Noise Temperatures ( $T_E$ ), to be discussed later in this chapter, can be used.

### Sensitivity

Closely related to the concept of noise figure (or noise factor) is the idea of sensitivity. Suppose a circuit, a component or a complete system has a noise figure NF (dB) and therefore a noise output  $N_o$  (dBm). Then the value in dBm of a signal generator input that increases the total output (signal + noise) by 10 dB is defined as the "sensitivity." That is,  $10 \times \log[(\text{signal} + \text{noise}) / (\text{noise})] = 10$  dB. The ratio (signal) / (noise) is then equal to 9.54 dB ( $=10 \times \log(9)$ ).  $N_o$  is equal to

kTBFG as shown in Fig 17.6. B is noise bandwidth. Using this information, the sensitivity is

$$S \text{ (dBm)} = -174 \text{ (dBm)} + 9.54 \text{ (dB)} + \text{NF (dB)} + 10 \log(B) \text{ (dB)} \quad (5)$$

In terms of the "open circuit voltage" from a 50-Ω signal generator (twice the reading of the generator's voltmeter) the sensitivity is

$$E \text{ (volts open circuit)} = 0.4467 \times 10^{S/20} \quad (6)$$

$N_o$  is 9.54 dB below the sensitivity value. This is sometimes referred to in specifications as the "noise floor." The signal level that is equal to the noise floor is sometimes referred to as the minimum detectable signal (MDS). Also associated with  $N_o$  is the concept of "noise temperature" which we discuss later under Micro-wave Receivers (Ref 3).

### Distortion in a Single Stage

Suppose the input to a stage is called X. If the stage is perfectly linear the output is Y, and  $Y = AX$ , where A is a constant of proportionality. That is, Y is a perfect replica of X, possibly changed in size. But if the stage contains something nonlinear such as a diode, transistor, magnetic material or other such device, then  $Y = AX + BX^2 + CX^3 + \dots$ . The additional terms are "distortion" terms that deliver to the output artifacts that were not present in the generator. Without getting too mathematical at this point, if the input is a pure sine wave at frequency f, the output will contain "harmonic distortion" at frequencies 2f, 3f and so on. If the input contains two signals at f1 and f2, the output contains *intermodulation distortion* (IMD) products at f1 + f2, f1 - f2, 2f1 + f2, 2f2 - f1, just to name a few. All semiconductor, vacuum tubes and magnetic materials create distortion and the radio designer's job is to limit the distortion products to acceptable levels. We wish to look at distortion from a system-design standpoint.

There are several ways to reduce distortion. One is to use a high-power device operated well below its maximum ratings. This leads to devices that dissipate more power in the form of heat. Unfortunately, these devices also tend to be noisier; so high power levels and low noise tend to be incompatible goals in most cases. (Some modern devices, such as certain GaAsFETs, achieve improved values of dynamic range.) Also, a large reduction in distortion is not always assured with this method, especially in transmitters.

Second, reduce the signal level into the device. This allows a lower power device

to be used that will tend to be less noisy. To get the same output level, though, we must increase the gain of the stage. Then we run into another problem: if the signal at the output of this lower power stage becomes too large, distortion is generated at the output. Also, as mentioned before, high-gain stages tend to be unstable at RF.

Third, reduce the stage gain. But then we must add another stage in order to get the required output level. This additional stage turns out to be a high-power stage. The addition of another stage adds more noise and distortion contamination to the signal.

Fourth, use negative feedback. This is a powerful technique that is discussed in detail in the **Amplifiers** chapter. In general, if we increase the stage gain and perhaps make it more powerful, we can use feedback to reduce distortion and stabilize performance with respect to component variations. The feedback stage may be noisier, although the use of loss-less feedback can improve this situation. Negative feedback is the preferred method for reducing distortion in radio design, but the gain reduction due to feedback means that more stages are needed. This tends to reintroduce some noise and distortion.

A fifth way reduces distortion by increasing selectivity. For example, harmonics of an RF amplifier can be eliminated by a tuned circuit. Products such as f1 + f2 and f1 - f2 can often also be eliminated. Third-order products such as 2f1 - f2 and so on (and higher odd-order products), frequently are sufficiently close to f1 and f2 that selectivity does not help much, but if they are somewhat removed in frequency these so-called "adjacent channel" products can be greatly reduced.

A sixth way is to use push-pull circuits (see **Amplifiers** chapter) that tend to greatly reduce "even-order" products such as 2f, 4f, f1 + f2, f1 - f2, and so on. But "odd-orders" such as 3f, 5f, 2f1 + f2, 2f1 - f2 are not reduced by this method except as noted later in the Modules in Combination section.

A seventh way uses diplexers to absorb undesired harmonics or other spurious products.

So there are compromises to be made. The designer must look for the compromise that gets the job done in an acceptable manner and is optimal in some sense. For example, devices are available that are optimized for linearity.

### IMD Ratio

If a pair of equal-amplitude signals creates IMD products, the IMD ratios (IMR)

**Fig 17.7—A: IMD ratio (as displayed on a spectrum analyzer), and B: intercept point.**

are the differences, in dB, between each of the two tones and each of the IMD products (see Fig 17.7).

### Intercept Point

The intercept point is a figure of merit that is commonly used to describe the IMD performance of an individual stage or a complete system. For example, third-order products increase at the rate of 3:1. That is, a 1-dB increase in the level of each of the two-tone input signals produces (ideally, but not always exactly true) a 3 dB increase in third-order IMD products. As the input levels increase, the distortion products seen at the output on a spectrum analyzer could catch up to, and equal, the level of the two desired signals, if the circuit did not go into a limiting process (see next topic). The input level at which this occurs is the input intercept point. Fig 17.7 shows the concept graphically, and also derives from the geometry an equation that relates signal level, distortion and intercept point. A similar process is used to get a second-order intercept point for second-order IMD. These formulas are very useful in designing radio systems and cir-

**Fig 17.8—The definitions of spurious-free dynamic range (SFDR) and compression-free dynamic range (CFDR). The derivation yields a very useful equation for SFDR.**

uits. If the input intercept point (dBm) and the gain of the stage (dB) are added the result is an output intercept point (dBm). Receivers are specified by input intercept point, referring distortion back to the receive antenna input. Transmitter specifications use output intercept, referring distortion to the transmit antenna output.

### Gain Compression

The gain of a circuit that is linear and has little distortion products deteriorates rapidly when the instantaneous input or output level reaches a critical point where the peak or trough of the waveform begins to "clip" or "saturate." The 1-dB compression point occurs when the output is 1 dB less than it would be if the stage were still linear. Some circuits do not need to be linear (and should not be linear), and we will look at several examples. In many applications linearity is necessary, especially in SSB receivers and transmitters. The situation for a linear circuit is optimum when the input and output become nonlinear simultaneously. This

means that the gain, bias and load impedance are all properly coordinated. We will study this more closely in later sections.

### Dynamic Range

There is a relationship between noise factor, IMD, gain compression and bandwidth in a building block stage. In general, an active circuit that has a low noise factor tends to have a poor intercept point and vice versa. A well-designed transistor or circuit tries to achieve the best of both worlds. Dynamic range is a measure of this capability. Suppose that a circuit has a third-order input intercept of +10 dBm, a noise factor of 6 dB and a noise bandwidth of 1000 Hz. We want to determine its dynamic range. At a certain level per tone of a two-tone input signal the third-order IMD products are equal to the noise level in the 1000-Hz band. The ratio, in dB, of each of the two tones to the noise level is called the "spurious free dynamic range" (SFDR). Fig 17.8 illustrates the problem and derives the proper formula. Note that

the bandwidth is an important player. For the example above, the dynamic range is  $DR = 0.67(10 - (-174 + 10 \log(1000) + 6)) = 99 \text{ dB}$ . Often the dynamic range is calculated using a 1.0-Hz bandwidth. This is called "normalization." Another kind of dynamic range compares the 1-dB compression level with the noise level. This is the CFDR (compression-free dynamic range). Fig 17.8 illustrates this also.

### Modules in Combination

Quite often the performance of a single stage can be greatly improved by combining two identical modules. Because the input power is split evenly between the two modules the drive source power can be twice as great and the output power will also be twice as great. In transmitters, especially, this often works better than a single transistor with twice the power rating. Or, for the same drive and output power, each module need supply only one-half as much power, which usually means better distortion performance. Often, the total number of stages can be reduced in this manner, with resulting cost savings. If the combining is performed properly, using hybrid transformers, the modules interact with each other much less, which can avoid certain problems. These are the system-design implications of module combining.

Three methods are commonly used to combine modules: parallel ( $0^\circ$ ), push-pull ( $180^\circ$ ) and quadrature ( $90^\circ$ ). In RF circuit design, the combining is often done with special types of "hybrid" transformers called splitters and combiners. These are both the same type of transformer that can perform either function. The splitter is at the input, the combiner at the output. We will only touch very briefly on these topics in this chapter and suggest that the reader consult the **Amplifiers** chapter and the very considerable literature for a deeper understanding and for techniques used at different frequency ranges. Fig 17.9 illustrates one example of each of the three basic types.

In a  $0^\circ$  hybrid splitter at the input the tight coupling between the two windings forces the voltages at A and B to be equal in amplitude and also equal in phase if the two modules are identical. The  $2R$  resistor between points A and B greatly reduces the transfer of power between A and B via the transformer, but only if the generator resistance is closely equal to  $R$ . The output combiner separates the two outputs C and D from each other in the same manner, if the output load is equal to  $R$ , as shown. No power is lost in the  $2R$  resistor if the module output levels are identical.

The  $180^\circ$  hybrid produces push-pull

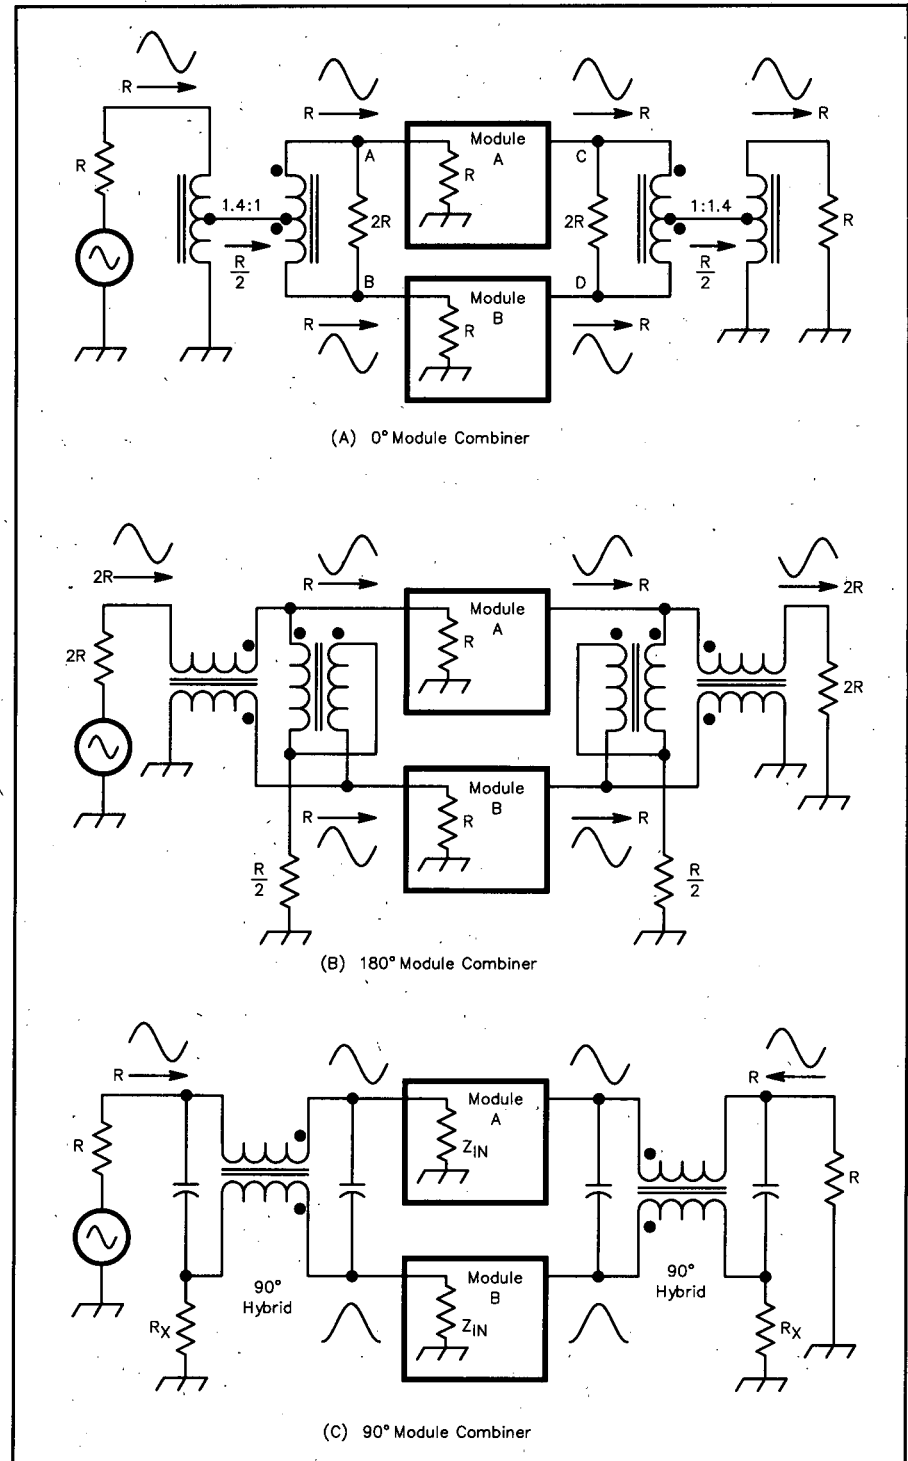

Fig 17.9—The three basic techniques for combining modules.

operation. The advantages of push pull were previously discussed. The horizontal transformers, 1:1 balun transformers, allow one side of the input and output to be grounded. The  $R/2$  resistors improve isolation between the two modules if the  $2R$  resistors are accurate, and dissipate power if the two modules are not identical.

In a  $90^\circ$  hybrid splitter, if the two modules are identical but their identical input

impedance values may not be equal to  $R$ , the hybrid input impedance is nevertheless  $R \Omega$ , a fact that is sometimes very useful in system design. The power that is "reflected" from the mismatched module input impedance is absorbed in  $R_X$ , the "dump" resistor, thus creating a virtual input impedance equal to  $R$ . The two module inputs are  $90^\circ$  apart. At the output, the two identical signals,  $90^\circ$  apart, are com-

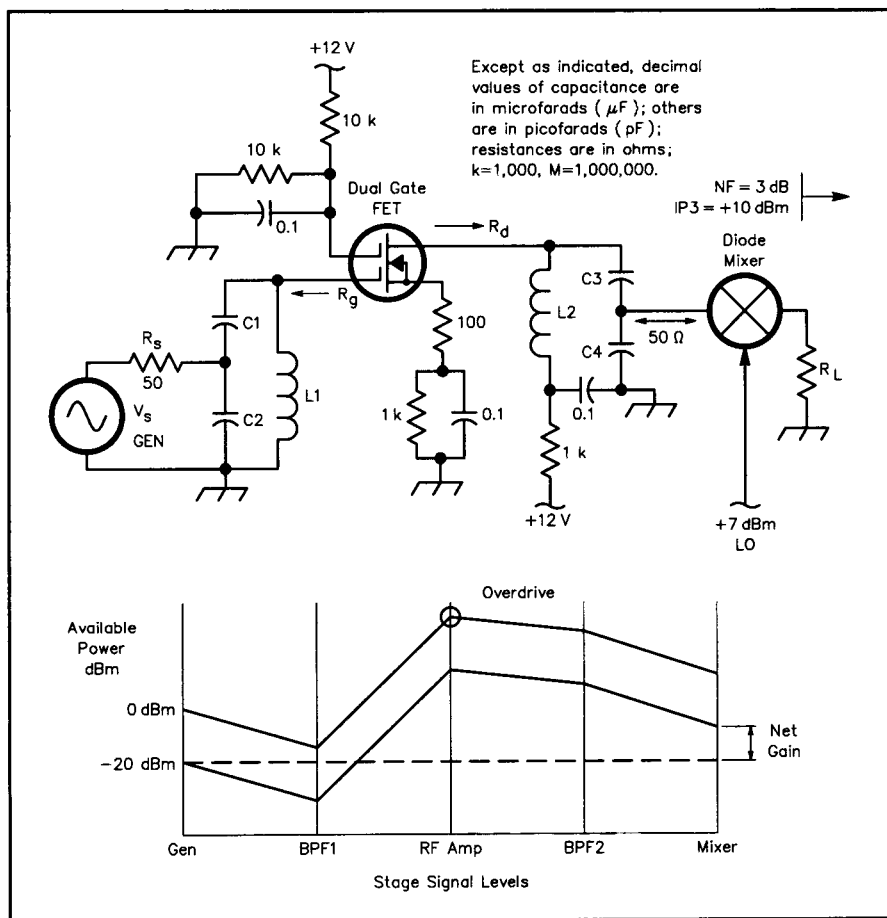

Fig 17.10—An example of cascaded stage design, a simple receiver front end.

bined as shown and the output resistance is also  $R$ . This basic hybrid is a narrowband device, but methods for greatly extending the frequency range are in the literature (Refs 4, 5, 6, 7, 8). One advantage of the  $90^\circ$  hybrid is that catastrophic failure in one module causes a loss of only one half of the power output.

## MULTISTAGE SYSTEMS

As the next step in studying system design we will build on what we've learned about single stages, and look at the methods for organizing several building block circuits and their interconnecting networks so that they combine and interact in a desirable and predictable manner. These methods are applicable to a wide variety of situations. Further study of this chapter will reveal how these methods can be adapted to various situations. We will consider typical receiving circuits and typical transmitting circuits.

## PROPERTIES OF CASCADED STAGES

Fig 17.10 shows a simple receiver "front end" circuit consisting of a

preselector filter, an RF amplifier, a second filter and a double balanced diode mixer. We want to know the gain, bandwidth, noise factor, second and third-order intercept points, SFDR and CFDR for this combination, when the circuitry following these stages has the values shown. Let's consider one item at a time.

### Gain of Cascaded Stages

The antenna tuned circuit L1C1C2 has some resistive loss; therefore the power that is available from it is less than the power that is available from the generator. Let's say this loss is 2.0 dB.

Next, find the available power gain of the RF amplifier. First, note that the generator voltage  $V_s$  is transformed up to a larger voltage  $V_g$  by the input tuned circuit, according to the behavior of this kind of circuit. This step-up increases the gain of the RF amplifier because the FET now has a larger gate voltage to work with. (A bit of explanation: The FET has a high input impedance therefore, since the generator resistance  $R_s$  is only  $50\Omega$ , a voltage step-up will utilize the FET's capabilities much better. But an excessive step-up opens up the possibility that the FET and other "downstream" circuits can be

overdriven by a moderately large signal. So this step-up process should not be carried too far). The gain also depends on the drain load resistance, which is the mixer input impedance, stepped up by the circuit L2C3C4. Again, there is some loss within this tuned circuit, say 2.0 dB. If the drain load is too large the FET drain voltage swing can become excessive, creating distortion. The RF amplifier can become unstable due to excessive gain. Note also that the unbypassed source resistor provides negative feedback, to help make the RF amplifier more predictable. Dual-gate FETs have relatively little reverse coupling.

We come now to the mixer, whose available gain is about -6 dB. This is the difference between its available IF output power and its available RF input power. This is a fairly low-level mixer, so it can be easily overdriven if the RF gain is too high. Harmonic IMD and two-tone IMD can become excessive (see later discussion in this chapter). On the other hand, as we will discuss later, too little RF gain will yield a poor receiver noise figure.

The concepts of available gain and transducer gain were introduced earlier. If we multiply the available gains of the input filter, RF amplifier, interstage filter and mixer, we have the available gain of the entire combination. The transducer gain is the ratio of the power actually delivered to  $R_L$  to the power that is available from the generator. To get the transducer gain of the combination, multiply the available gain of the first three circuits by the transducer gain of the last circuit (the mixer). This concept may require some thought on your part, but it is one that is frequently used and it adds understanding to how circuits are cascaded. One example, the transducer gain of a receiver, compares the signal power available from the antenna with the power into the loudspeaker (a perfectly linear receiver is assumed).

Fig 17.10 also shows an example of a commonly used graphical method for the available gain of a cascade. The loss or increase of available power at each step is shown. As the input increases the other values follow. But at some point, measurements of linearity or IMD will show that some circuit is being driven excessively, as the example indicates. To improve performance at that point, we may want to make gain changes or take some other action. If the overload is premature, a more powerful amplifier or a higher-level mixer may be needed. It may be possible to reduce the gain of the RF amplifier by reducing the step-up in the input LC circuit or the drain load circuit, but this may degrade noise figure too much. This is where the "optimization" process begins.

the “optimization” process begins.

A method that is often used in the lab is to plot the voltage levels at various points in the system. These voltages are easily measured with an RF voltmeter or spectrum analyzer, using a high-impedance probe. This is a convenient way to make comparative measurements, with the understanding that voltage values are not the same thing as power-gain values, although they may be mathematically related. Many times, these voltage measurements quickly locate excessive or deficient drive conditions during the design or troubleshooting process. Comparisons of measured values with previous measurements of the same kind on properly functioning equipment are used to locate problems.

### Selectivity of Cascaded Stages

The simplified receiver example of Fig 17.10 shows two resonant circuits (filters) tuned to the signal frequency. They attenuate strong signals on adjacent frequencies so that these signals will not disturb the reception of a desired weak signal at center frequency. **Fig 17.11** shows the response of the first filter and also the composite response of both filters at the mixer input.

Consider first the situation at the output of the first filter. If a strong signal is present, somewhat removed from the center frequency, the selectivity of the first filter may just barely prevent excessive signal level in the RF amplifier. When this signal is amplified and filtered again by the second filter, its level at the input of the mixer may be excessive. Our system design problem is to coordinate the amplifier gain and second filter selectivity so that the mixer level is not too great. (A computer simulation tool, such as *ARRL Radio Designer*, can be instructive and helpful.) Then we can say that for that level of undesired signal at that frequency outside the cascade is properly designed.

The decisions regarding the “expected” maximum level and minimum frequency offset of the undesired signal are based on the operating environment for the equipment, with the realistic understanding that occasionally both of these values may be violated. If improvement is needed, it may then be necessary to (a) improve the selectivity, (b) use a more robust amplifier and mixer or (c) reduce amplifier gain. Very often, increases in cost, complexity and system noise factor are the byproducts of these measures.

Cascaded signal filters are often used to obtain a selectivity shape that has a flat top response and rapid or deep attenuation beyond the band edges. This method is often preferred over a single, more complex “brick wall” filter that has a very steep rate of attenuation outside the passband.

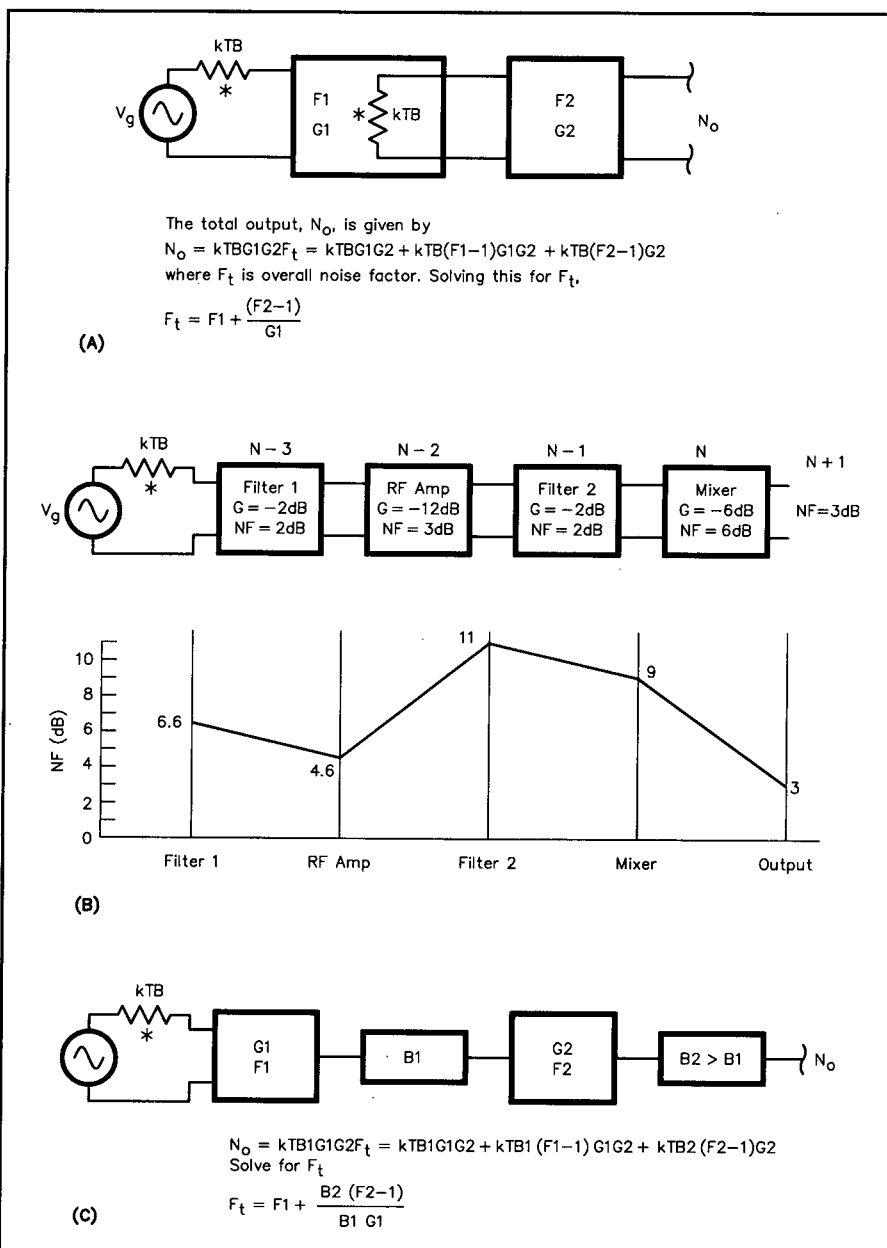

### Noise Factor of a Cascade

In the example of Fig 17.10, the overall noise factor of the two-stage circuit is defined in the same way as for a single stage. It is the degradation in signal-to-noise ratio (S/N) from the signal generator to the output. This total noise factor can be found by direct measurement or by a stage-by-stage analysis. If we wish to optimize the total noise factor or look for trade-offs between it and other things such as gain and distortion, a stage-by-stage analysis is needed.

The definition of noise factor for a single stage applies as well to each stage in the chain. For each stage there is a signal and thermal noise generator, internal sources of

**Fig 17.11—The gain and cumulative selectivity, between the generator and the mixer, of the example circuit in Fig 17.10.**

**Fig 17.12—A: the noise factor of a two-stage network. B: cumulative noise factor for the example in Fig 17.10. C: noise factor when the bandwidth increases toward the output.**

excess noise and a noise bandwidth. In a cascade, the signal and thermal noise sources for a particular stage are found in the previous stage, as shown in **Fig 17.12A**. But this thermal noise source has already been accounted for as part of the excess noise for the previous stage, therefore this thermal noise must not be counted twice in the calculation. On this basis, **Fig 17.12A** derives the formula for the noise factor of a two-stage system. This formula can then be used to find the noise factor of the multisegment system in **Fig 17.12B** by applying it repetitively, first to stage N+1 and N, then to N and N-1, then to N-1 and N-2 and so on, where

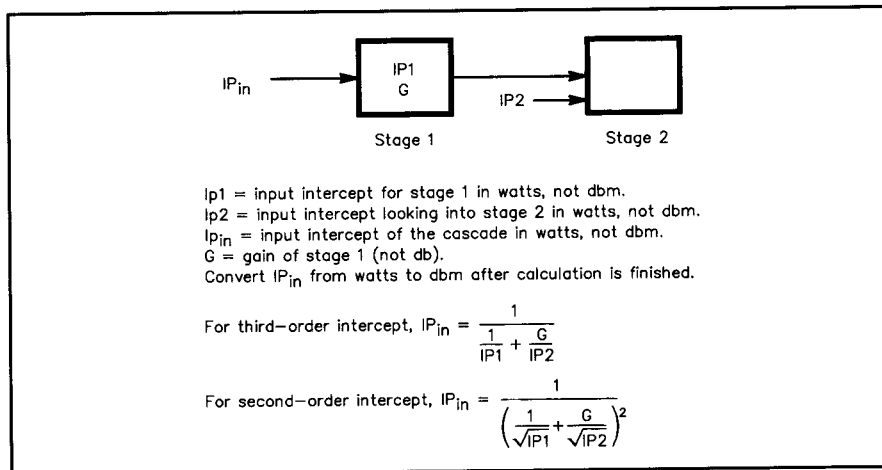

N is the total number of stages and N+1 is the rest of the system after the last stage. **Fig 17.12B** shows the cumulative noise figure (dB) at each point in the example of **Fig 17.10**. The graphical method aids the analysis visually.

Note that the diode mixer's noise figure approximately equals its gain loss. In applying the formula, if G1 is a lossy device, not an amplifier, then F1 equals its attenuation factor and G1 = 1/F1. Also, observe the critical role that values of RF amplifier gain and noise figure play in establishing the overall noise factor (or noise figure), despite the high noise figure that follows it.

In **Fig 17.12A** and **B**, we assumed that the noise bandwidth does not increase toward the output. If the noise bandwidth does increase toward the output a complication occurs. **Fig 17.12C** provides a modified formula that is more accurate under these conditions. This situation is often encountered in practice, as we will see, especially in the discussion of receiver design (Refs 9, 10).

### Distortion in Cascaded Circuits

The IMD created in one stage combines with the distortion generated in following stages to produce a cumulative effect at the output of the cascade. The phase relationships between the distortion products of one stage and those of another stage can vary from 0° (full addition) to 180° (full subtraction). It is customary to assume that they add in-phase as a worst case. Under these conditions, **Fig 17.13** shows how to determine distortion at the input of a stage. Formulas are given for finding the third-order and second-order input intercept points in dBm. These formulas can be applied repetitively, in a manner similar to the noise-factor formula, to get the cumulative intercept point at each stage of the cascade. The output intercept point, in dBm, of a stage is equal to its input intercept point, in dBm, plus the gain, in dB, of the stage. When a purely passive, linear stage is part of the analysis, use a large

**Fig 17.13**—This is how IMD is calculated in cascade circuits.

value of intercept such as 100 dBm ( $10^7$  W, Ref 11).

## Personal Computer Methods of Analysis

The methods of analysis of cascaded gain, noise factor, intercept point and dynamic range that we have described are very tedious when performed manually, especially when the effects of “what if?” value changes in various stages are desired. With the right kind of personal computer software that a home experimenter might be likely to possess, these calculations are performed almost instantaneously and a manual “optimization” process can be performed by the experimenter, using realistic values. In particular, the many available spreadsheet programs that have graph plotting features are very nice for this work. As values are changed, the modified tables and graph plots show up almost immediately. Fig 17.14 illustrates these procedures for the example of Fig 17.10. The calculations are performed by subroutines called “macros.” This particular example uses Microsoft Excel, but several other spreadsheets are available, and they work in a similar manner. When using these methods, keep in mind that changing one value can affect other values. For instance the gain, noise-factor and intercept-point values of an amplifier all interact.

Some experience and skill are required to get real-world results using computer simulations. These methods are now widely used in engineering organizations, and the serious radio experimenter should get “in touch” with these modern techniques and with computers as design tools.

## COUPLING NETWORKS

In radio systems, the design of the transition network between one building block and the next is as important as the design of the blocks themselves. Impedance transformation, frequency response, adjustability and complexity are the main issues to consider. There are two general types of networks:

- Resonant networks with tuned circuits that are centered at some frequency,  $f$ , and cover perhaps no more than  $\pm 0.3 f$ , and
- Broadband networks that cover at least a 2:1 frequency ratio.

Complex multielement filters are treated in the **Filters** chapter. Here we are concerned with simpler networks that, although they may have some selectivity, are used mostly to transform impedances and tune out reactance.

## Resonant Networks

Resonant matching circuits are ex-

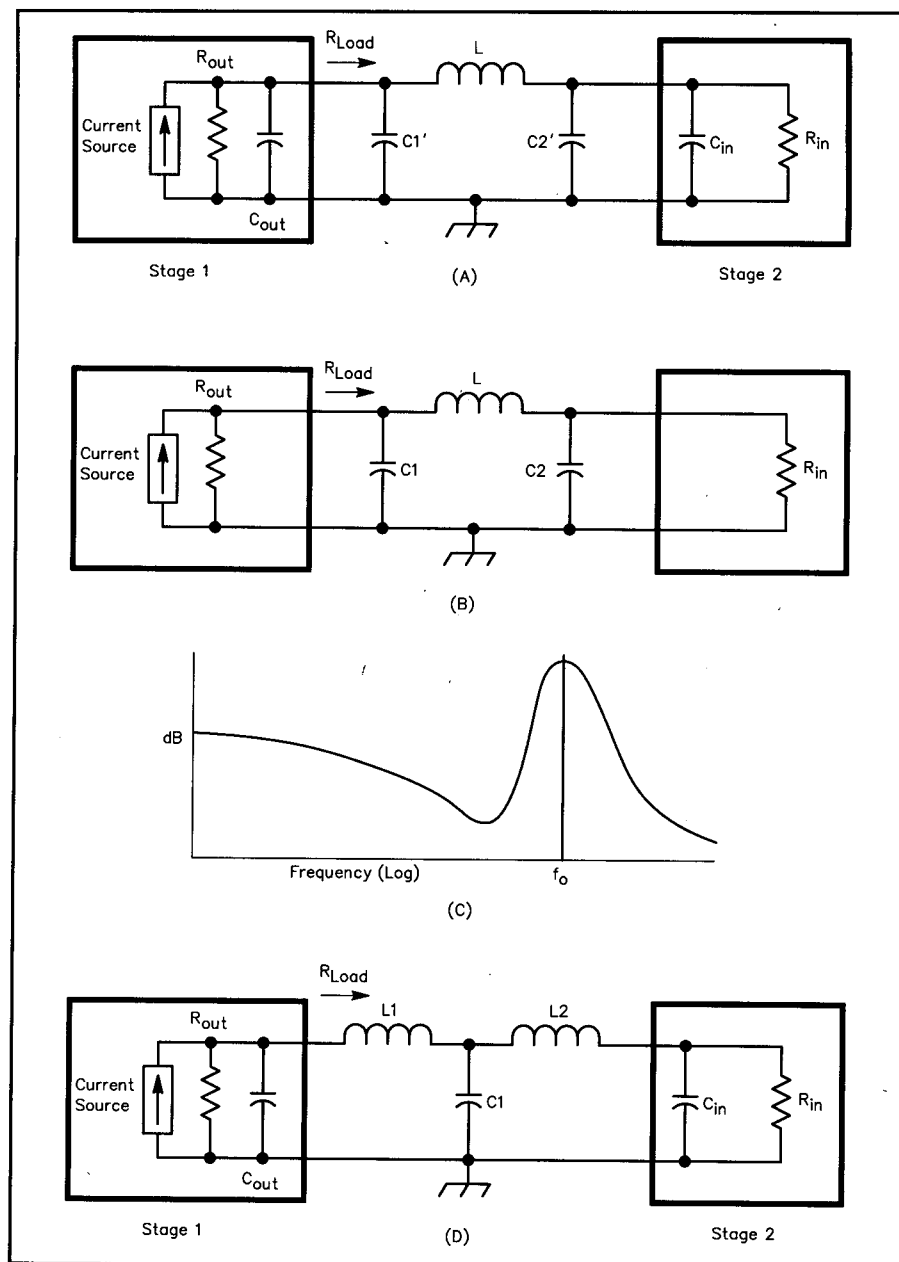

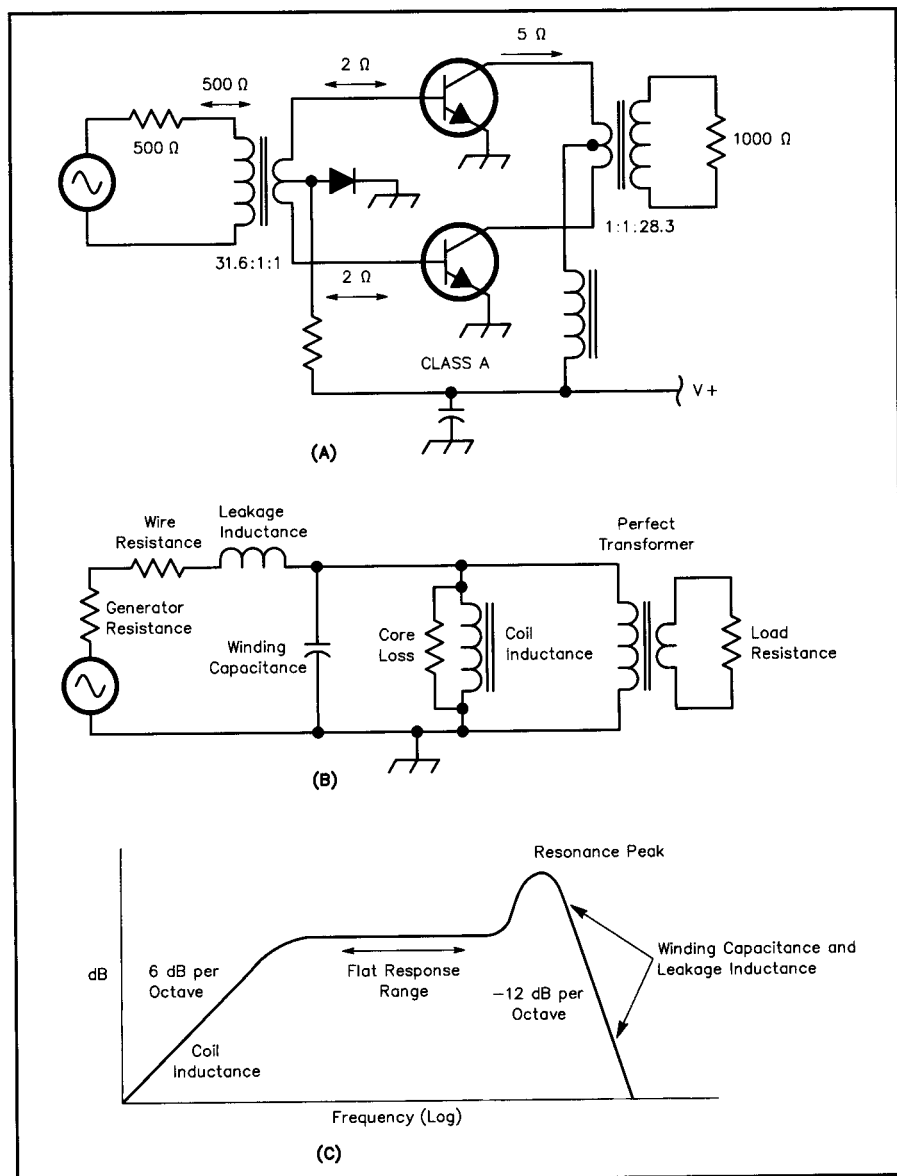

Fig 17.15—A pi network is used to absorb stray C, provide some selectivity and transform impedances at frequency  $f_0$ .

amples of what are called “ladder” networks, consisting of alternating shunt and series elements. Fig 17.15 is one simple and very useful example, the pi network, which we will consider briefly in order to get a general idea of how resonant matching circuits function.

In 17.15A the driver circuit, stage 1, has an output capacitance  $C_{out}$  that we would like to “tune out” or “absorb” into the pi network so that the impedance to ground of stage 1 will be a pure resistance, that is,  $R_{Load}$  in parallel with  $R_{out}$ . The next stage, stage 2, has an input resistance shunted by a capacitance,  $C_{in}$ . We would like to absorb this capacitance into the pi network

also. The pi network then looks like 17.15B. The problem is then to define  $C1$ ,  $L$  and  $C2$  so that the input resistance to the pi network is the desired value of  $R_{Load}$ , which establishes the desired value of gain for stage 1. The procedures for finding these values are given in the **Amplifiers** chapter and the reader is encouraged to study these methods and become competent in their use.

From a system design point of view, we note that the selectivity of the network depends on the values of  $C1$  and  $C2$ . If they are large, the selectivity becomes sharp, perhaps too sharp. The answer is to reduce the C values and if necessary (if

**Fig 17.16—Conventional transformers in an RF power amplifier. Leakage reactances, stray capacitances and core magnetizations limit the bandwidth and linearity, and also create resonance peaks.**

$C_{out}$  and  $C_{in}$  are large) load the network resistively at input or output or both so that the selectivity can be reduced. More complex networks can expand the frequency response and these are also covered in the **Amplifiers** chapter.

Note that Fig 17.15B resembles a conventional three element low-pass filter. The difference is that the values are chosen to get the resonance effect at frequency  $f_0$  (Fig 17.15C) and also the desired impedance transformation at  $f_0$ . These filters, for 2, 4, 6 and so on elements, are known as "Impedance Transforming Chebyshev" filters (Ref 12). For filters with 3, 5, 7 and so on elements, see (Ref 13). The circuit has "low-pass" properties, as seen in Fig 17.15C. With shunt inductors and series capacitance, the response of Fig

17.15C would be reversed, left to right, and would have "high-pass" properties.

Another frequently used simple ladder network has a "T" configuration, shown in Fig 17.15D. It is preferred for certain applications and is discussed in detail later in this chapter under "Network Equations." Also, the tuned circuits in Fig 17.4 and Fig 17.10 are ladder networks of a slightly different kind, shown in a slightly different way. Knowledge in depth of tuned ladder networks, with the aid of the Smith Chart and the *ARRL MicroSmith* Chart software, is a valuable resource for the radio circuit designer (Refs 14, 15).

### Broadband Transformers

The most important broadband imped-

ance transforming device is the transformer. We will briefly consider two types: the so-called "conventional" transformer and the transmission-line transformer. Here we briefly review the merits and shortcomings of each, but this subject is so large and complex that we must defer to other chapters and the references for the most part. We are mainly interested in some frequently encountered examples of how transformers are used to solve radio system-design problems.

### Conventional Transformers

Fig 17.16 shows a push-pull amplifier that we will use to point out the main properties and the problems of conventional transformers. The medium of signal transfer from primary to secondary is magnetic flux in the core. If the core material is ferromagnetic then this is basically a nonlinear process that becomes increasingly nonlinear if the flux becomes too large or if there is a dc current through the winding that biases the core into a nonlinear region. Nonlinearity causes harmonics and IMD. Push-pull operation eliminates the dc biasing effect if the stage is symmetrical. The magnetic circuit can be made more linear by adding more turns to the windings. This reduces the ac volts per turn, increases the reactance of the windings and therefore reduces the flux. For a given physical size, however, the wire resistance, distributed capacitance and leakage reactance all tend to increase as turns are added. This reduces efficiency and bandwidth. Higher permeability core materials and special winding techniques can improve things up to a point, but eventually linearity becomes more difficult to maintain. Fig 17.16B is an approximate equivalent circuit of a typical transformer. It shows the leakage reactance and winding capacitance that affect the high-frequency response and the coil inductance that affects the low-frequency response. Fig 17.16C shows how these elements determine the frequency response, including a resonance peak at some high frequency.

The transformers in a system are correctly designed and properly coordinated when the total distortion caused by them is at least 10 dB less than the total distortion due to all other nonlinearities in the system. Do not over-design them, in relation to the rest of the equipment. During the design process, distortion measurements are made on the transformers to verify this.

The main advantage of the conventional transformer, aside from its ability to transform between widely different impedances over a fairly wide frequency band, is

the very high resistance between the windings. This isolation is important in many applications and it also eliminates coupling capacitors, which can sometimes be large and expensive.

In radio circuit design, conventional transformers with magnetic cores are often used in high-impedance RF/IF amplifiers, in high-power solid-state amplifiers and in tuning networks such as antenna couplers. They are seldom used any more in audio circuits. Hybrid transformers, such as those in Fig 17.9, are often "conventional."

## Transmission-Line Transformers

A transmission line, consisting of two parallel or concentric (coaxial) conductors separated by a dielectric, is a self-contained system. That is, an electric field and a magnetic flux exist between the conductors, and these fields both decay very rapidly everywhere else. In Fig 17.17A, the generator is grounded and the power travels through the transmission line to the load. The load resistance is equal to the characteristic impedance,  $Z_0$ , of the transmission line. The study of transmission lines at high frequencies tells us that the bottom of the load, point D, may not be at ground potential because of the impedance along the length of the line, called the "common-mode impedance," between points A and D (and also between B and C). Points C and D "float" above ground, except at exact multiples of a half wavelength, where the impedances to ground at A and D (or B and C) would be the same.

This ungrounding effect is greatly enhanced over a very wide frequency range by using a high-permeability magnetic material in conjunction with a transmission line that is only a small fraction of a wavelength (at the highest frequency of interest), in the manner shown in Fig 17.17B. The first important feature of this arrangement is that when operated as shown there is almost no magnetic flux in the core; the transmission line does the work. Therefore the common-mode impedance can be made quite large using a relatively small core (or cores). The load is therefore well isolated from ground (it floats). Observe also that any point of the output load resistor can be connected to ground with impunity (except as noted below). Often the center point is grounded as shown in Fig 17.17B.

The second feature is that one or multiple lengths of core-loaded transmission line can be used to design impedance transforming transmission-line transformers that have some very desirable properties. These transformers utilize the prin-

**Fig 17.17—Transmission-line transformers and some of their properties. A:** common-mode impedance along the length of a transmission line. **B:** "loading" the line with ferrite cores helps isolate the load from ground and the generator. **C:** a common-mode voltage appears across the core due to a ground connection at the output. Such common-mode voltages bring Faraday's Law into play. **D and E:** a 4:1 impedance transformer with a common-mode voltage. **F:** an unexpected voltage source causes a common-mode voltage.

ciples of traveling waves in a dielectric medium for their operation. They can operate between any combination of balanced or unbalanced input or output.

The most important property of these transformers is that core magnetization can be greatly reduced, as compared to conventional transformers. Transformers of relatively small size can convey large signals with low loss and low distortion. However, problems due to significant amounts of flux in the magnetic core(s) can occur when there is a return path to ground at the output end, as shown in Fig 17.17B when the optional ground is connected, and also in Fig 17.17C. This grounding is responsible for a common-mode voltage  $V_{cm}$  across the core(s), which in turn increases both magnetic flux in the core(s) and perhaps also dielectric losses in the core(s). The problem also occurs in various transformer connections as shown in Fig 17.17D and E. Flux prob-

lems are most prevalent at the lower end of the frequency range. Power loss in the cores increases and in transmitters core heating becomes a greater problem. An extraneous voltage or current source in the circuit also causes problems as shown in Fig 17.17F. In all of these situations, use cores of sufficient cross-sectional area, winding length and permeability to get the desired common-mode impedance and linearity (Refs 16, 17, 18, 19). Also, methods are often feasible (see References) that reduce the common-mode voltage drops described above. In conclusion, the correct use of transmission-line transformers requires an understanding of the common-mode voltage gradients across the cores and how to deal with them. Note also that the generator "ground" and the load "ground" may be totally unrelated to each other. For example, the load "ground" may be at the top of a tower.

There is a very large collection of litera-

ture on this subject and space does not permit a detailed rundown on every aspect. In particular, the phase lags that occur in the short lengths of transmission lines can sometimes cause certain kinds of problems. The “equal delay” or Guanella design is then used.

Transmission-line transformers usually operate at low impedance levels, require transmission lines of certain  $Z_0$  values (for maximum frequency response) and can be easily built for low ratios of input to output impedance. The literature (also see the **Amplifiers** chapter) shows clever ways to build more complex designs for higher impedance ratios. One variation of the transmission-line transformer discussed in the literature is the “twisted wire” transformer, where the requirement for the exactly correct  $Z_0$  is relaxed and a smaller frequency range is acceptable. These are often easier to build than true transmission-line transformers and, if properly done, will work over two or three octaves (Refs 16, 17, 18, 19). A later section of this chapter gives more details about transmission-line transformers.

## THE AMATEUR RADIO COMMUNICATION CHANNEL

In order to design radio equipment it is first necessary to know what specifications the equipment must have in order to establish and maintain communication. This is a very large and complex subject that we cannot fully explore here, however, it is possible to point out certain properties of the communication channel, especially as it pertains to Amateur Radio, and to discuss equipment requirements for successful communication. The “channel” is:

- the frequency band that is being transmitted and to which the distant receiver is tuned, and
- the electromagnetic medium that conveys the signal.

The Amateur Radio bands are, in fact, a very difficult arena for communications and a severe test of radio-equipment design. The very wide range of received signal levels, the high density of signals whose channels often overlap or are closely adjacent, the relatively low power levels and the randomness (the lack of formal operating protocols) are the main challenges for Amateur Radio equipment designers. An additional challenge is to design the equipment for moderate cost, which often implies technical specifications that are somewhat below commer-

cial and military standards. These relaxed standards sometimes add to the amateur’s problems.

## Received Noise Levels

There are three major sources of noise arriving at the receive antenna,

- atmospheric noise generated by disturbances in the Earth’s environment,
- galactic noise from outer space and
- noise from transmitters other than the desired signal.

Let’s briefly discuss each of these kinds of noise.

Atmospheric noise (including man-made noise) is maximum at frequencies below 10 MHz, where it has *average* values about 40 dB above the thermal noise at 290 K ( $K = \text{Kelvins}$ , absolute temperature). Above 10 MHz, its strength decreases at 20 dB per *octave*. At VHF and above, it is of little importance (Ref 20). However, various studies have found that at certain times and locations and in certain directions this noise approaches the level of thermal noise at 290 K, even at the lower frequencies. Therefore the conventional wisdom that a low receiver noise figure is not important at low HF is not completely true. Amateurs, in particular, exploit these occurrences, and most amateur HF receivers have noise figures in the 8 to 12-dB range for this reason, among others. A very efficient antenna at a low frequency can modify this conclusion, though, because of its greater signal and noise gathering power (for example, a half-wave dipole gathers about 12 dB more power at 1.8 MHz than a half-wave dipole at 30 MHz (Ref 21)). When the noise level is high, an attenuator in the antenna lead can reduce receiver vulnerability to strong interfering signals without reducing the S/N ratio of weaker signals. In other words, the system (that is, receiver plus noisy antenna) dynamic range is improved (the receiver intercept point increases and the system noise is reduced). The antenna noise, after attenuation, should be several dB above the receiver internal noise. This is a typical example of a communication-link design consideration that may not be necessary if the receiver is of high quality.

## Receive Antenna Directivity

If the receive antenna has gain, and can be aimed in a certain direction, it often happens that atmospheric noise is less in that direction. A lower receiver noise figure may then help. Or, if the noise arrives uniformly from all directions but the desired signal is increased by the antenna gain, then the S/N ratio is increased. That

is, the noise is constant but the signal is greater. (Explanation: if the noise is the same from all directions the high-gain antenna receives more noise from the desired direction but rejects noise from other directions; therefore the total received noise tends to remain constant.) This is one of the advantages of the HF rotary beam antenna. The same gain can also cause strong undesired signals to challenge the receiver’s dynamic range (or null out an undesired signal).

## Galactic Noise

The *average* noise level from outer space is about 20 dB above that of thermal noise at 20 MHz and decreases at about 20 dB per *decade* of frequency (Ref 20). But at microwave frequencies, high-gain antennas with very-low-noise-figure receivers are able to locate sources of relatively intense (and very low) galactic noise. Amateurs working at microwave frequencies up to 10 GHz go to great lengths to get their antenna gains and receiver sensitivities good enough to take advantage of the high and low noise levels.

## Transmitter Noise

**Fig 17.18A** shows the spectral output of a typical amateur transmitter. The desired modulation lies within a certain well defined bandwidth, which is determined by the type of modulation. Because of unavoidable imperfections in transmitter design, there are some out-of-band modulation artifacts such as high-order IMD products. The signal filter (SSB, CW and so on) response also has some slope outside the passband. There is also a region of phase noise generated in the various mixers and local oscillators (LOs). These phase noise sidebands are “coherent.” That is, the upper frequency sidebands have a definite phase relationship to the lower frequency sidebands. At higher values of frequency offset, a noncoherent “additive” noise shelf may become greater than phase noise and it can extend over a considerable frequency band. Other outputs such as harmonics and other transmitter-generated spurious emissions are problems.

The general design goals for the transmitter are:

1. Make the unavoidable out-of-band distortion products as small as technology and equipment cost and complexity will reasonably allow,
2. Design the synthesizers and other local oscillators and mixers so that phase noise, as measured in a bandwidth equal to that of the desired modulation, is less than the out-of-band distortion products in goal 1 and,

3. Make the wideband noise sufficiently small that the noise will be less than any unavoidable receiver noise at nearby receivers with the same bandwidth.

If the additive noise is very small, LO phase noise may come back into the picture. In narrowband systems such as Morse code (CW) it can be very difficult or impractical to make transmitted phase noise less than the normal Morse code sidebands (see later discussion on this topic). The general method to reduce wideband noise from the transmitter is to place the narrowband modulation band-pass filter at as high a signal level as possible and to follow that with a high-level mixer and then a low-noise first-stage RF amplifier.

Phase-noise amplitude varies with modulation. That is, the LO phase noise is modulated onto the outgoing signal by the “reciprocal mixing” process (the signal becomes the “LO” and the LO phase noise becomes the “signal”). If the actual LO to phase noise ratio is  $X$  dB, the ratio of the transmit signal to its phase noise is also  $X$  dB. In SSB the magnitude of the phase-noise sidebands is maximum only on modulation peaks. In CW it exists only when the transmitter is “key down.” The additive noise, on the other hand, may be much more constant. If the power amplifiers are Class A or Class AB, additive noise does not require any actual signal and tends to remain more nearly constant with modulation.

In a communication link design, the receiver’s culpability must also be considered. The receiver’s LOs also generate phase noise that is modulated onto an adjacent-channel signal (reciprocal mixing) to produce an in-band noise interference, as shown in Fig 17.18B. In view of this, the transmitter and receiver share equal responsibility regarding phase noise, and there is little point in making either one a great deal better unless the other is improved also. Nevertheless, high-quality receivers with low phase noise exist, and they are vulnerable to transmitter phase noise. The converse situation also exists; receiver phase noise can contaminate a clean incoming signal (Refs 22, 23, 24).

### Receiver Gain and Transmitter Power Requirements

The minimum level of a received signal is a function of the antenna noise level and the bandwidth. As just one example, for an HF SSB system with a 2.0-kHz bandwidth and a noise level 10 dB above thermal (−131 dBm in a 2.0-kHz band) the minimum readable signal, say 3 dB above the noise level, would be −128 dBm. Assume the receiver-generated noise is negligible. If the

**Fig 17.18—A: transmitter spectrum with discrete out-of-band products, phase noise and white noise. B: reciprocal mixing of LO phase noise onto an incoming signal.**

audio output to a loudspeaker is, say +20 dBm (0.1 W), then the total required receiver gain is 148 dB, which is an enormous amount of amplification. For a CW receiver with 200-Hz bandwidth, the minimum signal would be −138 dBm and the gain would be 158 dB. Receivers at other frequencies with lower noise levels can require even higher gains to get the desired audio output level. If the transmission path attenuation can be predicted or calculated, the required transmitter power can be estimated. These kinds of calculations are often done in UHF and microwave amateur work, but less often at HF (see the microwave receiver section for an example).

We do, however, get some “feel” for the receiver gain requirements, how the receiver interacts with the “channel,” and that the minimum signal power is an almost incredibly small  $1.6 \times 10^{-16}$  W. On the other hand, amateur receiver S-meters are calibrated up to an input signal level of −13 dBm (60 dB above 100  $\mu$ V from a 50- $\Omega$  source). Therefore the receiver must deal with a desired signal range of at least 115 dB (128 − 13) for the SSB example or at least 125 dB for the CW example (assuming that AGC limits the signal levels within the receiver).

### Fading

Radio signals very often experience

changes in strength due either to reflections from nearby objects (multipath) or, in the case of HF, to multiple reflections in the ionosphere. At a particular frequency and at a certain time, a signal arriving by multipath may decrease severely. The effect is noticed over a narrow band of frequencies called the “fading bandwidth.” At HF, the center frequency of this fade band drifts slowly across the spectrum. Communication links are degraded by these effects, so equipment design and various communication modes are used to minimize them. For example, SSB is less vulnerable than conventional AM. In AM, loss of carrier or phase shift of the carrier, relative to the sidebands, causes distortion and reduces audio level.

### THE UHF/MICROWAVE CHANNEL

At frequencies above about 300 MHz, we need to account for the interaction of the Earth environment with the transmitted and received signals. Here are some of the things to consider:

1. Line-of-sight communications distance, as a function of receiver and transmitter antenna height.
2. Losses from atmospheric gasses and water vapor (above several gigahertz).
3. Temperature effects on paths: reflec-

tions, refractions, diffractions and transmission “ducts.”

4. Atmospheric density inversions due to atmospheric pressure variations and weather fronts.
5. Tropospheric reflections and scattering.
6. Meteor scattering (mostly at VHF but occasionally at UHF).
7. Receive-antenna sky temperature.

Competitive amateur operators who are active at these frequencies become proficient at recognizing and dealing with these communication channel effects and learn how they affect equipment design. They become proficient at estimating channel performance, including path loss, receive system noise figure (or noise temperature), antenna radiation patterns and gain (Ref 25).

## IMPROVING THE RADIO LINK

Aside from the above considerations, there are many other ways to get better communication. Here are a few of them:

### Automatic Link Evaluation (ALE)

The personal computer has brought about the development of computer-supervised radios that search for a clear frequency that has the right propagation to support communication between two or more distant locations. These also use propagation forecasts. (Refs 26, 27, 28.)

### Automatic Power Level Adjustment

By measuring the received signal level in comparison with noise and interference, it is possible to automatically tell the distant station to adjust power level (Refs 29,30).

### Digital Communication

The use of data transmission and reception equipment, centered around the personal computer, is becoming widespread. Using error correction, redundancy (repeats and acknowledgments) and fast turnaround, very reliable work is being accomplished by amateurs. Special waveforms that are more “robust” for the HF bands have recently been introduced.

### Operator Skill

In any mode of Amateur Radio communication, the operating and technical skills and also the social responsibility of the transmitting and receiving operators are still, and will always be, crucial parts of the communication link. The traditional SSB and CW modes are still very popular and enjoyable (and also effective if properly used), even though they are theoretic-

ally less effective than sophisticated digital modes. In this traditional environment, the operating skills of the individuals are even more important. The point we make in this chapter is that equipment features that enhance the operator’s ability to “get the job done” are important parts of the equipment and system design considerations.

### Repeaters

VHF and UHF communication distances for low-power gear are greatly increased by strategically located repeater stations. The **Repeaters** chapter of this *Handbook* gives more coverage of this very popular technology.

### Spread Spectrum

A few amateurs are experimenting with spread-spectrum techniques. This rapidly expanding technology is being used more and more in military, industrial, commercial and law-enforcement organizations. The rapidly oncoming “information highway,” personal communications service (PCS) and computer-network systems are looking at spread-spectrum methods to improve privacy and effectiveness, especially where many users share the spectrum. Powerful error-correction methods and automatic transmitter power-level management help to reduce information loss due to cochannel interference. (Refs 31, 32.)

### Satellites

Communication over long terrestrial distances using Earth satellite transponders has become a popular mode, due to the pioneering efforts of a group of advanced amateurs over the past 30 years or so.

### Modulation Methods

Quadrature amplitude modulation (QAM) has recently become more popular because of the advent of high-definition television (HDTV). QAM uses several discrete amplitude levels, combined with several discrete phase values, to permit a high information rate within a narrow bandwidth. This has potential for Amateur Radio.

## RECEIVER DESIGN TECHNIQUES

We will now look at the various kinds of receivers that are used by amateurs and at specific circuit designs that are commonly used in these receivers. The emphasis is entirely on analog approaches. Methods that use digital signal processing (DSP) for various signal processing functions are

covered in the **DSP** chapter.

## EARLY RECEIVER DESIGN METHODS

**Fig 17.19** shows some early types of receivers. We will look briefly at each. Each discussion contains information that has wider applicability in modern circuit design, and is therefore not merely of historical interest. A lot of good old ideas are still around, with new faces.

### The Crystal Set

In Fig 17.19A the antenna circuit (capacitive at low frequencies) is series resonated by the primary coil to maximize the current through both, which also maximizes the voltage across the secondary. The semiconductor crystal rectifier then demodulates the AM signal. This demodulation process utilizes the carrier of the AM signal as a “LO” and frequency translates (mixes) the RF signal down to baseband (audio). The rectifier and its output load impedance (the headphones) constitute a loading effect on the tuned circuit. For maximum audio output, a certain amount of coupling to the primary coil provides an optimum impedance match between the rectifier circuit and the tuning circuit. The selectivity is then somewhat less than the maximum obtainable. To improve the selectivity, reduce the secondary L/C ratio and/or decrease the coupling to the primary. Some decrease in audio output will usually result.

This basic mechanism for demodulating an AM signal by using a rectifier is identical to that used in nearly all modern AM receivers. One important feature of this rectifier is a signal level “threshold effect” below which rectification quickly ceases. Therefore the crystal set, without RF amplification, is not very good for very weak signals. Early crystal receivers used large antennas to partially solve this problem, but they were vulnerable to strong signals (their dynamic range was not very good). However, a large antenna does make greater tuner selectivity possible (if needed) because looser coupling can be used in the tuner. That is, the loading of the secondary resonator by the antenna and rectifier can both be reduced somewhat.

There is one other interesting property of this detector. The two AM sidebands add in phase (coherently) at the audio output, but noise above and below the carrier frequency add in random phase (noncoherently). Therefore the detector provides a 3-dB improvement in signal-

to-noise ratio, compared to the signal before detection, when receiving a double-sideband AM signal (Ref 33).

### The Tuned Radio Frequency (TRF) Receiver

Fig 17.19B shows a TRF receiver. One, or possibly many, tuned RF stages are followed by a vacuum-tube implementation of the crystal rectifier (infinite-impedance square-law detector) described in the previous section. The RF amplification overcomes the threshold effect of the detector and the multiple tuned circuits (called “synchronous tuning”), usually isolated from each other by amplifier devices, allow much better selectivity. This selectivity is greatly reduced at the high end of the tuning range because the tuning capacitance becomes small. At the low end of the tuning dial, modulation sidebands may be rolled off or “clipped” due to excessive selectivity. This variation in selectivity, and also in gain, are the TRF’s main drawbacks, which helped popularize the superheterodyne approach. The figure shows triode-tube amplifiers (they could also be three lead transistors: single-gate FETs or bipolar) that are neutralized to prevent self oscillation. This receiver is called a “Neutrodyne.” Multigrid tubes or dual gate FETs do not need neutralization.

### The Regenerative Receiver

Fig 17.19C (with the quench oscillator inactive) is a simple example of a regenerative receiver. The basic principle is that positive RF feedback, via the plate winding, is used to increase the RF gain up to and slightly beyond the point of self oscillation. With no signal, the internal shot and thermal noise peaks and a small bias voltage on the grid capacitor (caused by a very slight grid current) combine to produce a stable and self-limiting oscillation that is similar to the behavior of an ordinary oscillator, except that right at the peak of the oscillation cycle the amplification is extremely large and the detector is therefore very sensitive. The Q of the tuned circuit is greatly increased by the introduction of negative resistance (see the **Oscillators** chapter), but the small grid-current loading limits the increase. With greater or lesser feedback, or if a strong signal appears, the gain and Q drop rapidly.

The self oscillation heterodynes with an incoming CW or SSB signal to produce an audio beat note. The main advantages of the “regen” are the beat note, the absence of a weak-signal threshold effect and amplification. Slightly below the oscillation point,

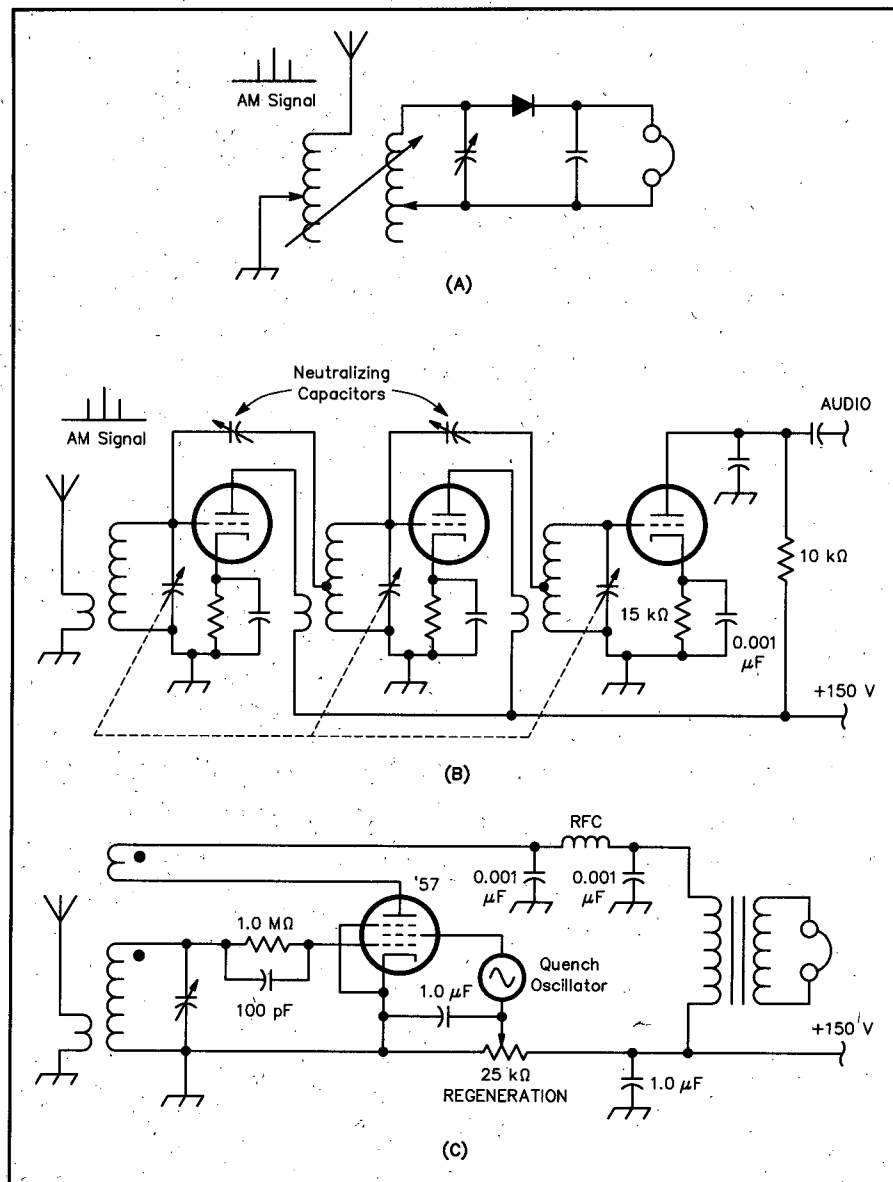

Fig 17.19—Early receiver designs. A: crystal set. B: tuned radio-frequency (TRF) receiver. C, a regenerative receiver.

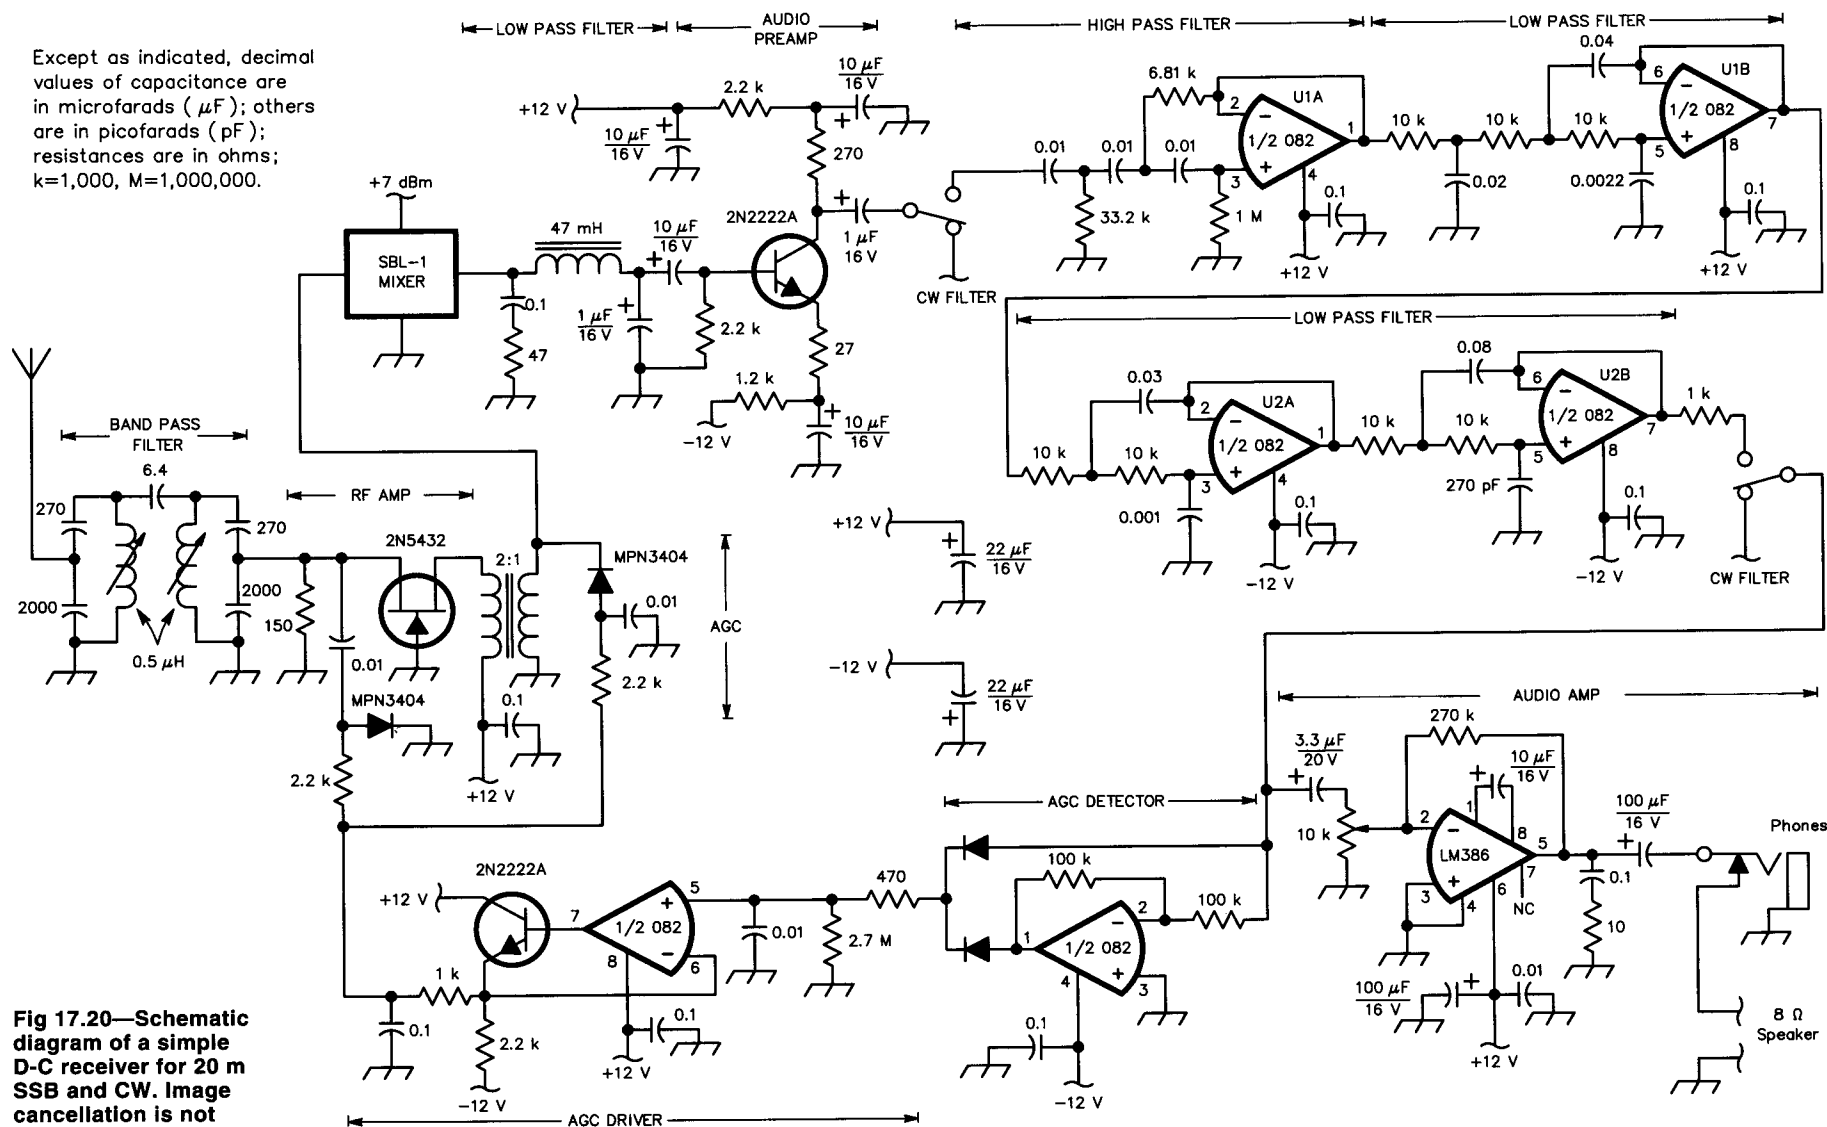

makeshift AM reception is possible. From about 1920 to 1935, the regen was the favorite HF receiver among amateurs. It was the subject of much design and development by them. It also required considerable operating skill (Refs 34, 35).

### The Superregenerative Receiver

Fig 17.19C (with the quench oscillator active) is a simple superregenerative receiver. The idea here is that the output of the 20-kHz quench oscillator modulates the detector and drives it through the point of oscillation and through the point of maximum gain and sensitivity at a super-audible rate. This results in an audio signal that is free of the au-

dible heterodyne that the ordinary regen produces. Therefore, the receiver is more useful for AM or FM voice reception. More technically speaking, the modulation process produces a double-sideband suppressed-carrier signal with two main sidebands,  $F_{sig} \pm F_{osc}$ , plus a wide assortment of lesser sidebands, spurious responses and other artifacts that are difficult (but not impossible) to control. Super regens were used for many years for 30-100 MHz voice reception, where the high ratio of signal frequency to quench frequency made the circuit more manageable. The classic amateur article on this subject by Ross Hull (at ARRL) appears in the July 1931 *QST*. See also any edition of the famous

Except as indicated, decimal values of capacitance are in microfarads ( $\mu\text{F}$ ); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000.

**Fig 17.20—Schematic diagram of a simple D-C receiver for 20 m SSB and CW. Image cancellation is not used, but RF amplification and audio derived AGC are included.**

## MODERN RECEIVER DESIGN METHODS

The superheterodyne and the direct-conversion receiver are the most popular modern receivers and the chief topic of this discussion. Both were conceived in the 1915-1922 time frame. Direct conversion was used by Bell Labs in 1915 SSB experiments; it was then called the "homodyne" detector. E. H. Armstrong devised the superhet in about 1922, but for about 12 years it was considered too expensive for the (at that time) financially strapped amateur operators. The advent of "single signal reception," pioneered by J. Lamb at ARRL, and the gradual end of the Great Depression era brought about the demise of the regenerative receiver. We begin with a discussion of the direct conversion receiver, which has been rediscovered by amateur equipment builders and experimenters in recent years.

### Direct Conversion (D-C) Receivers

The direct conversion (D-C) receiver, in its simplest form, has some similarities to the regenerative receiver :

- The signal frequency is converted to audio in a single step,

- An oscillator very near the signal frequency produces an audible beat note,
- Signal bandwidth filtering is performed at baseband (audio),
- Signals and noise (both receiver noise and antenna noise) on both sides of the oscillation frequency appear equally in the audio output. The image (on the other side of zero beat) noise is an "excess" noise that degrades the noise factor and dynamic range (Ref 36).

There are three major differences favoring the D-C receiver:

- There is no delicate state of regeneration involved. A low-gain or passive mixer of high stability is used instead.
- The oscillator is a separate and very stable circuit that is buffered and coupled to the mixer.
- The D-C (that uses modern circuit design) has much better dynamic range.

The regen has enormous RF gain (and Q multiplication) and therefore little audio gain is needed. The D-C delivers a very low-level audio that must be greatly amplified and filtered. RF amplification, band-pass filtering and automatic gain control (AGC) can be easily placed ahead of the mixer with beneficial results.

An enhancement of the D-C concept can

perform a fairly large reduction of the signal and noise image responses mentioned above. It is a major technical problem, however, to get a degree of reduction over a wide frequency range, say 1.6-30 MHz, that compares with that easily obtainable using superheterodyne methods.

### D-C Receiver Design Example

Fig 17.20 is a schematic diagram of a simple D-C receiver that utilizes all of the principles mentioned above except image rejection. The emphasis is on simplicity for both SSB and CW reception on the 14-MHz band. The LO is standard *Handbook* circuitry and is not shown. Fig 17.21 shows a simple example of an active CW band-pass filter centered at 450 Hz.

The input RF filter shields the receiver from large out-of-ham-band signals and has a noise figure of 2 dB. The grounded-gate RF amplifier has a gain of 8 dB, a noise figure of 3 dB and an input third-order-intercept point of 18 dBm. Its purpose is to improve a 14-dB noise figure (at the antenna input) without the amplifier to about 8.5 dB. It also eliminates any significant LO conduction to the antenna and provides opportunities for RF AGC. The total gain ahead of the mixer is about 6 dB, which degrades the IMD performance of the mixer and subsequent circuitry some-

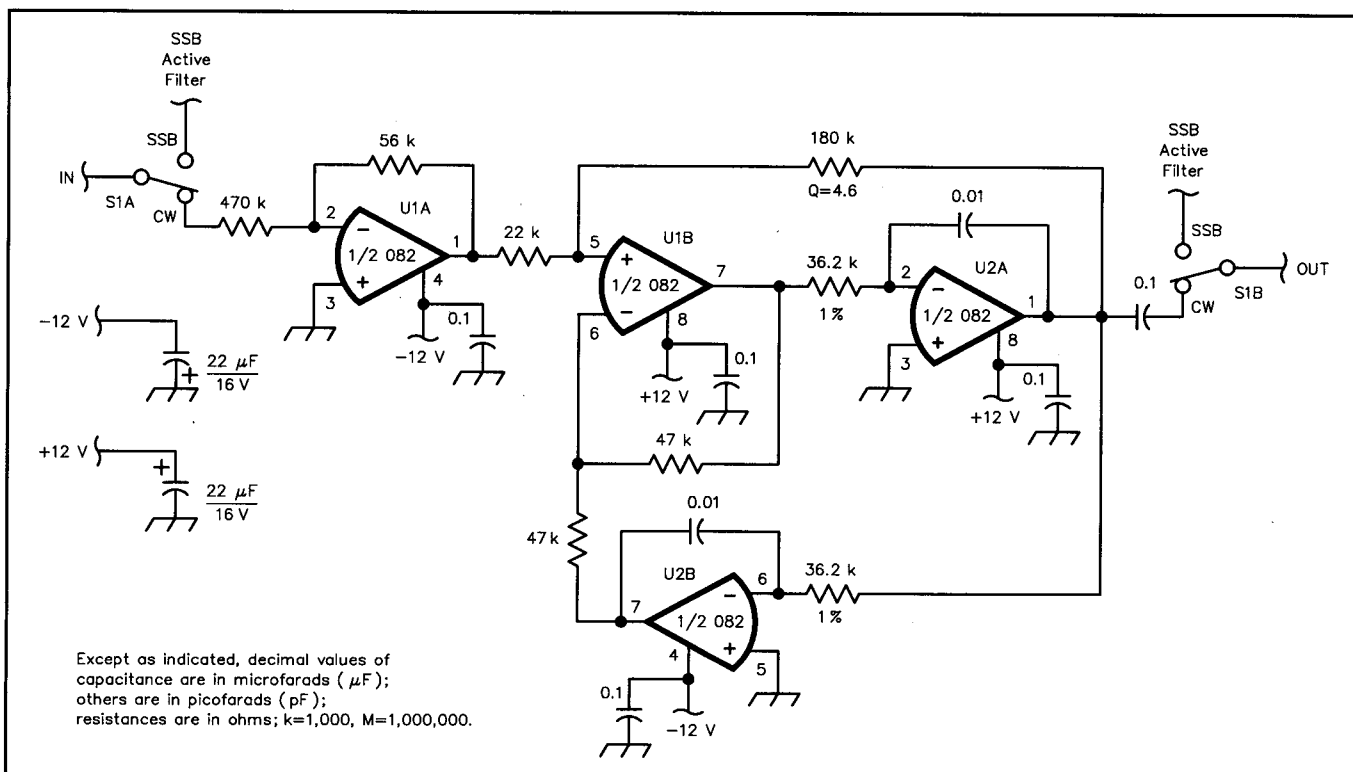

Fig 17.21—Schematic diagram of an active CW band-pass filter for the D-C receiver in Fig 17.20.

what. However, the receiver still has a third-order intercept (IP3) of about 6 dBm for two tones within the range of the audio filter. The IP3 is 11 dBm (quite respect-

able) when one of the two tones is outside the range of the low-pass audio filter that precedes the first audio amplifier. The low-pass filter protects the audio ampli-

fier from wideband signals and noise. The intercept point could be improved by eliminating the RF amplifier, but the antenna input noise figure would then be much worse. This is a common trade-off decision that receiver designers must make.

The above analysis would be correct for a conventional receiver, but in this case there is a small complication that we will mention only briefly. The noise sources ahead of the mixer, both thermal and excess, that are on the image side (the side of the carrier opposite a weak desired signal) are translated to the baseband and appear as an increased noise level at the input of the first audio amplifier. If the SFDR (previously defined) in a 1000-Hz bandwidth were ordinarily 95 dB, using the above numbers, the actual SFDR would be perhaps 2.5 dB less. An image-reject mixer would correct this problem. Observe that the low noise figure of the RF amplifier minimizes the gain needed to get the desired overall noise figure. Also, its good intercept point minimizes strong-signal degradation contributed by the amplifier. The input BPF eliminates problems from second-order IMD. Flicker-effect (1/f) noise in the mixer audio output may also be a problem, which the RF amplification reduces and the mixer design should minimize.

The preceding analysis illustrates the kind of thinking that goes into receiver design. If we can quantify performance in this manner we have a good idea of how well we have designed the receiver.

For the circuit in Fig 17.20 and the numbers given above, the gain ahead of the first audio amplifier is 0 dB. As stated before, this amplifier is protected from wideband interference by the 2-element low-pass audio filter ahead of it, which attenuates at a rate of 12 dB per octave. This filter could have more elements if desired. By minimizing front-end gain, the tendency for the audio stages to overload before the earlier stages do so is mini-

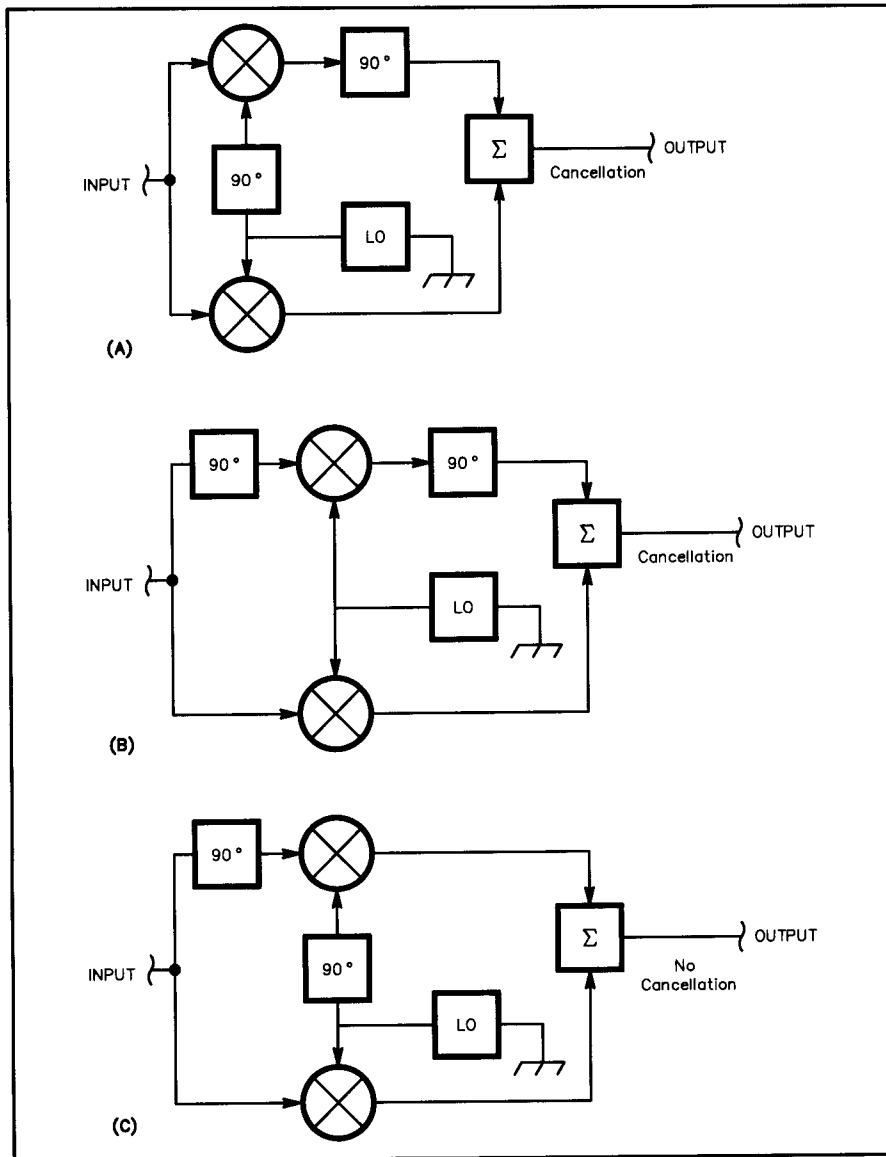

Fig 17.22—Both A and B are workable image cancelling mixer stages. The scheme at C will not cancel image signals.

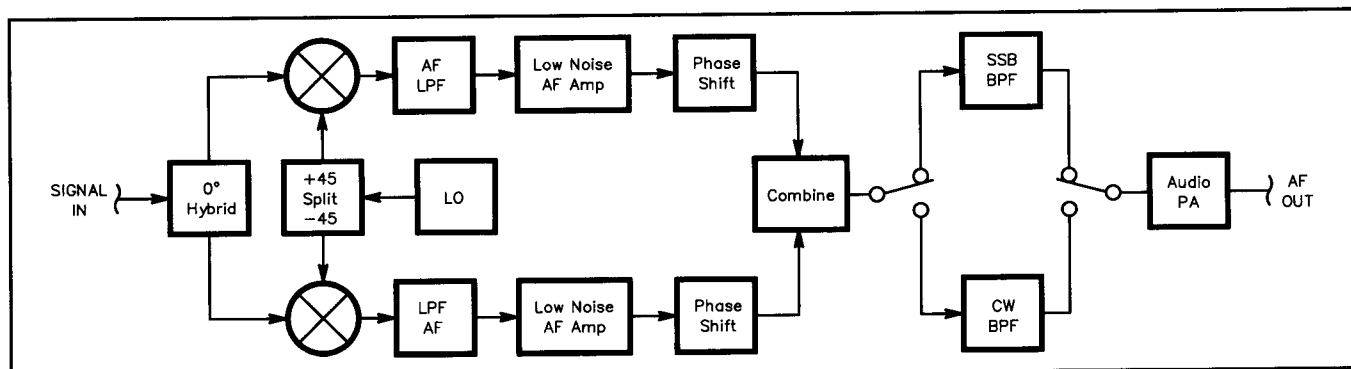

Fig 17.23—Typical block diagram of an image cancelling D-C receiver.

mized—if the audio circuitry is sufficiently “robust.” This should be checked out using two-tone and gain-compression tests on the audio circuits. Audio-derived AGC helps prevent signal-path overload by strong desired (in-band) signals. Additional AGC can be applied in the audio section by using a variable-gain audio op amp (MC3340P).

The audio SSB and CW band-pass filters are simplified active op-amp filters that could be improved, if desired, by using methods mentioned in some of the references. In an advanced design, digital signal processing (DSP) could be used. Good shape factor is the main requirement for good adjacent-channel rejection. Good transient response (maximally flat group delay) would be a “runner-up” consideration. Digital FIR filters and analog elliptic filters are good choices.

### Image Rejection in the D-C Receiver

Rejection of noise and signals on one side of the LO is a major enhancement and also a major complication of the D-C receiver. The Projects segment of this chapter describes one such receiver in detail. Here is an overview of the subject (Refs 37, 38).

**Fig 17.22** shows two correct ways to build an image canceling mixer and one incorrect way. The third way does not perform the required phase cancellations for image reduction. In practice, two  $\pm 45^\circ$  phase shifters are used, rather than one  $90^\circ$  stage. As mentioned before, it is very difficult to get close phase tracking over a wide band of signal and LO frequencies. In amateur equipment, front panel “tweaker” controls would be practical.

The block diagram in **Fig 17.23** is a typical approach to an image-canceling D-C receiver. The two channels, including RF, mixers and audio must be very closely matched in amplitude and phase. The audio phase-shift networks must have equal gain and very close to a  $90^\circ$  phase difference. **Fig 17.24** relates phase error in degrees and amplitude error in dB to the rejection in dB of the opposite (image) sideband. For 30 or 40 dB of rejection, the need for close matching is apparent.

### Audio Phase Shifters

**Fig 17.25A** shows an example of an audio phase-shift network. The stage in 25B is one section, an active “all-pass” network that has these properties:

- The gain is exactly 1.0 at all frequencies and
- The phase shift changes from  $180^\circ$  at very low frequency to  $0^\circ$  at very high frequency.

The shift of this single stage is  $+90^\circ$  at  $f=1/(2\pi RC)$ . By cascading several of these with carefully selected values of RC the set of stages has a smooth phase shift across the audio band. A second set of

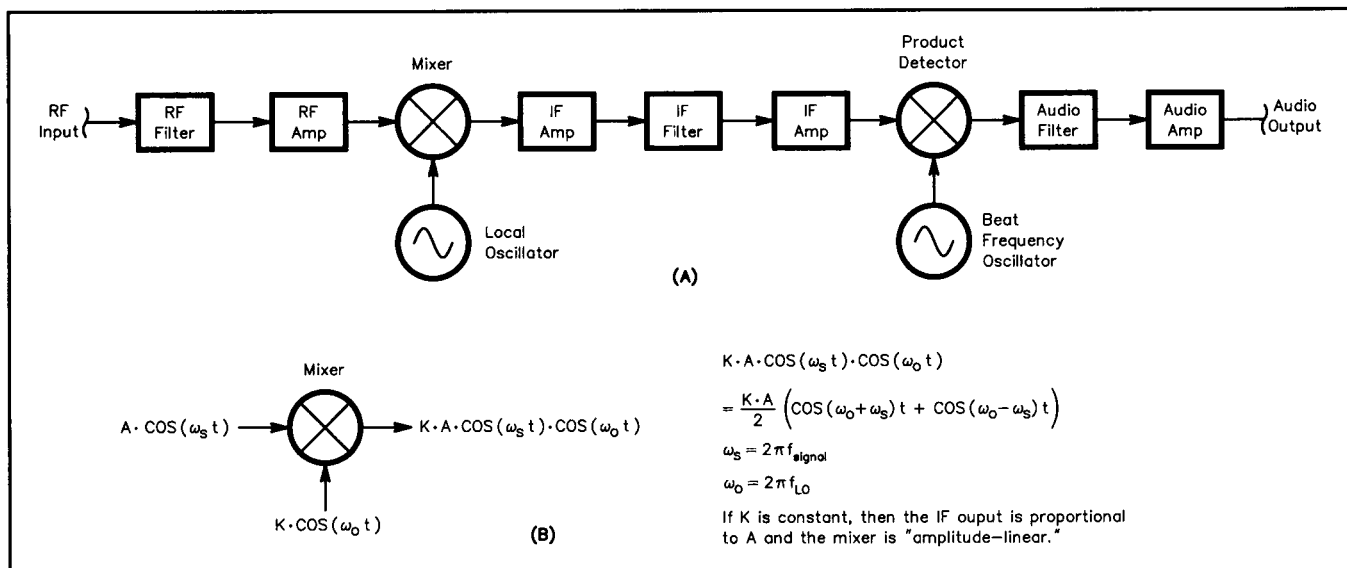

stages is chosen such that the phase difference between the two sets is very close to  $90^\circ$ . The choices of R and C values have been worked out using computer methods; you can also find them in other handbooks

**Fig 17.24—A plot of sideband rejection versus phase error and amplitude unbalance.**

**Fig 17.25—A: an example of an audio phase-shift circuit. B: a single all-pass stage. C: phase error vs audio frequency for a pair of circuits like that in A: with appropriate values of R and C.**

**Fig 17.26—(A) Basic block diagram of a superhet receiver. (B) Showing how the input signal and a constant LO input produce a linear mixing action.**

(Ref 39). Fig 17.25C shows the phase error for two circuits like the one shown in Fig 17.25A. Note the rapid increase in error at very low audio frequencies (an improvement would be desirable for CW work). These frequencies should be greatly attenuated by the audio band-pass filters that follow. The D-C receiver in the Projects section of this chapter uses these circuits.

### D-C Receiver Problem Areas

Because of the high audio gain, microphonic reactions due to vibration of low-level audio stages are common. Good, solid construction is necessary. Another problem involves leakage of the LO into the RF signal path by conduction and/or radiation. The random fluctuations in phase of the leakage signal interact with the LO to produce some unpleasant modulation and microphonic effects. Hum in the audio can be caused by interactions between the LO and the power supply; good bypassing and lead filtering of the power supply are needed. A small amount of RF amplification is beneficial for all of these problems.

## THE SUPERHETERODYNE RECEIVER

### GENERAL DISCUSSION

The superheterodyne ("superhet") method is by far the most widely used approach to receiver and transmitter design. Fig 17.26A shows the basic elements as applied to an SSB/CW receiver, which we will consider first. We will consider a superhet transmitter later in this chapter.

RF from the antenna is filtered

(preselected) by a band-pass filter of some kind to reduce certain kinds of spurious responses and then (possibly) RF amplified. A mixer, or frequency converter circuit, *multiplies* (in the time domain) its two inputs, the signal and the LO. The result of this multiplication process is a pair of output intermediate frequencies (IFs) that are the sum and difference of the signal and LO frequencies. If the mixer is "linear," it is a perfect multiplier, these are the only output frequencies present, and it has all of the properties of any other linear circuit except for the change of frequency. Fig 17.26B includes the mathematics that verify this linear behavior.

One of these outputs is selected to be the "desired" IF by the designer. It is then band-pass filtered and amplified. The bandwidths and shape factors of these filters are optimized for the kind of signal being received (AM, SSB, CW, FM, digital data). Two of the main attributes of the superhet are that this signal filtering band shape and also the IF amplification are constant for any value of the receive signal frequency. An excessively narrow preselector filter could, however, have some effect on the desired signal, as we saw in the case of the TRF receiver.

A second mixer, or "detector" as it is usually called, translates the IF signal to baseband (audio) where it is further amplified, possibly filtered, and applied to an output transducer (headphones, loudspeaker, some other signal processor or display).

A superhet receiver may also contain multiple frequency conversions (IFs). Later discussion will focus on strategies

used to select these IFs.

Let's begin with a detailed discussion of the classic down-conversion superhet. Almost all of the topics apply as well to the various other kinds of receiver designs in subsequent sections.

### Superhet Characteristics: A Down-Conversion Example

The desirability of the superhet approach is offset somewhat by certain penalties and problem areas. As a vehicle for mentioning these difficulties, seeing how to deal with them and discussing analysis and design methods; we use the tutorial example in Fig 17.27. That is a "down converting" single-conversion 14-MHz superhet with a 1.5-MHz IF. This receiver is simple and capable of fairly good performance in the 1.8 to 30-MHz frequency range. Fig 17.27 is intentionally incomplete and meant for instructional purposes only; do not attempt to duplicate it as a project.

### Block Diagram

The block labels of Fig 17.27 show that a preselector and RF amplifier are followed by downward frequency conversion to 1.5 MHz. This is followed by IF amplification and crystal filtering, a product detector, audio band-pass filters and an audio power output stage. Equal emphasis is given to SSB and CW. AGC circuitry is included. The audio and AGC circuits are the same as those in Fig 17.20 and Fig 17.21. As a first step, let's look at spurious responses of the mixer.

### Mixer Spurious Responses

Mixers and their spurious responses are

covered in detail in the **Mixers** chapter, but we will present a brief overview of the subject for our present purposes. We then will see how this information is used in the design process.

The mixer is vulnerable to RF signals other than the desired signal. Various harmonics of any undesired RF signal and harmonics of the LO combine to produce spurious IF outputs (called harmonic IMD). If these spurious outputs are within the IF passband they appear at the receiver output. The strength of these outputs depends on: harmonic number and strength of the RF signal as it appears at the mixer input, the harmonic number of the LO, the LO power rating (7 dBm, 17 dBm, and so on) and the design of the mixer.

Commercially available double-balanced diode mixers are so convenient, easy to use and of such low cost and high quality that they are used in many Amateur Radio receiver and transmitter projects. These mixers also do a good job of rejecting certain kinds of spurious responses. Our numerical examples will be based on typical published data for one of these mixers (Ref 40).

**Fig 17.28A** shows an example for the mixer tuned to a desired signal at 14.00 MHz with the LO at 15.50 MHz. The locations of undesired signals that cause a spurious response are shown in **Fig 17.28B**; they are at 14.75, 15.00, 16.00 and 17.00 MHz (there are many others of lesser importance). Each of these undesired signals produces a 1.50-MHz output from the mixer. The figure indicates the harmonics of the undesired signal and the harmonics of the LO that are involved in each instance. The “order” of the spurious product is the sum of these harmonic numbers, for example the one at 16.00 MHz is a sixth-order product. The spurious at 17.00 MHz is called the “image” because it is also 1.50 MHz away from the LO, just as the 14.00 desired signal is 1.5 MHz away from the LO. It is a second-order response, as is also the response at 14.00 MHz.

**Fig 17.28C** is a chart that shows the relative responses for various orders of harmonic IMD products for a signal level (desired or undesired) of 0 dBm and an LO level of +7 dBm. The values are typical for a great many +7-dBm mixers having various brand names and they improve greatly for higher level mixers (at the same RF levels). The second-order (desired and image) both have a reference value of 0 dB and the others are in dB below those two.

We can now consider the receiver design that suppresses these spurious responses so that they do not interfere with a weak desired signal at 14.00 MHz. If an

interfering signal is reduced in amplitude at the mixer RF input by 1.0 dB, the suppression of that spur is improved by  $1.0 \times \text{Signal Harmonic Number dB}$ . This is true in principle, but in reality the reduction may be somewhat less. For example, the spur produced by 15.00 MHz is reduced 3 dB for each dB that we reduce its level.

We accomplish this task by choosing the right mixer, limiting the amount of RF amplification and designing adequate selectivity into the preselector circuitry. With respect to selectivity, though, note that in many other mixing schemes the interfering signal is so close to the desired frequency that selectivity does little good. Then we must use a mixer with a higher LO level and/or reduce RF gain.

The design method is illustrated by the following numerical example. Suppose that a signal at 14.75 MHz (the IF/2 spur) is at -20 dBm (very strong) at the antenna and -10 dBm at the mixer RF port. From the chart, this spur will be reduced by  $71 + 2(0 - (-10)) = 91$  dB to a level of  $-10 - 91 = -101$  dBm. If this is not enough then a preselector will help. If the preselector attenuates 14.75 MHz by 5 dB, the total spur reduction will be  $71 + 2(0 - (-15)) = 101$  dB to a level of  $-15 - 101 = -116$  dBm, a 15-dB improvement. Notice that spurs involving high harmonics of the signal frequency attenuate more quickly as the input RF level is reduced.

On the other hand, if we consider the image signal at 17 MHz, all of the reduction of this spur must come from the preselector. In other words, selectivity is the only way to reduce the image response unless an image reducing mixer circuit is used (Ref 41). In this example, additional spur reduction is obtained by using a preselector circuit topology that has improved attenuation above the passband.

In designing any receiver we must be reasonable about spur and image reduction. Receiver cost and complexity can increase dramatically if we are not willing to accept an occasional spurious response due to some very strong and seldom occurring signal. In the case of a certain persistent interference some specific cure for that source can usually be devised. A sharply tuned “trap” circuit, a special preselector or a temporary antenna attenuator are a few examples. In practice, for down-conversion superhets, 90 dB of image reduction is excellent and 80 dB is usually plenty good enough for amateur work.

In classical down-conversion superhets, the preselection circuits are tuned and bandswitched in unison with the LO. They must all “track” each other across the dial. The cost and complexity of this arrange-

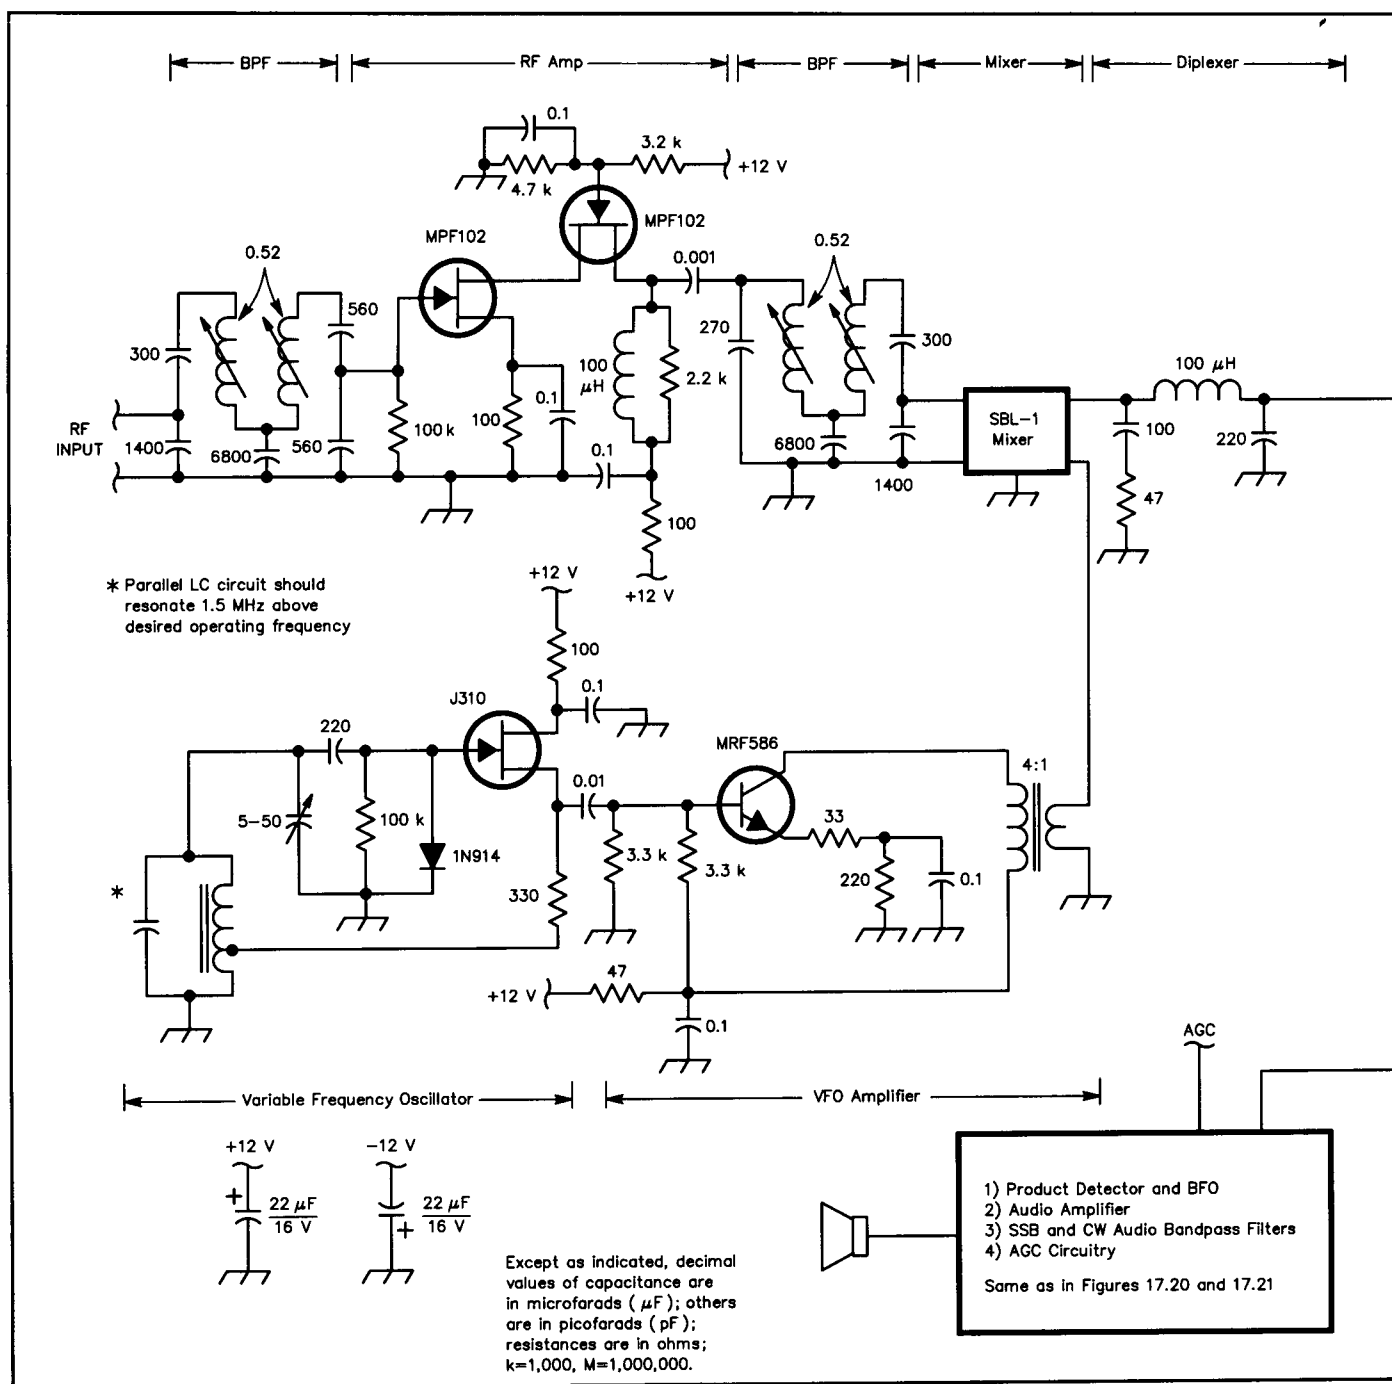

**Fig 17.28—A:** mixer at 14.00 MHz with LO at 15.50 and IF at 1.50. **B:** locations of strong signals that interfere with desired signal at 14.00 MHz due to harmonic IMD. **C:** typical chart of harmonic IMD products for a double balanced diode mixer with 0 dBm signal and 7 dBm LO.

ment have made this approach prohibitive in modern commercial multiband designs (Ref 42). For amateur work the approach in **Fig 17.27** is more practical, using switched or even plug-in band-pass preselectors and oscillator coils. A frequency counter, offset by the 1.5 MHz IF and connected to the LO, eliminates the need for a calibrated dial.

## Two-Tone Intermodulation Distortion

Another important mixer spurious response is two-tone IMD. This distortion has been covered previously in this chapter, and the **Mixers** chapter gives more detail. From a system design standpoint, the trade-offs between receiver noise figure and IMD have been covered in this

**Fig 17.27—Specific example of a down-conversion superhet that is used to explain and analyze superhet behavior and design.**

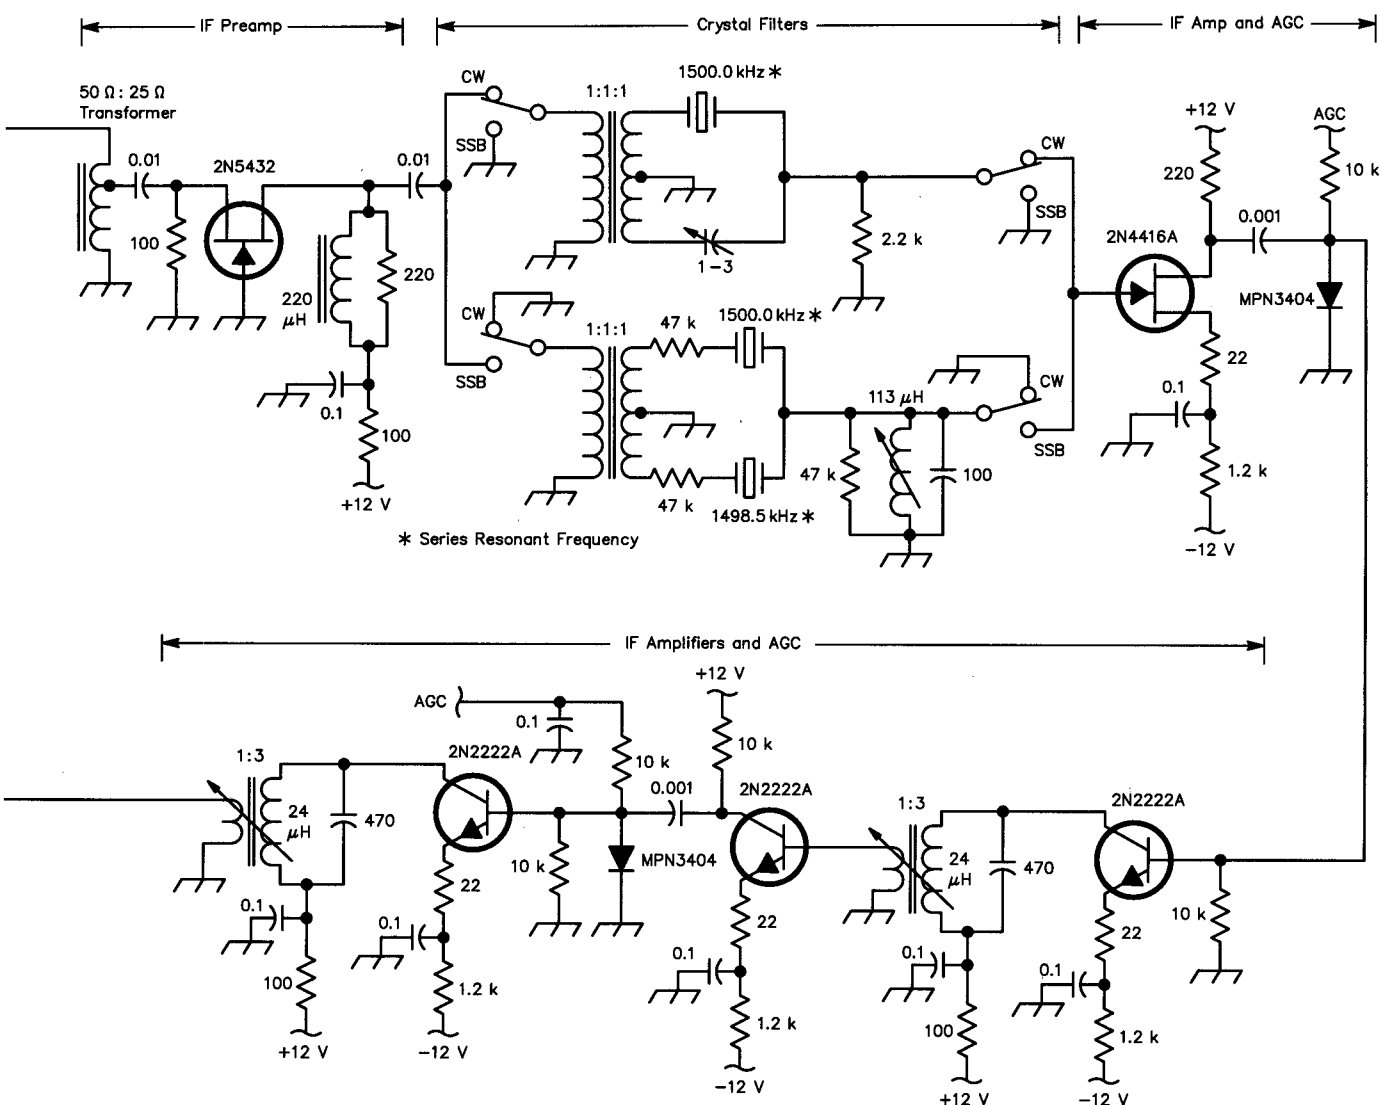

chapter, and the choices of mixer, RF gain (if any) and selectivity are decided in a study exercise of performance, cost and complexity. A receiver that has a 10 to 20-dBm third-order intercept point for two signals 20 kHz and 40 kHz removed is an excellent receiver in many applications. Some advanced experimenters have built receivers with 25 to 40-dBm values of IP3. Values of 40 dBm are near the state of the art (Refs 43, 44, 45).

A matter of considerable interest concerns

the way that IMD varies as the separation between the two tones increases. In Fig 17.27, for example, if one tone is 1.0 kHz (or 100 kHz) above 14.00 the other is 2.0 kHz (or 200 kHz) above. We see that for very close tone separations the IF filter may not prevent the tones from reaching the circuits following the IF filter. As the separation increases, first one, then both, tones fall outside the IF filter passband and the IMD becomes much less. However the mixer and the amplifier after the mixer are still vulner-

able. At greater separations the preselector starts to protect these two stages, but the RF amplifier is not well protected by the first RF filter until the tone separation becomes greater, perhaps 200 kHz. It is a common procedure to plot a graph of receiver third-order input intercept point vs tone separation and then look for ways to improve the overall performance.

The stages after the IF filter are protected by AGC so that, hopefully, tones in the IF passband do not overdrive the cir-

circuits after the IF filter. But in the example of Fig 17.27 there is also a narrowband audio filter and the AGC is derived from the output of this filter. This means that circuits *after* the IF filter but *ahead* of the audio filter may not always be as well protected as we would like. Strong tones that get through the IF filter may be stopped by the audio filter and not affect the AGC. This particular example illustrates a very common problem in all kinds of receivers that have *distributed* selectivity. It is also found universally in multiple conversion receivers, as we will discuss later.

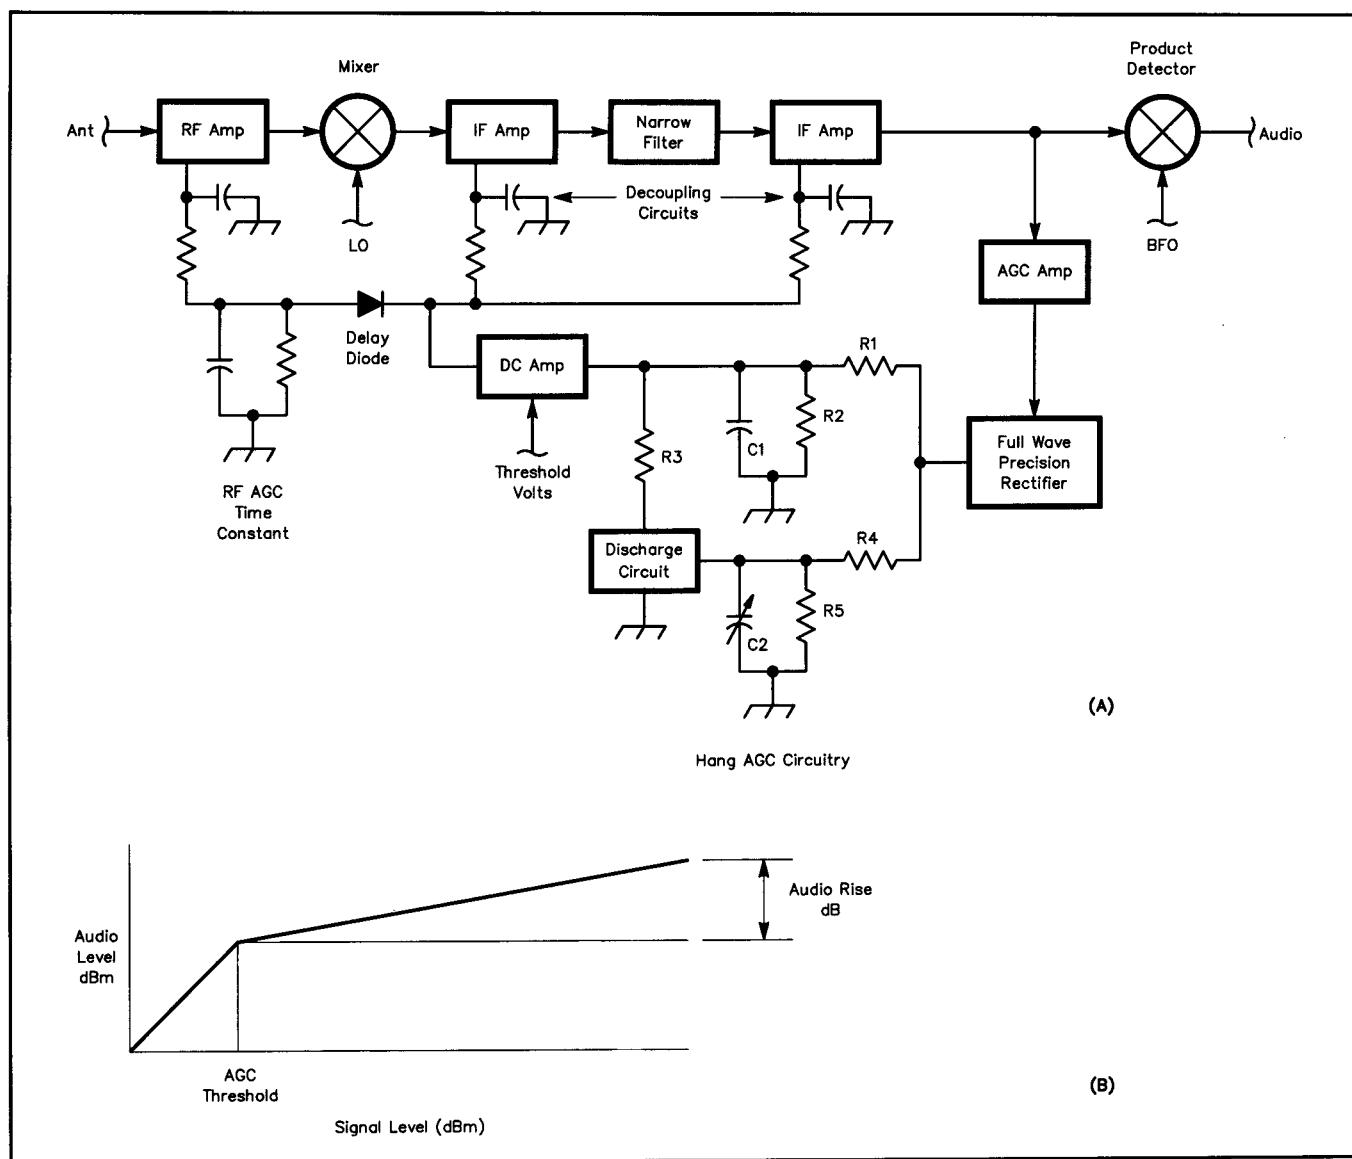

### Gain and Noise Figure Distribution

Based on the information given so far, the approach to designing a superhet receiver, whether a downconverter or any other kind, can now be summarized by the following guidelines:

1. Try to keep the gain ahead of the mixer and the narrow band-pass filters (SSB, CW and so on) as low as possible. For a fixed components cost (such as mixers and amplifiers), this minimizes the IMD, both two tone and harmonic.
2. Reducing the gain implies that the noise

figure may be a little higher. It is always best to avoid making the noise figure any lower than necessary. Noise figure is usually more important at microwave frequencies than at HF, and strong signal interference is usually less important. Where interference is a problem an increase in noise figure is almost always mandatory, except possibly when a higher-level mixer is used. A narrowband preselector, for example, will increase the noise figure (and also the intercept point) because of its passband attenuation.

3. Amplifier circuits and modules always

**Fig 17.29—AGC principles. A: typical superhet receiver with AGC applied to multiple stages of RF and IF. B: audio output as a function of antenna signal level.**

- involve a trade-off of some kind between intercept point and noise figure. Designers look for devices and circuits that optimize the SFDR for the particular kind of receiver under design.
4. If the receiver has distributed selectivity, make the first IF filter good enough that the AGC/IF-overload problem mentioned above is minimized.
  5. To *minimize* the gain ahead of the mixer, *follow* the mixer with a low-noise, high-dynamic-range amplifier with no more gain than necessary, say 10 dB or so (see Fig 17.27).
  6. Terminate the mixer in such a way that its IMD is minimized. Fig 17.27 shows a simple IF diplexer that absorbs the output image at 29.5 MHz (14.0 + 15.5).
  7. The RF terminal of the mixer should be short circuited at the image frequency so

- that noise at the image frequency (from the preceding circuitry) is minimized.
8. Because a large amount of overall gain is needed, reducing front-end gain implies that the gain after the first IF filter must be very large. The problem of IF and audio noise then arises. It is very desirable to use a low-noise amplifier right after the first IF filter (see Fig 17.27) and to restrict the bandwidth of the IF/AF amplifiers. A second IF/AF filter downstream, and also possibly an image-reducing product detector, are excellent ways to accomplish this. This step also minimizes the degradation of receiver noise figure that can be caused by this wideband noise.
  9. The LO must have very low phase noise to reduce reciprocal mixing. Also, the mixer must have good balance (meaning

isolation or rejection) from LO port to RF and IF ports so that broadband additive noise from the LO amplifiers does not degrade the mixer noise figure. This is especially important when the RF amplifier gain has been minimized. If the mixer is not balanced in this sense at the LO port, a band-pass filter between LO and mixer is very desirable (Refs 46, 47).

### AUTOMATIC GAIN CONTROL (AGC)

The amplitude of the desired signal at each point in the receiver is controlled by AGC. Each stage has a distortion vs signal-level characteristic that must be known, and the stage input level must not become excessive. The signal being received has a certain signal-to-distortion ratio that must not be degraded too much

by the receiver. For example, if an SSB signal has  $-30$  dB distortion products the receiver should have  $-40$  dB quality. A correct AGC design ensures that each stage gets the right input level. It is often necessary to redesign some stages in order to accomplish this (Ref 48).

### The AGC Loop

Fig 17.29A shows a typical AGC loop that is often used in amateur receivers. The AGC is applied to the stages through RF decoupling circuits that prevent the stages from interacting with each other. The AGC amplifier helps to provide enough AGC loop gain so that the gain-control characteristic of Fig 17.29B is achieved. The AGC action does not begin until a certain level, called the AGC threshold, is reached. The Threshold Volts input in Fig 17.29A serves this purpose. After that level is exceeded, the audio level slowly increases. The audio rise beyond the threshold value is usually in the 5 to 10-dB range. Too much or too little audio rise are both undesirable for most operators.

As an option, the AGC to the RF amplifier is held off, or “delayed,” by the 0.6-V forward drop of the diode so that the RF gain does not start to decrease until larger signals appear. This prevents a premature increase of the receiver noise figure. Also, a time constant of one or two seconds after this diode helps keep the RF gain steady for the short term.

Fig 17.30 is a typical plot of the signal levels at the various stages of a certain ham band receiver. Each stage has the proper level and a 115-dB change in input level produces a 10-dB change in audio level. A manual gain control would produce the same effect.

### AGC Time Constants

In Fig 17.29, following the precision rectifier, R1 and C1 set an “attack” time, to prevent excessively fast application of AGC. One or two milliseconds is a good value for the  $R1 \times C1$  product. If the antenna signal suddenly disappears, the AGC loop is opened because the precision rectifier stops conducting. C1 then discharges through R2 and the  $C1 \times R2$  product can be in the range of 100 to 200 ms. At some point the rectifier again becomes active, and the loop is closed again.

An optional modification of this behavior is the “hang AGC” circuit (Ref 49). If we make  $R2 \times C1$  much longer, say 3 seconds or more, the AGC voltage remains almost constant until the R5C2 circuit decays with a switch selectable time constant of 100 to 1000 ms. At that time R3 quickly discharges C1 and full receiver gain is quickly restored. This type of con-

Fig 17.30—Gain control of a ham-band receiver using AGC. A manual gain control could produce the same result.

trol is appreciated by many operators because of the lack of AGC “pumping” due to modulation, rapid fading and other sudden signal level changes.

### AGC Loop Problems

If the various stages have the property that each 1-V change in AGC voltage changes the gain by a constant amount (in dB), the AGC loop is said to be “log linear” and regular feedback principles can be used to analyze and design the loop. But there are some difficulties that complicate this textbook model. One has already been mentioned, that when the signal is rapidly decreasing the loop becomes “open loop” and the various capacitors discharge in an open-loop manner. When the signal is increasing beyond the threshold, or if it is decreasing slowly enough, the feedback theory applies more accurately. In SSB and CW receivers rapid changes are the rule and not the exception.

Another problem involves the narrow band-pass IF filter. The group delay of this filter constitutes a time lag in the loop that can make loop stabilization difficult. Moreover, these filters nearly always have much greater group delay at the edges of the passband, so that loop problems are aggravated at these frequencies. Overshoots and undershoots, called “gulping,” are very common. Compensation networks that advance the phase of the feedback help to offset these group delays. The design problem arises because some of the AGC is applied before the filter and some after the filter. It is a good idea to put as much fast AGC as possible after the filter and use a slower decaying AGC ahead of

the filter. The delay diode and RC in Fig 17.29A are helpful in that respect. Complex AGC designs using two or more compensated loops are also in the literature. If a second cascaded narrow filter is used in the IF it is usually a lot easier to leave the second or “downstream” filter out of the AGC loop.

Another problem is that the control characteristic is often not log-linear. For example, dual-gate MOSFETs tend to have much larger dB/V at large values of gain reduction. Many IC amplifiers have the same problem. The result is that large signals cause instability because of excessive loop gain. There are variable gain op amps and other ICs available that are intended for gain control loops.

Audio frequency components on the AGC bus can cause problems because the amplifier gains are modulated by the audio and distort the desired signal. A hang AGC circuit can reduce or eliminate this problem.

Finally, if we try to reduce the audio rise to a very low value, the required loop gain becomes very large, and stability problems become very difficult. It is much better to accept a 5 to 10 dB variation of audio output.

Because many parameters are involved and many of them are not strictly log-linear, it is best to achieve good AGC performance through an initial design effort and finalize the design experimentally. Use a signal generator, attenuator and a signal pulser (2-ms rise and fall times, adjustable pulse rate and duration) at the antenna and a synchronized oscilloscope to look at the IF envelope. Tweak the time constants and

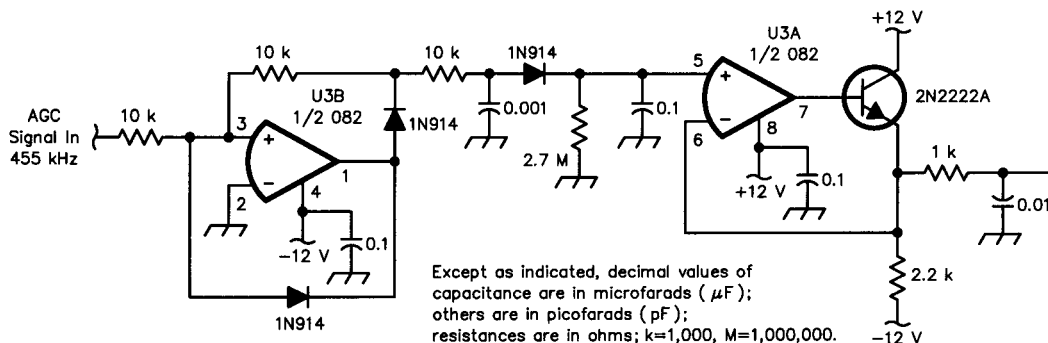

Fig 17.31—Some gain controllable amplifiers and a rectifier suitable for audio derived AGC.

AGC distribution by means of resistor and capacitor decade boxes. Be sure to test throughout the passband of each filter. The final result should be a smooth and pleasant sounding SSB/CW response, even with maximum RF gain and strong signals. Patience and experience are helpful.

### Audio-Derived AGC

The example in Fig 17.20 shows audio-derived AGC. There is a problem with this approach also. At low audio frequencies the AGC can be slow to develop. That is, low-frequency audio sine waves take a long time to reach their peaks. During this time the RF/IF/AF stages can be overdriven. If the RF and IF gains are kept at a low level this problem can be reduced. Also, attenuating low audio frequencies prior to the first audio amplifier should help. With audio AGC, it is important to avoid so-called “charge pump” rectifiers or other slow-responding circuits that require multiple cycles to pump up the AGC voltage. Instead, use a peak-detecting circuit that responds accurately on the first positive or negative transition.

### AGC Circuits

Fig 17.31 shows some gain controllable circuits and also a suitable rectifier for audio derived AGC.

Fig 17.31A shows a precision half-wave rectifier and a two-stage 455-kHz IF amplifier with PIN-diode gain control. This circuit is a simplified adaptation from a production receiver, the Collins 651S. The IF amplifier section shown is preceded and followed by selectivity circuits and additional gain stages with AGC. The 1.0-μF capacitors aid in loop compensation. The favorable thing about this approach is that the transistors remain biased at their optimum operating point. Right at the point where the diodes start to conduct, a small increase in IMD may be noticed, but that goes away as diode current increases

slightly. Two or more diodes can be used in series, if this is a problem (it very seldom is).

Fig 17.31B is an audio-derived AGC circuit using a full-wave rectifier that responds to positive or negative excursions of the audio signal. The RC circuit follows the audio closely.

Fig 17.31C shows a typical circuit for the MC1350P RF/IF amplifier. The graph of gain control vs AGC volts shows the change in dB/V. If the control is limited to the first 20 dB of gain reduction this chip should be favorable for good AGC transient response and good IMD performance. Use multiple low-gain stages rather than a single high-gain stage for these reasons. The gain control within the MC1350P is accomplished by diverting signal current from the first amplifier stage into a “current sink.” This is also known as the “Gilbert multiplier” architecture. Another chip of this type is the NE/SA5209. This type of approach is simpler to implement than discrete-circuit approaches, such as dual-gate MOSFETs that are now being replaced by IC designs.

Fig 17.31D shows the high-end performance Comlinear CLC520AJP (14-pin DIP plastic package) voltage controlled amplifier. It is specially designed for accurate log-linear AGC from 0 to 40 dB with respect to a preset maximum voltage gain from 6 to 40 dB. Its frequency range is dc to 150 MHz. It costs about \$14 in small quantities and is an excellent IF amplifier for high-performance receiver or transmitter projects.

### IF FILTERS

There are some aspects of IF-filter design that influence the system design of receivers and transmitters. The influence of group delay, especially at the band-pass edges, on AGC-loop performance has been mentioned. Shape factor is also significant (the ratio of two bandwidths,

usually 60-dB:6-dB widths). To get good adjacent-channel rejection, the transition-band response should fall very quickly. Unfortunately, this goal aggravates group-delay problems at the passband edges. It also causes poor transient response, especially in CW filters. Another filter phenomenon can cause problems: at sharp passband edges signals and noise produce a raspy sound that is annoying and interferes with weak signals.

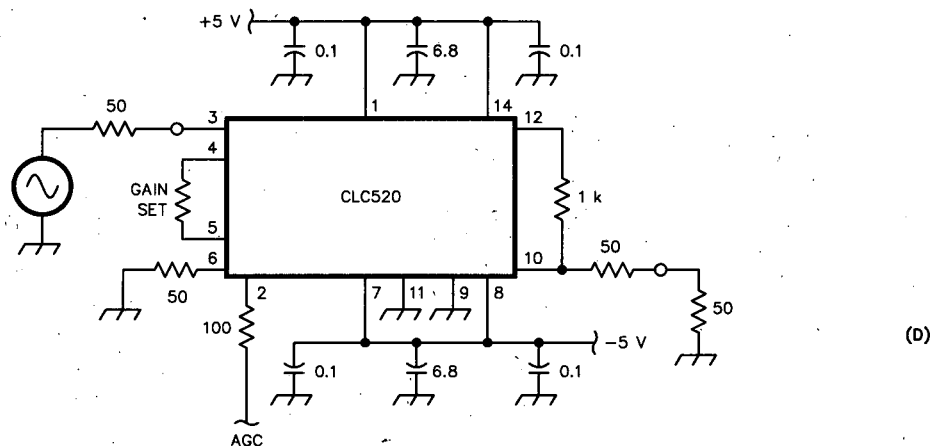

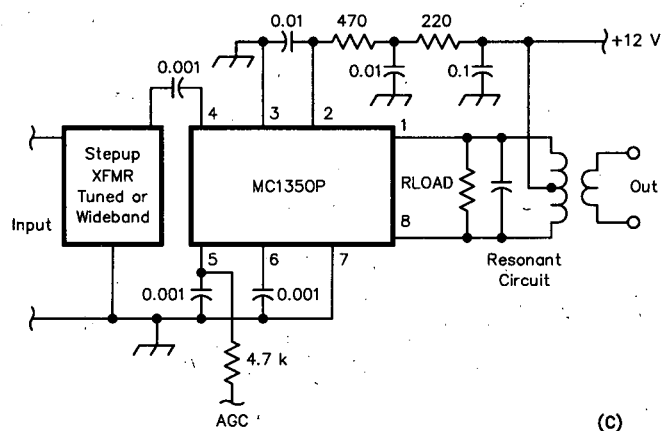

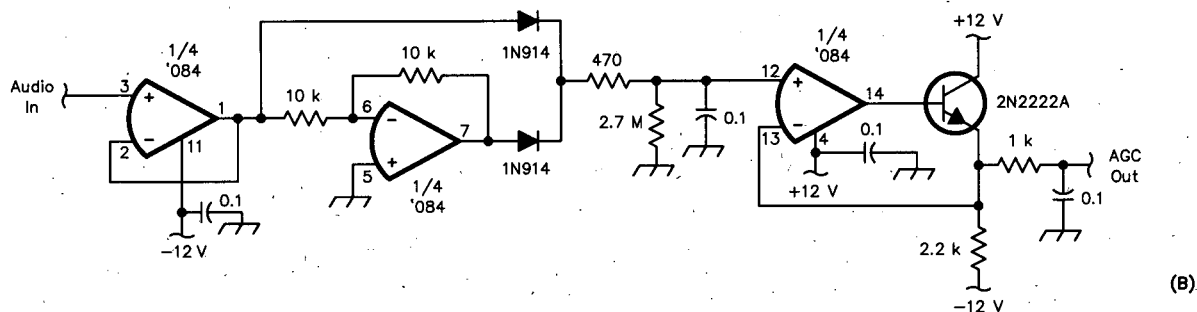

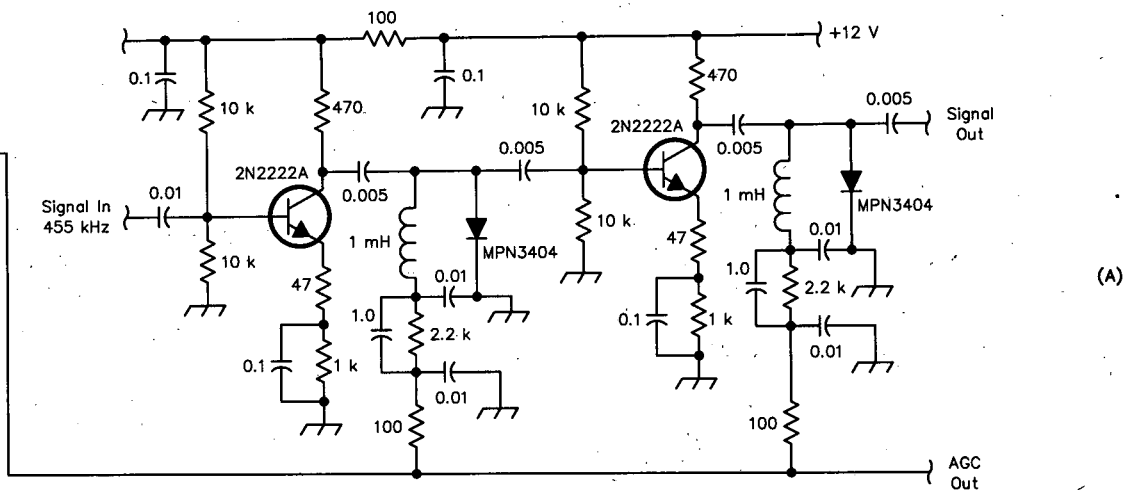

A desirable filter response would be slightly rounded at the edges of the passband, say to -6 dB, with a steep rolloff after that. This is known as a “transitional filter” (Ref 50). Cascaded selectivity with two filters, each having fewer “poles” (than a single filter would) is also a good approach. Both methods have a smoother group delay across the passband and reduce the problems mentioned above.

### Ultimate Attenuation

In a high-gain receiver with as much as 110 dB of AGC the ultimate attenuation of the filter is important. Low-level leakage through or around the filter produces high-pitch interference that is especially noticeable on CW. Give special attention to parts layout, wiring and shielding. (Filter selector switches are often leakage culprits.) Cascaded IF filters also help very considerably.

### Audio Filter Supplement

An audio band-pass filter can be used to supplement IF filtering. This can help to improve signal-to-noise ratio and reduce adjacent-channel interference. Supplementary audio filtering also helps reduce the high-frequency leakage problem mentioned above. Another significant problem: If AGC is made in the IF section, strong signals inside the IF passband but outside the audio passband can “pump” or modulate the AGC, rendering weak desired signals hard to copy. This is espe-

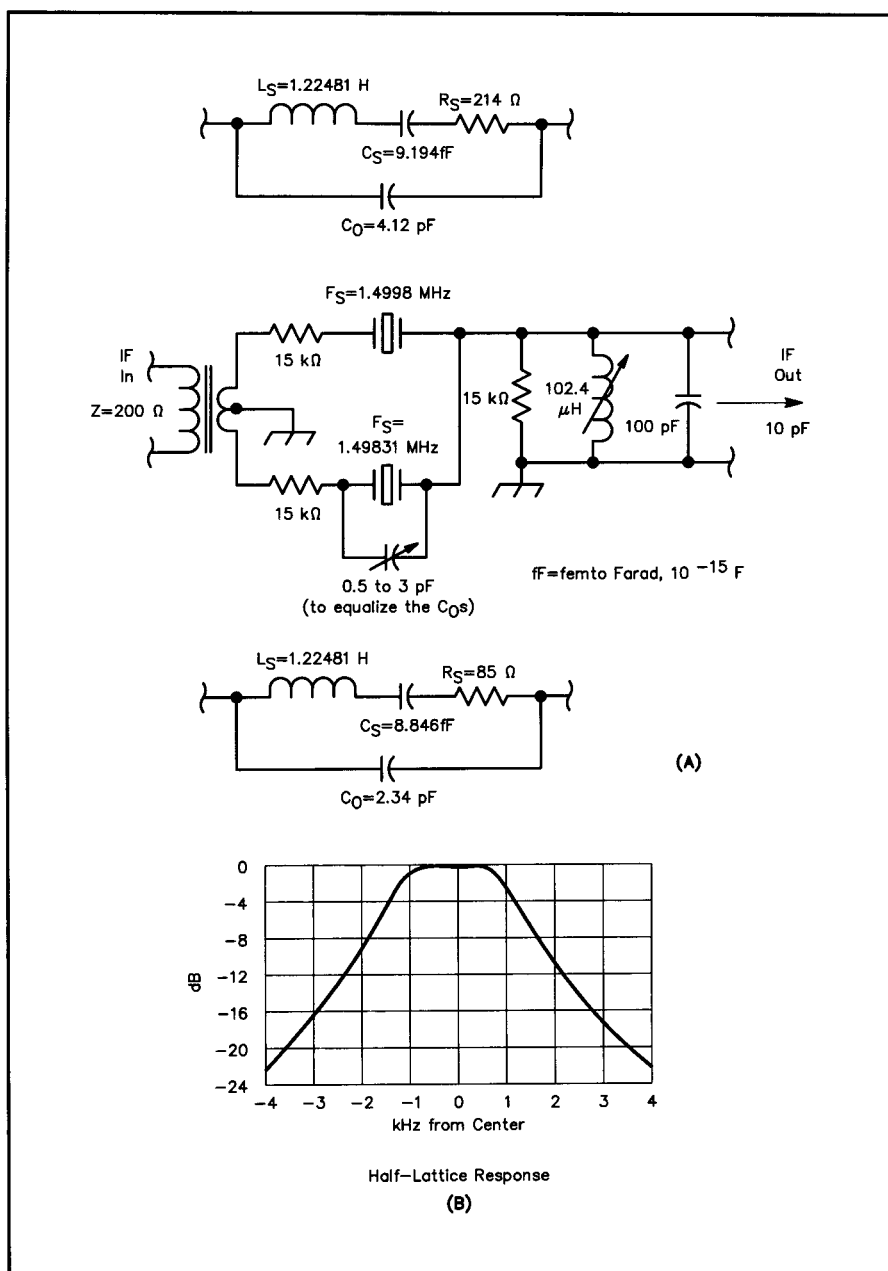

**Fig 17.32—A single-crystal filter circuit for a simple CW receiver design. See also Fig 17.27.**

cially noticeable during periods of high band activity, such as in a contest. These filters can use analog (see Fig 17.20 and Fig 17.21) or digital (DSP) technology.

### Some Simple Crystal Filters

Fig 17.32 and Fig 17.33 present two crystal filters to consider for a simple down-conversion receiver with a 1.5-MHz IF (see Fig 17.27). The crystals are a set of three available from JAN Crystals. (See the Address List in the **References** chapter for their current address. Mention the *ARRL Handbook*.) The filters are both driven from a low-impedance source ( $200\ \Omega$ , for example).

**Fig 17.33—A two-crystal half-lattice filter for a simple SSB receiver. See also Fig 17.27.**

### CW Filter

Fig 17.32A is a “semilattice” filter using a single crystal for CW work (Ref 50). Capacitor  $C_C$  balances the bridge circuit at the crystal’s parallel-resonant frequency because it is equal to the holder capacitance  $C_O$  of the crystal. The response is then symmetrical around the series resonant frequency of the crystal. The selectivity is determined by the value of  $R_{out}$ . As the value decreases the selectivity sharpens as shown in 32B. If this filter is combined with an audio band-pass filter as in Fig 17.21, pretty good CW selectivity is possible. In Fig 17.32C, the capaci-

tor is increased to  $8.3\text{ pF}$  and a notch appears at  $-1.7\text{ kHz}$ . This is the “single signal” adjustment. Also, note that the response on the high side is degraded quite a bit. The notch can be located above or below center frequency by adjusting the capacitor value; the degradation is on the opposite side of center.

### SSB Filter

Fig 17.33 is a “half lattice” filter (Ref 50). The schematic diagram shows the LCR values and the series resonant frequencies of the two crystals. One of these ( $1.4998\text{ MHz}$ ) is the same type as the one used in the CW filter. The trimmer capaci-

tor equalizes the two values of  $C_o$ , the crystal shunt capacitance (very important) in case they are not already closely matched. Place the trimmer across the crystal that has the lowest value of  $C_o$ . The response curve shows good symmetry and modest adjacent-channel rejection. The output tuned circuit absorbs load capacitance to get a pure  $R_{load}$  (also important). The follow-up audio speech band-pass filter in Fig 17.20 will improve the overall response very considerably.

### Mechanical Filters

Mechanical filters use transducers and the magnetostriction principle of certain materials to obtain a multiresonator narrow band-pass filter in the 100 to 500-kHz range. They are very frequency stable, accurate and reliable. An interesting example, for radio amateurs, is the Rockwell-Collins (Costa Mesa, California) "Low Cost Series" of miniaturized torsional-mode filters for 455.0 kHz. They come in three styles with 3 dB/60 dB bandwidths of 0.5/2.0, 2.5/5.2 and 5.5/11 kHz. In small quantities (1-4), they sell for \$77 each (1994 price,—mention the ARRL *Handbook* article), including tax and shipping. Used filters are sometimes available from various sources (Ref 42).

### Multielement Crystal Filters

A discussion of more complex crystal filters appears in the **Filters** chapter of this *Handbook*. In this chapter we have considered only two very simple examples that might appeal especially to student designers and builders of a receiver that downconverts to an IF less than 2 MHz or so.

From the system design standpoint, note that for voice reception amateurs often use optional IF filters with less than the conventional bandwidth for SSB (for example 1.8 kHz), even though they reduce higher frequency speech components. This helps to improve adjacent-channel interference, which is a severe problem on some amateur bands.

It is common practice to use multipole crystal filters in the range from 5 to 10 MHz, because they can be economically designed for that frequency range. It is also common to cascade these filters with other types, such as mechanical or LC filters, at lower IFs (more about this later).

### Filter Switching

Filter switching for different modes (AM, SSB, CW, RTTY and so on) requires some careful design to prevent impedance mismatching, leakage (discussed before) and spurious coupling to other circuitry. There are three general methods for

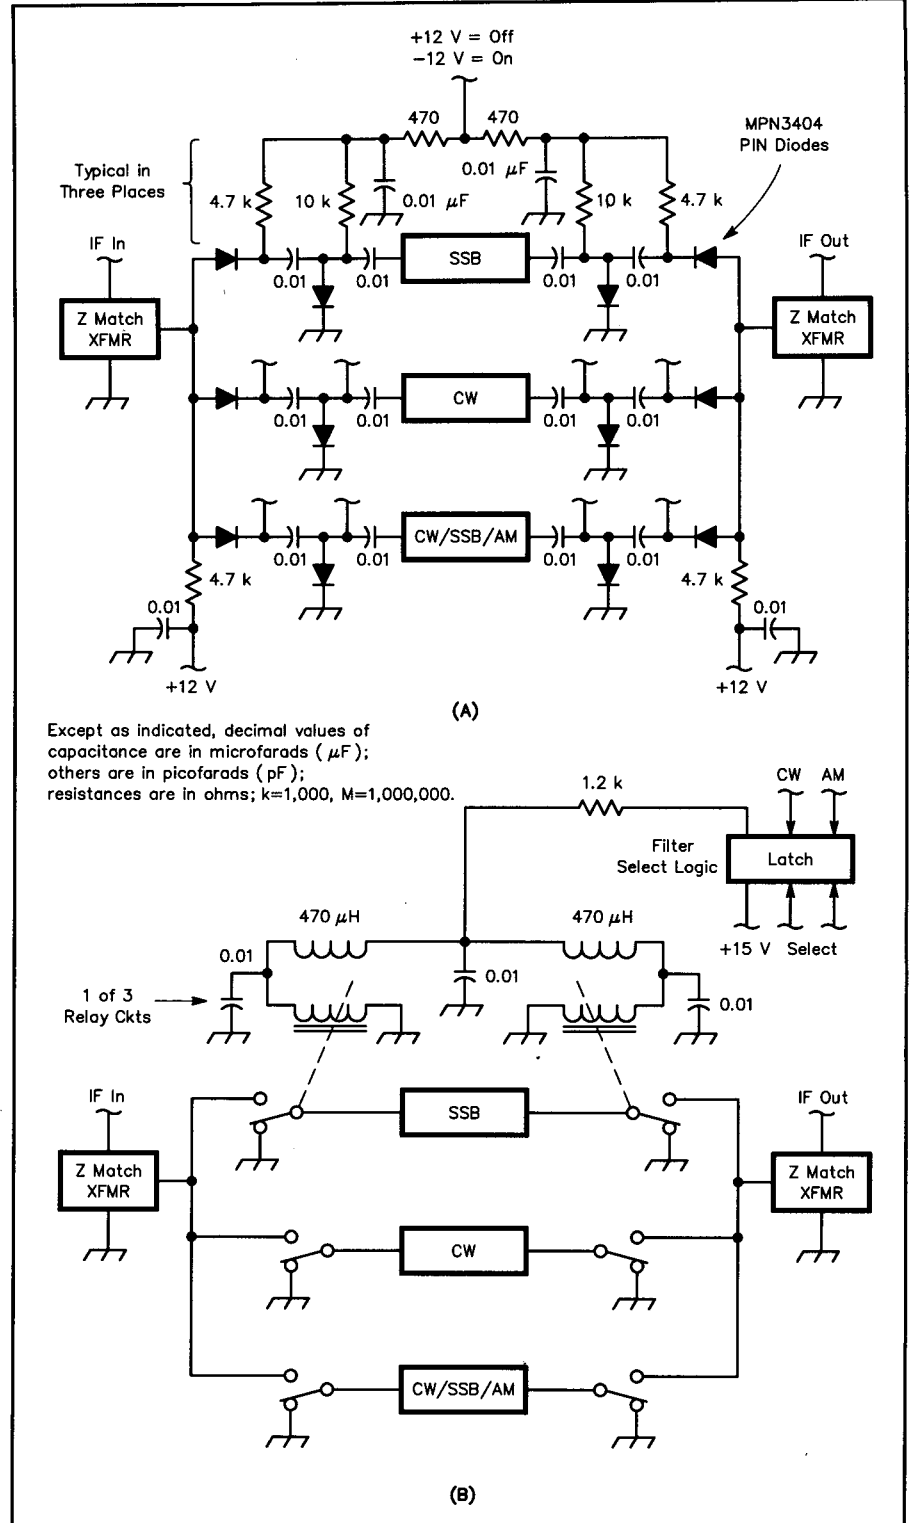

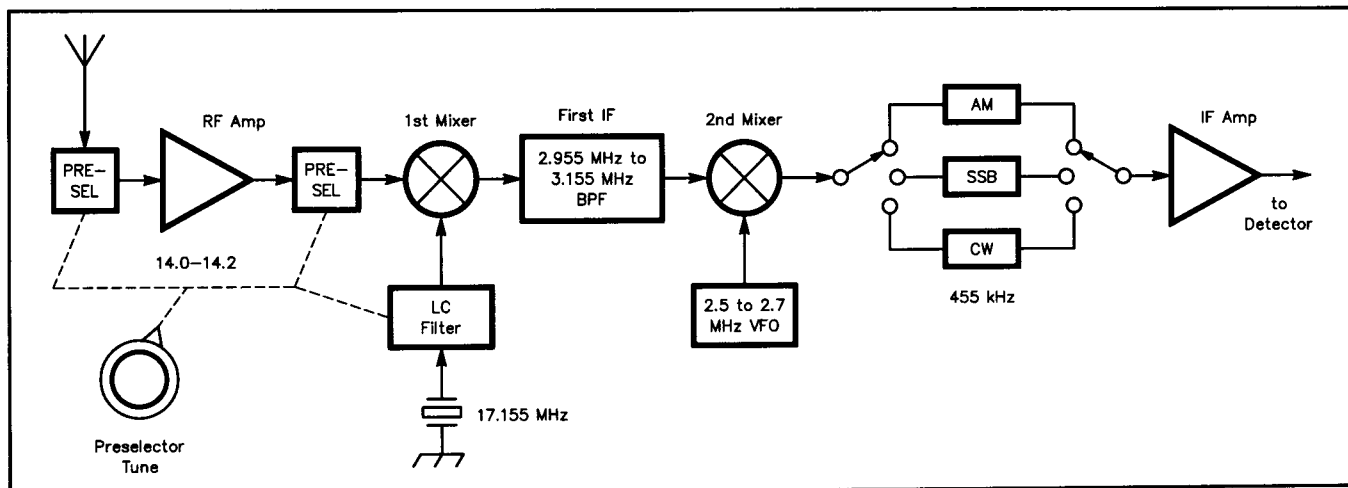

Fig 17.34—IF filter switching using relays or PIN diodes.

switching: mechanical, relays, solid-state (diodes or transistors). The latter two are needed in radios controlled by computers or logic circuits.

Mechanical switches require good isolation between the wafers and usually some kind of shielding arrangements.

Fig 17.34 shows examples of relay and diode switching that work quite well. The relays can be inexpensive miniature Radio Shack 275-241 SPDT units, one at each input and one at each output. The diodes can be inexpensive Motorola MPN3404 PIN diodes. These circuits assume that all

**Fig 17.35—Block diagram of a double-conversion superhet that eliminates some of the tracking problems of the conventional superhet.**

filters are terminated with the same impedance values (Ref 42).

In PIN diode applications, IMD *can* be a problem with inadequate bias or excessive signal levels. The application (PIN diode and circuit) should be tested at the highest expected signal level.

One major problem involves high-level IF-output-signal leakage or BFO leakage into the input of the filter, which can produce high passband ripple and other unpleasant problems such as AGC malfunctions.

### THE VLF IF RECEIVER

An approach to IF selectivity that has been used frequently over the years in both home built and factory made amateur receivers uses a second down conversion from an IF at, say 4 or 5 MHz or even 455 kHz, to a very low frequency, usually 50 to 85 kHz. At these frequencies several double tuned LC filters, separated by amplifier stages, make possible excellent improvements in SSB/CW frequency response and ultimate attenuation along with a relatively flat group delay. These amplifier stages can also have AGC. Low-cost (four-pole) crystal filters (SSB and CW) at the higher IF followed by two lower-IF channels (SSB and CW) make a very desirable combination. This is also an effective way to assure a narrow noise bandwidth for the overall receiver. One requirement is that the circuitry ahead of the VLF downconverter must provide good rejection of an image frequency that is only 100 to 170 kHz away (Refs 41, 46, 51, 52, 53, 54, 55).

### AM DEMODULATION

There is some interest among amateurs in double-sideband AM reception on the

HF broadcast bands. Coherent AM detection is a way to reduce audio distortion that is caused by a temporary reduction of the carrier. This "selective fading" is due to phase cancellations caused by multipath propagation. By inserting a large, locally created carrier onto the signal this effect is reduced. The term "exalted carrier reception" is sometimes used. In reception of a double-sideband AM signal, the phase of the inserted carrier must be identical to that of the incoming carrier. If not, reduced audio and also audio distortion result. Therefore the common method is to use a phase-locked loop (PLL) to coordinate the phases of the incoming carrier and the locally generated carrier. This requires a Type II PLL, which drives, or integrates, the phase difference to zero degrees (Refs 41, 56, 57).

### MULTIPLE CONVERSION SUPERHETS

There are a couple of drawbacks to the downconverting receiver just described. First, the LO must be bandswitched. Also, its tuning must track with the preselector tuning even though the preselector is offset from the signal frequency by the amount of the IF. A tuning dial scale is required for each band, and the receiver must be fitted to it at the factory. This adds a lot of cost and complexity.

A solution to these problems is shown in Fig 17.35. A crystal controlled first mixer is preceded by a gang-tuned preselector and is followed by a wideband first IF that is 200-kHz wide. The second mixer has a VFO that tunes a 200-kHz range. To change bands, the crystal is switched and the preselector is bandswitched. An additional tuned circuit removes the wideband additive noise from

the crystal LO, so that it does not degrade the noise figure of the *unbalanced* mixer circuit.

One of the main design problems is to select the first IF, its bandwidth and the second mixer design so that harmonic IMD products (involving the signal, crystal frequency, first IF, second IF and VFO frequency) do not cause appreciable interference. In the example of Fig 17.35, a first IF at 2.9275 MHz (the signal frequency would be 14.2275 MHz) and a VFO at 2.7 MHz produce a fourth-order spurious response at 455 kHz, therefore the first IF filter must attenuate 2.9275 MHz sufficiently and the second mixer must reject the fourth-order response sufficiently. We have discussed the fourth-order (IF/2) response previously.

One of the main bonuses of this approach is that the tunable second LO can be very stable and accurately calibrated. This calibration is the same for any signal band. Another advantage is that the first crystal LO is very stable and has little phase noise. A third bonus is that the high value of the first IF simplifies the preselector design for good image rejection in the first mixer (Ref 58).

The second mixer is vulnerable to two-tone IMD caused by strong interfering signals that lie within, or near, the 200-kHz-wide first-IF bandwidth, and that have been amplified by the circuitry preceding it. They do not make AGC because they are outside the narrow signal filters.

This cascaded-selectivity problem, which we have discussed previously, makes it necessary to very carefully control the gain and noise-figure distribution ahead of the second mixer. Also, put the narrow signal filter right after the second mixer and follow that with a low-noise IF

amplifier, so that “front end” gain can be minimized. In more expensive receivers of this kind, the first IF is sharply gang-tuned along with the second LO in order to reduce this problem (Ref 59).

This general approach has been extended in order to make a general-coverage receiver that has acceptable spurious responses. The first IF can be switched between two different frequency ranges and various combinations of up conversion and down conversion are used. This subject is interesting, but more complex than we can cover here. This approach is also not frequently used at this time.

## THE UP CONVERSION SUPERHET

The most common approach to superhet design today is the “up converter.” This designation is reserved for receivers in which the first IF is greater than the highest receive frequency. First IF values can be as low as 35 MHz for low-cost HF receivers or as high as 3 GHz for wideband receivers (and spectrum analyzers) that cover the 1 MHz to 2.5 GHz range. Let’s begin by discussing the general properties of all up conversion receivers (Ref 42).

### An Up Converter Example

The block diagram in Fig 17.36 is one example for HF amateur SSB/CW use. The input circuit responds uniformly to a wide frequency band, 1.8 to 30 MHz. A 1.8 to 30-MHz band-pass filter is at the input. The absence of any narrow preselection is typical, but in difficult environments an electronically tuned or electromechanically tuned preselector is often used. Another option is a set of “half octave” (2 to 3 MHz, 3 to 4.5 MHz and so on) filters switched by PIN diodes or relays. This type of filter eliminates second-order IMD. For example, if we are listening to a weak signal at 2.00 MHz, two strong signals at 2.01 and 4.01 MHz would not create a spur at 2.00 MHz because the one at 4.01 MHz would be greatly attenuated. Fig 17.8 gives more information on this subject.

### Wideband Interference

The wideband circuitry in the front end is vulnerable to strong signals over the entire frequency range if no preselection is used. Therefore the strong-signal performance is a major consideration. Total receiver noise figure is usually allowed to increase somewhat in order to achieve this goal. Double balanced passive (or often active) mixers with high intercept points (second and third-order) and high LO levels are common. A typical high-quality up conversion HF receiver has a third-order intercept (IP3) of 20 to 30 dBm and a

noise figure of 10 to 14 dB. High-end performers will have an IP3 of 32 to 40 dBm and a noise figure of 8 to 12 dB.

As a practical matter, in all but the most severe situations with collocated transmitters, there is very little need in Amateur Radio for the most advanced receiver specifications. One reason for this involves statistics. To get two-tone IMD interference on a *high-quality* receiver at some particular frequency there must be two strong signals, or perhaps one very strong and a second weaker signal, on just the right pair of frequencies and at the same time. In nearly all cases, the “chances” of this are small. In Amateur Radio contest situations, these kinds of interactions are more probable. For persistent cases, other remedies are usually available.

### After the Mixer

We would really like to go from the mixer directly into an SSB or CW filter, but at the high frequency of the first IF this is not realistic. Therefore we run into a major compromise: It is necessary to have at least one additional wide-band frequency conversion before getting to the narrow filters. The first IF filter can be as narrow as cost and technology will permit. In the 35 to 110-MHz range crystal filters with bandwidths of 10 to 20 kHz are available, but they are somewhat expensive in small quantities. Fig 17.36 shows an option with far less cost. The LC filter in the first IF is about 1.0-MHz wide but it has enough attenuation at 50 MHz to yield excellent image rejection in the second mixer. If we use a high-input-intercept, low-gain, low-noise amplifier followed by a strong second mixer (minimize the gain ahead of the second mixer and let the receiver noise figure go up a couple of dB) the overall receiver performance will be excellent, especially with the kinds of efficient antennas that amateurs use.

### Terminating the Mixers

In the upconversion receiver, getting a pure wideband resistive termination for the mixer IF port is a problem. The output of the first mixer in Fig 17.36 contains undesired frequencies. For example, a 10-MHz signal produces 70-MHz (desired IF), 90-MHz (image) and 80-MHz (LO leakage). For a 2-MHz signal there would be 70, 72 and 74-MHz outputs. A filter that passes 70-MHz, rejects the others and at the same time terminates the mixer resistively over a wide band is a complicated band-pass diplexer.

Usually the termination is an amplifier input impedance plus a much simpler band-pass diplexer. The amplifier input

should be a pure resistance, and it may then be required to deal with the vector sum of all three products. Diode upconverter mixers have typically 30 to 40 dB LO-to-IF isolation. If the LO level is 23 dBm, the amplifier may be looking at  $-7$  to  $-17$  dBm of LO feedthrough, which is fairly strong. The output of the amplifier and also the next stage must deal with these amplified values. The second mixer is much easier to terminate with a diplexer, as Fig 17.36 shows (Ref 60).

At lower signal and LO levels (7 dBm or less), MMIC amplifiers like the MAV-11 may provide a good termination across a wide bandwidth. However, susceptibility to IMD must be checked carefully.

At the RF terminal of the mixer, any noise at the image frequency from previous stages (such as RF amplifier, antenna or even thermal noise) must not be allowed to enter the mixer because it degrades the mixer noise figure. The RF terminal should be short circuited at the image frequency if possible.

### Choosing the First IF

The choice of the first IF is a compromise between cost and performance. First, consider harmonic IMD. Published data for several high-level diode-mixer models show that if the IF is greater than three times the highest signal frequency (greater than 90 MHz for a 0 to 30-MHz receiver) the rejection of harmonics of the signal frequency increases considerably. For example 3 times an interferer at 33 MHz produces a 99 MHz IF. The input 30-MHz low-pass filter would attenuate the 33-MHz signal and so would help considerably. On the other hand, 24.75 times 4 is also 99 MHz, but the mixer does a better job of rejecting this fourth harmonic. Other spurious responses tend to improve also.

However, other factors are involved, most important of which are the LO designs for the first and second mixers. In up-converters, the LOs are invariably synthesizers whose output frequencies are phase locked to a low-frequency reference crystal oscillator. As the LO frequencies increase, two other things increase: cost and quantity of high-frequency synthesizer components, and synthesizer phase noise. Also, the exact choice is interwoven with the details of the synthesizer design. Special IFs, such as 109.350 MHz, are chosen after complex trade-off studies. The cost of the first-IF signal-path components, especially filters, tends to increase also.

For all of these reasons, the IF is quite often chosen at a lower frequency. In Fig 17.36, a 70-MHz IF is shown. Crystal

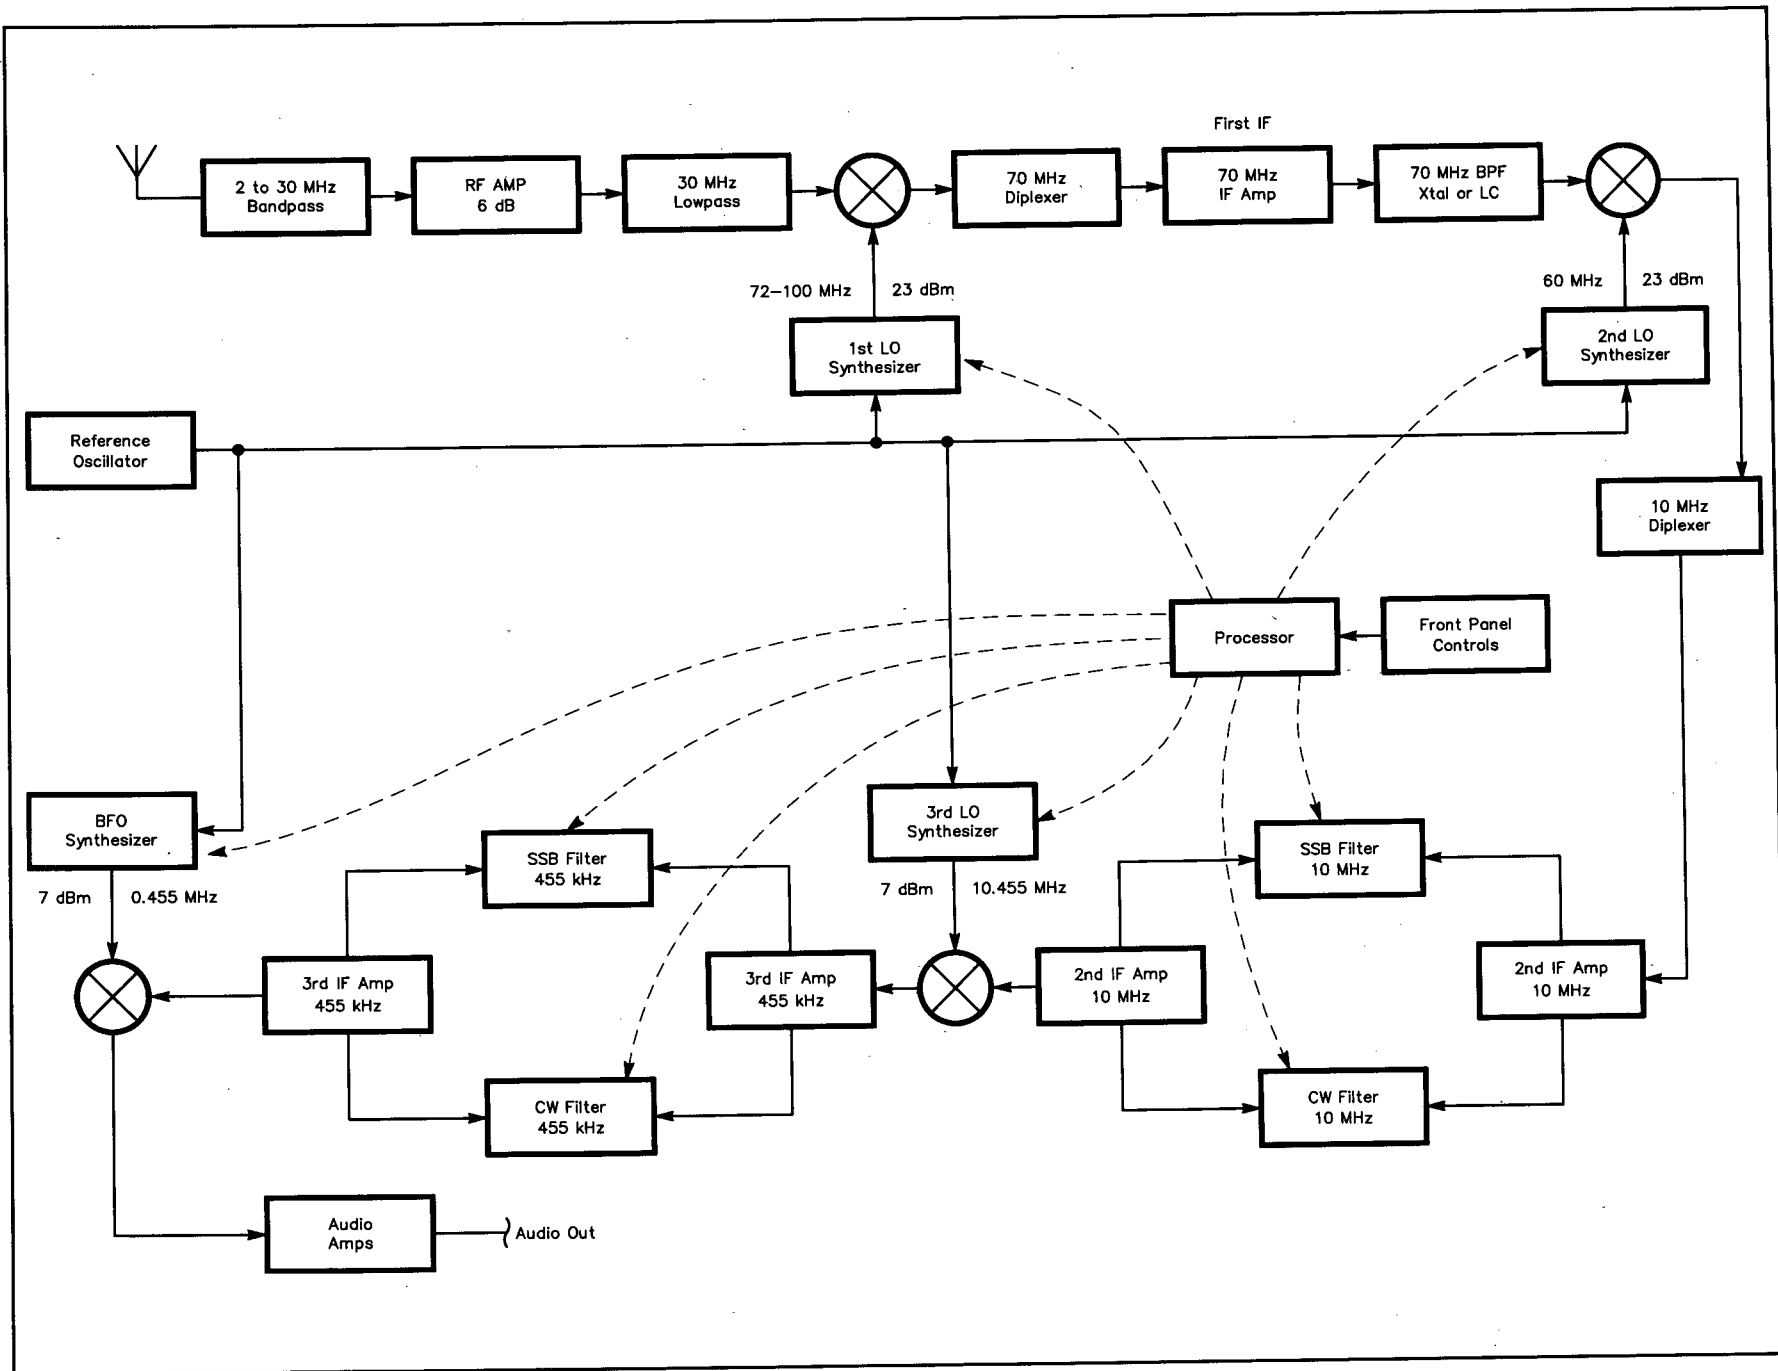

Fig 17.36—Block diagram of an HF up-conversion receiver for SSB and CW. Microprocessor control of receiver functions is included. LOs are from synthesizers.

filters at this frequency are widely available at reasonable cost. LC filters with a 1.0 MHz (or less) bandwidth are easy to construct and get working. A 45-MHz IF is also popular. Helical resonator filters are excellent candidates at higher IF frequencies, although they can be a bit large.

The problems associated with lower IFs can be greatly improved by using a higher performance mixer. The costs are a better mixer and a more powerful LO amplifier.

### The “Gray Area”

In the upconverter front end we encounter the “cascaded selectivity” problem that was mentioned previously in this chapter. Strong signals that are *within* the first IF passband but *outside* the SSB/CW passband (the gray area) do not make AGC and therefore are not controlled by AGC. These signals intermodulate in the mixers and in the amplifiers that precede the SSB/CW filters. It is important to realize that the receiver gray-area IMD performance is the composite of all these stages, and not just the first mixer alone. It is not until the first IF filter takes effect that things get a lot better. This degradation for strong adjacent-channel signals is an artifact of the upconverting superhet receiver. In practice, it often happens that reciprocal mixing with the adjacent channel signals (caused by receiver synthesizer phase noise) also gets into the act. Phase noise on the interfering signals is also not uncommon. The design problem is to make IMD in the gray area as small as reasonably possible. The example of Fig 17.36 is an acceptable compromise in this respect for a fairly high quality receiver.

### Triple Conversion

The block diagram of Fig 17.36 shows a 10-MHz second IF. This IF is selected for two reasons:

- There are narrowband crystal filters available (including homemade ladder filters) in that vicinity.
- The image frequency for the second mixer is at 50 MHz, which can be highly attenuated by the first IF filter.

It is entirely possible to let the rest of the IF remain at this frequency, and many receivers do just that. Nonetheless, there are some advantages to having a third conversion to a lower IF. For example, it is desirable to get the large amount of IF gain needed at two different frequencies, so that stability problems and leakage from the output to input are reduced. Also, a wide variety of excellent filters are readily available at 455 kHz and other low frequencies.

Note that there is a cascade of the SSB

and CW filters at the two frequencies. The desirability of this was discussed earlier and it is a powerful concept for narrow-band receiver design. Placing cascaded filters at two different frequencies has another advantage that we will look into presently.

For the third mixer the image frequency is at 10.910 MHz, therefore the 10-MHz filter must have good rejection at that frequency. If the first IF filter has good rejection at 70.910 MHz it will help reduce this image also. We are looking for 90 to 100 dB rejection of this potentially serious image problem. If the first IF uses a 1.0 MHz wide LC filter, as we have suggested, some additional 10 MHz LC filtering will probably be needed.

### The 50 kHz IF

The third IF could be the cascaded LC filter circuits at VLF, one for SSB and one for CW, which we discussed earlier. This is an excellent approach that has been used often. The image frequency for the third mixer is only 100 kHz away, so that problem needs careful attention. Image canceling mixers have been used to help get the required 90 to 100 dB (Ref 41).

### Local Oscillator (LO) Leakage

It is easy to see that with four LOs running, some at levels of 0.2 W or more, interactions between the mixers can occur. In a multiple-conversion receiver mechanical packaging, shielding, circuit placement and lead filtering are very critical areas. As one example of a problem, if the 60-MHz second LO leaks into the first mixer, a vulnerability to strong 10-MHz input signals results. It is called “IF feedthrough” because the second IF is 10 MHz. Other audible “tweets” are very common; they occur at various frequencies that involve harmonics of LOs beating together in various mixers. It is a major exercise to devise a “frequency scheme” that minimizes tweets, or at least puts them where they do not cause too much trouble (for amateurs, outside the ham bands). After that the “dog work” of reducing the remaining tweets below the noise level begins. It is a very educational experience. Synthesizers produce numerous artifacts that can also be very troublesome. It is a very common dilemma to build a receiver using “cheap” construction and poorly conceived packaging, and then try to bully the thing into good behavior.

### Frequency Tuning

The synthesized first and second LOs present several different ways to tune the receiver frequency. This chapter cannot get into the details of synthesizer design,

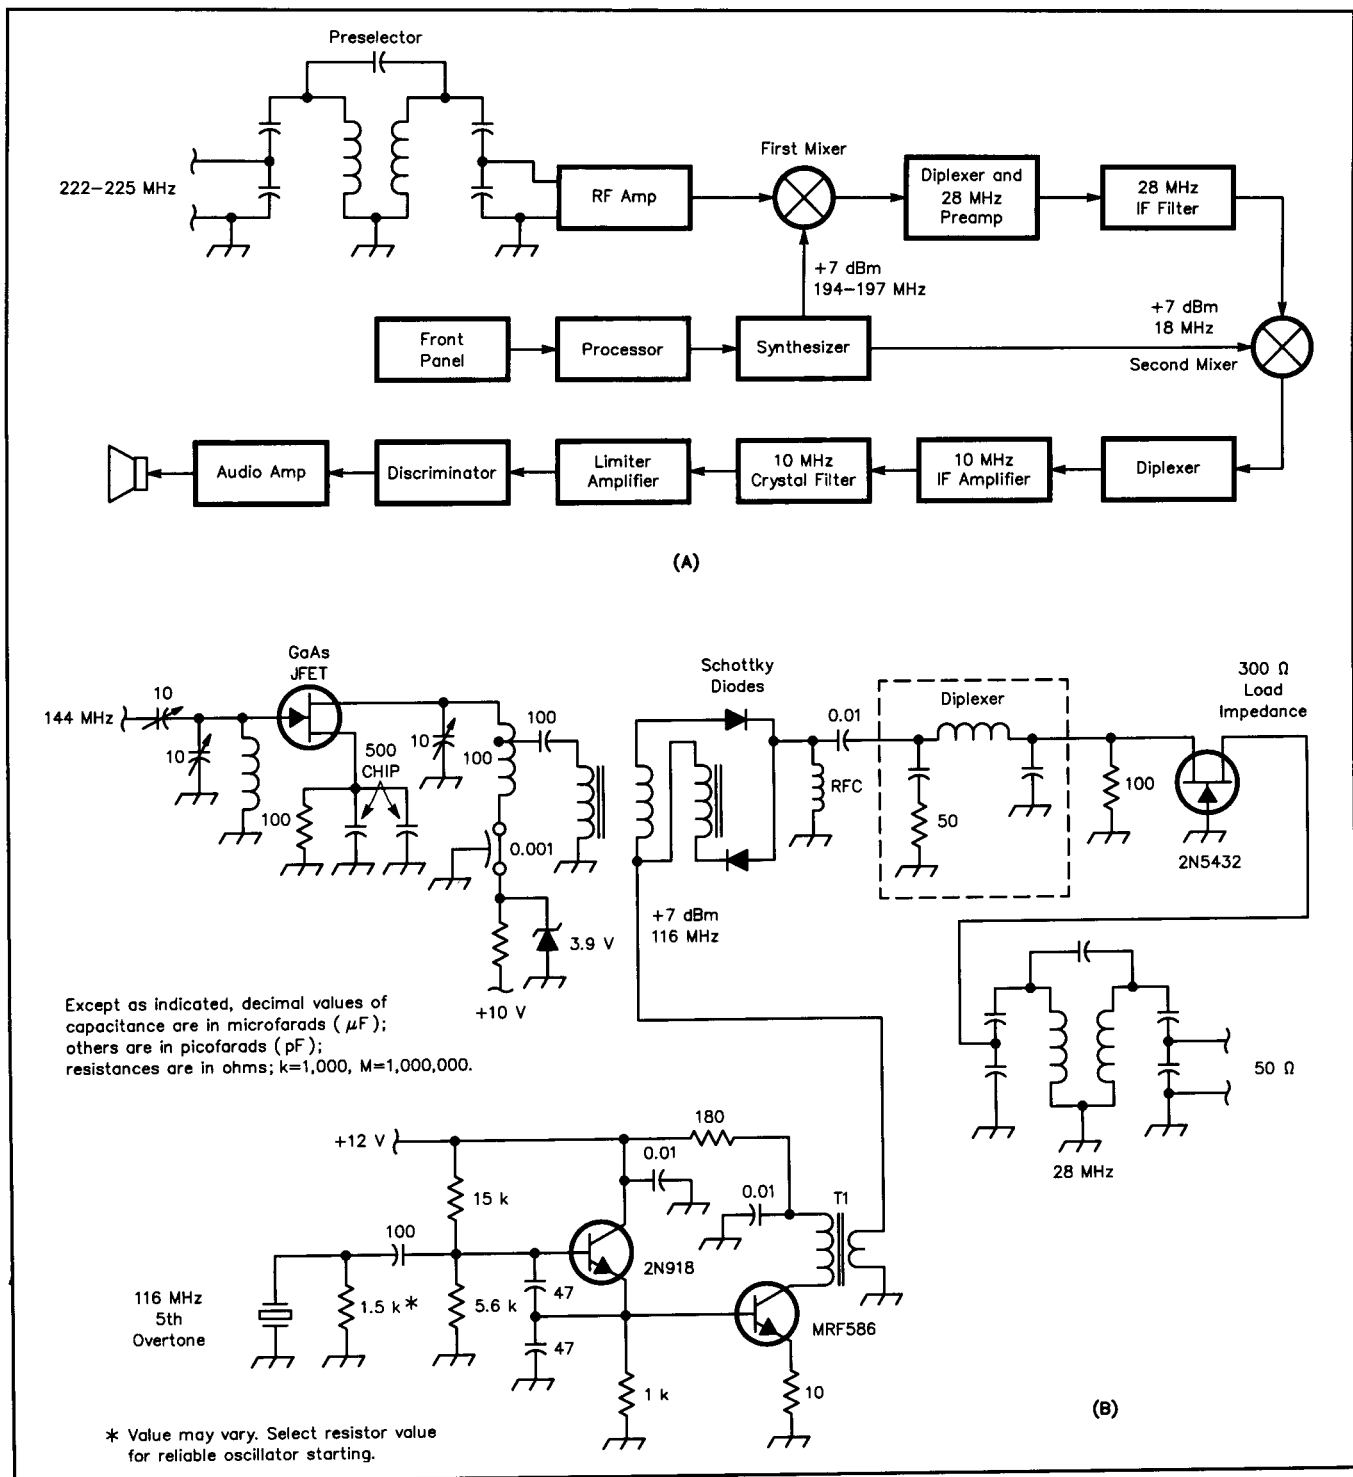

so these are only a few brief remarks. Let’s discuss two options from a system-design standpoint:

- Do all of the tuning in the first LO. If steps of 10 Hz (or 1 Hz) are needed, a single-loop synthesizer that tunes in, say 500-kHz or 1.0-MHz steps, can be used. Then, a direct digital synthesizer (DDS) that tunes in 10-Hz (or 1-Hz) steps is included in the main loop in what is termed a “translation loop.” The DDS frequency is added into the loop in such a manner that its imperfections are not increased by frequency multiplication. Because the reference frequency for the loop is high (500 kHz or 1.0 MHz) the phase noise of the main loop is quite small, if the loop and the circuitry are correctly designed and if the LO frequency is not extremely high. The digital frequency readout is obtained from the bits that program the synthesizer. A simpler approach might use a free-running VFO plus a low-cost frequency counter instead of the DDS. The counter can be designed to display the receiver signal frequency.
- If the first IF filter is sufficiently wideband it is possible to tune the first LO in steps of 500 kHz or 1.0 MHz and tune the second LO in 10-Hz steps. This may be a simpler method because the second LO need only be tuned over a small range.

With this second approach the first LO could be a crystal oscillator with switched overtone crystals, one for each ham band. The second LO could be a combination of crystal and VFO. One disadvantage (not extremely serious for amateur work) is that the LOs are not locked to a very accurate reference. Another is that a separate crystal (easy to get) is needed for each band. A frequency counter on the second LO could be used to get a close approximation to the signal frequency. This approach might be of interest to the home builder who is not yet ready to get involved with synthesizers. A 500-kHz crystal calibrator in the receiver would mark the band edges accurately.

### Passband Tuning

While listening to a desired signal in the presence of another partially overlapping and interfering signal, whether in SSB or CW mode, it is often possible to “move” the interference at least somewhat out of the receiver passband without affecting the tune frequency (pitch) of the desired signal. In Fig 17.36, if the processor has independent fine tuning control of the second and third LOs and also the BFO, it is a matter of software design to accomplish this. It is done by controlling the overlap or intersection of the passbands of the 10-MHz filters and the 455-kHz filters. There

**Fig 17.37—Some narrowband FM circuits. A: block diagram of a typical NBFM receiver. B: a front-end circuit with preselection and down conversion.**

are three things that can be done: the bandwidth can be decreased, the center frequency of the passband can be moved and both can be done simultaneously (Ref 61).

This scheme works best when both SSB or both CW filters are of high quality and have the same bandwidth (for example, 2.5 kHz and 500 Hz), fairly flat response and the same shape factor. As the pass-

band is made narrower by decreasing the overlap, however, the composite shape factor is degraded somewhat (it gets larger). For CW especially, this is not detrimental. A very steep-sided response at narrow bandwidths is not desirable from a transient-response standpoint. The effect is not serious for SSB either.

Later discussion in the Transceiver sec-

tion of this chapter will present another method of passband tuning using a variable frequency mixer scheme rather than software control. This method is commonly found in manufactured equipment.

### Noise Blanking

The desire to eliminate impulse noise from the receiver audio output has led to the

development of special IF circuits that detect the presence of a noise impulse and open the signal path just long enough to prevent the impulse from getting through. Most often, a diode switch is used to open the signal path. An important design requirement is that the desired IF signal must be delayed slightly, ahead of the switch, so that the switch is opened precisely when the noise arrives at the switch. The circuitry that detects the impulse and operates the switch has a certain time delay, so the signal in the mainline IF path must be delayed also. The Transceiver section of this chapter describes how a noise blanker is typically implemented. (See also Refs 48, 62.)

## VHF AND UHF RECEIVERS

The basic ideas presented in previous sections all operate equally well in receivers that are intended for the VHF and UHF regions. One difference, however, is that narrow-band frequency modulation (NBFM) is commonly used. In recent times, however, SSB has increased in popularity because of its potentially narrower channel spacing; (Ref 63). The commercial use of SSB at VHF has been encouraged by the use of a -10 dB pilot carrier combined with amplitude companding. This is known as amplitude-compandered SSB or ACSSB. Improvements in synthesizer design and frequency stability have also contributed to the growth of VHF SSB. We will focus the differences between VHF/UHF and HF receivers.

### Narrowband FM (NBFM) Receivers

Fig 17.37A is a block diagram of an NBFM receiver for the VHF/UHF amateur bands.

#### Front End

A low-noise front end is desirable because of the decreasing atmospheric noise level at these frequencies and also because portable gear uses short rod antennas at ground level. Nonetheless, the possibilities for gain compression and harmonic IMD, multitone IMD and cross modulation are also substantial. So dynamic range is an important design consideration, especially if large, high-gain antennas are used. FM limiting should not occur until after the NBFM signal filter. Because of the high occupancy of the VHF/UHF spectrum by powerful broadcast transmitters and nearby two-way radio services, front-end preselection is desirable, so that low noise figure can be achieved economically within the amateur band. Fig 17.37B is an example of a simple front end for the 144- to 148-MHz band.

#### Downconversion

Downconversion to the final IF can oc-

cur in one or two stages. Favorite IFs are in the 5 to 10-MHz region, but at the higher frequencies rejection of the image 10 to 20-MHz away can be difficult, requiring considerable preselection. So at the higher frequencies an intermediate IF in the 30 to 50-MHz region is a better choice. Fig 17.37A shows dual downconversion.

#### IF Filters

The customary frequency deviation in amateur NBFM is about 5 kHz RMS (7-kHz peak) and the audio speech band extends to 5 kHz. This defines a minimum modulation index (defined as the deviation ratio) of  $7/5 = 1.4$ . An inspection of the Bessel function plots shows that this condition confines most of the 300 to 5000-Hz speech information sidebands within a 12 to 15-kHz-wide bandwidth filter. With this bandwidth, channel separations of 20 or 25 kHz are achievable.

Many amateur NBFM transceivers are channelized in steps that can vary from 5 to 25 kHz. For low distortion of the audio output (after FM detection), this filter should have good phase linearity across the bandwidth. This would seem to preclude filters with very steep descent outside the passband, that tend to have very nonlinear phase near the band edges. But since the amount of energy in the higher speech frequencies is naturally less, the actual distortion due to this effect may be acceptable for speech purposes. A possible qualifier to this may be when preemphasis of the higher speech frequencies occurs at the transmitter and deemphasis compensates at the receiver (a commonly found feature).

#### Limiting

After the filter, hard limiting of the IF is needed to remove any amplitude components. In a high-quality receiver, special attention is given to any nonlinear phase shift that might result from the limiter circuit design. This is especially important in phase-coherent data receivers. In amateur receivers for speech it may be less important. Also, the "ratio detector" (see **Mixers** chapter) largely eliminates the need for a limiter stage, although the limiter approach is probably still preferred.

#### FM Detection

The discussion of this subject is deferred to the **Mixers** chapter. Quadrature detection is used on some popular NBFM multistage ICs. An example receiver chip will be presented later. Also see the Transceivers section of this chapter.

#### NBFM Receiver Weak-Signal Performance

The noise bandwidth of the IF filter is

not much greater than twice the audio bandwidth of the speech modulation, as it would be in wideband FM. Therefore such things as capture effect, the threshold effect and the noise quieting effect so familiar to wideband FM are still operational, but somewhat less so, in NBFM. For NBFM receivers, sensitivity is specified in terms of a SINAD (see the **Test** chapter) ratio of 12 dB. Typical values are -110 to -125 dBm, depending on the low-noise RF preamplification that often can be selected or deselected (in strong signal environments).

#### LO Phase Noise

In an FM receiver, LO phase noise superimposes phase modulation, and therefore frequency modulation, onto the desired signal. This reduces the ultimate signal-to-noise ratio within the passband. This effect is called "incidental FM (IFM)." The power density of IFM (W/Hz) is equal to the phase noise power density (W/Hz) multiplied by the square of the frequency offset from the carrier (the familiar parabolic effect in FM). If the receiver uses high-frequency deemphasis at the audio output (-6 dB per octave from 300 to 3000 Hz, a common practice), the IFM level at higher audio frequencies can be reduced. Levels of total (integrated) IFM from 10 to 50 Hz are high quality for amateur voice work. Ordinarily, as the signal increases the noise would be "quieted" (that is, "captured") in an FM receiver, but in this case the signal and the phase noise riding "piggy back" on the signal increase in the same proportion. As the signal becomes large the signal-to-noise ratio therefore approaches some final value (Ref 23). A similar ultimate SNR effect occurs in SSB receivers. On the other hand, a perfect AM receiver tends to suppress LO phase noise (Ref 33).

#### NBFM ICs

A wide variety of special ICs for NBFM receivers are available. Many of these were designed for "cordless" or cellular telephone applications and are widely used. Fig 17.38 shows some popular versions for a 50-MHz NBFM receiver. One is an RF amplifier chip (NE/SA5204A) for 50-Ω input to 50-Ω output with 20 dB of gain. This gain should be reduced to perhaps 8 dB. The second chip (NE/SA602A) is a front-end device (Ref 75) with an RF amplifier, mixer and LO. The third is an IF amplifier, limiter and quadrature NBFM detector (NE/SA604A) that also has a very useful RSSI (logarithmic received signal strength indicator) output and also a "mute" function. The fourth is the LM386, a widely used audio-amplifier chip. An-

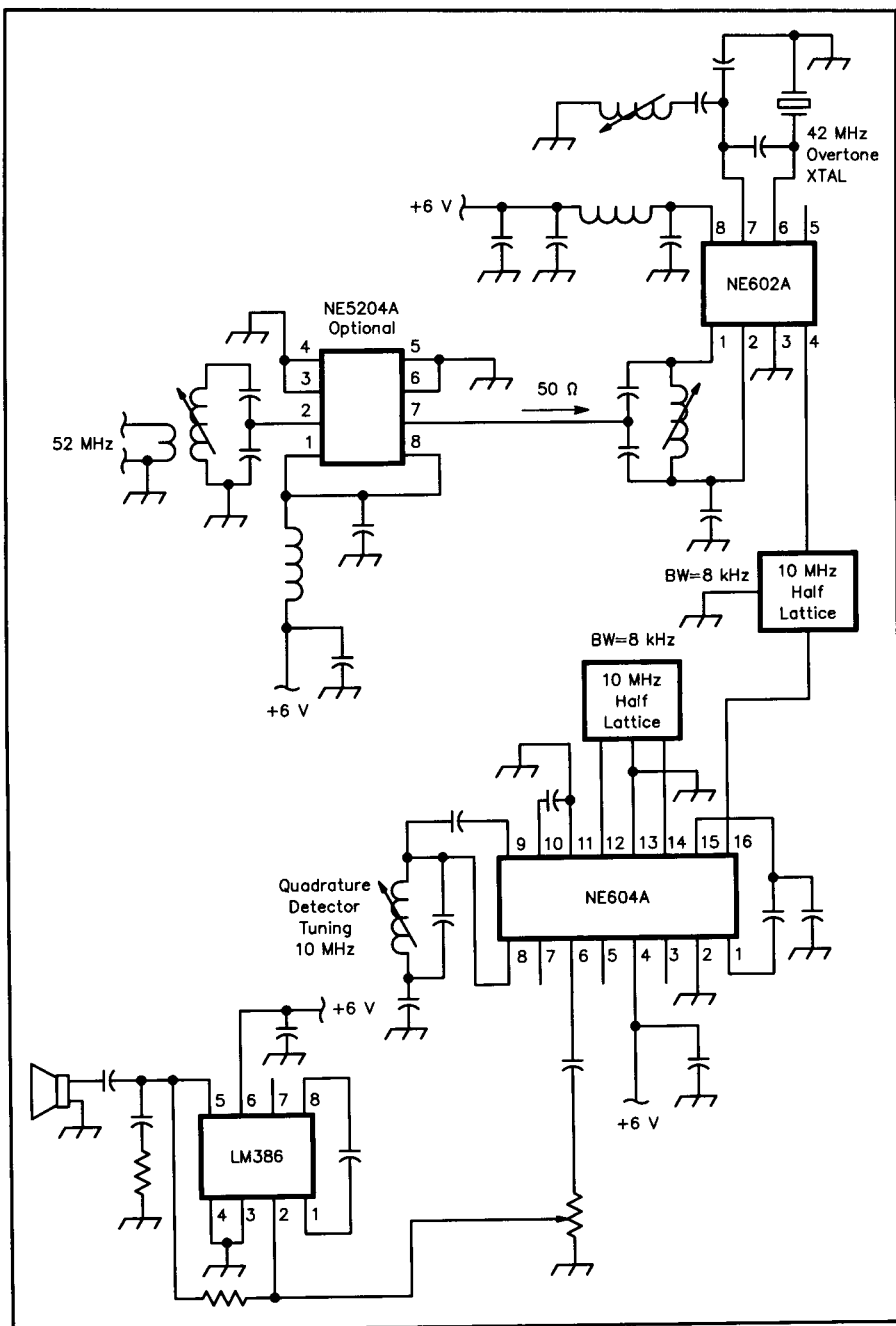

Fig 17.38—The NE/SA5204A, NE/SA602A, NE/SA604A NBFM ICs and the LM386 audio amplifier in a typical amateur application for 50 MHz.

other NBFM receiver chip, complete in one package, is the MC3371P.

The NE/SA5204A plus the two tuned circuits help to improve image rejection. An alternative would be a single double tuned filter with some loss of noise figure. The Mini-Circuits MAR series of MMIC amplifiers are excellent devices also. The crystal filters restrict the noise bandwidth as well as the signal bandwidth. A cascade of two low-cost filters is suggested by the vendors (Ref 64). Half-lattice filters at 10 MHz are shown, but a wide variety of alternatives, such as ladder networks, are possible.

Another recent IC is the MC13135, which features double conversion and two IF amplifier frequencies. This allows more gain on a single chip with less of the cross-coupling that can degrade stability. This desirable feature of multiple down-conversion was mentioned previously in this chapter.

The diagram in Fig 17.38 is (intentionally) only a general outline that shows how chips can be combined to build complete equipment. The design details and specific parts values can be learned from a careful study of the data sheets and application

notes provided by the IC vendors. Amateur designers should learn how to use these data sheets and other information. The best places to learn about data sheets are data books and application notes.

## UHF Techniques

The Ultra High Frequency spectrum is considered to be the range from 300 MHz to 3 GHz. All of the basic principles of radio system design and circuit design that have been discussed so far apply as well in this range, but the higher frequencies require some special thinking about the methods of circuit design and the devices that are used.

### 430-MHz Methods

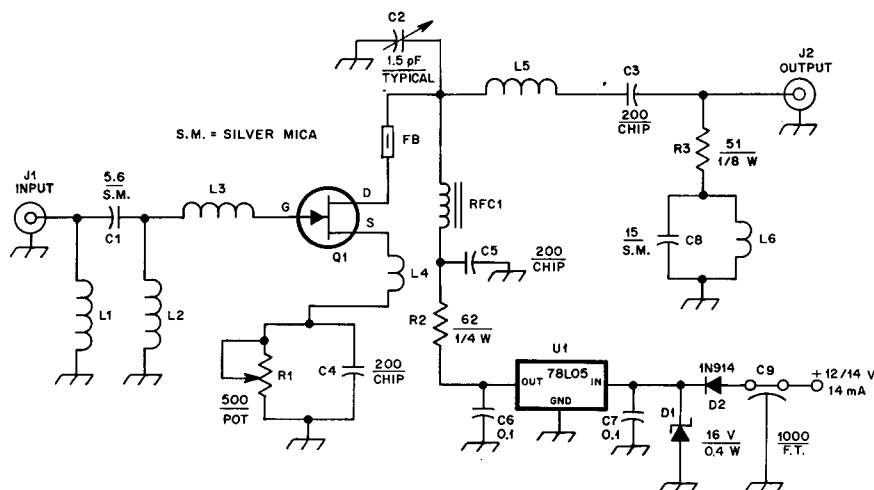

Fig 17.39 shows the schematic diagram and the physical construction of a typical RF circuit at 430 MHz. It is a GaAsFET preamplifier intended for low noise Earth-Moon-Earth or satellite reception.

The construction uses chip capacitors, small helical inductors and a stripline surface-mount GaAsFET, all mounted on a G10 (two layers of copper) glass-epoxy PC board. The very short length of interconnection leads is typical. The bottom of the PC board is a ground plane. At this frequency, lumped components are still feasible, while microstrip circuitry tends to be rather large.

At higher frequencies, microstrip methods become more desirable in most cases because of their smaller dimensions. However, the advent of tiny chip capacitors and chip resistors have extended the frequency range of discrete components. For example, the literature shows methods of building LC filters at as high as 2 GHz, using chip capacitors and tiny helical inductors (Refs 65, 66). Commercially available amplifier and mixer circuits operate at 2 GHz, using these types of components on ceramic substrates.

### ICs for UHF

In recent years a wide variety of highly miniaturized monolithic microwave ICs (MMIC) have become available at reasonable cost. Among these are the Avantek MODAMP and the Mini Circuits MAR and MAV lines (see Ref 89). Designer kits containing a wide assortment of these are available at reasonable cost. They come in a wide variety of gains, intercepts and noise figures for frequency ranges from dc to 2 GHz. A more expensive option, for more sophisticated receiver applications, are the hybrid "cascadable" amplifiers, built on ceramic substrates and mounted in TO5 or TO8 metal cans. Most of these circuits are intended for a 50-Ω to 50-Ω interface.

\* = EYELET SOLDERED BOTH SIDES

- C1—5.6-pF silver-mica capacitor or same as C2.
- C2—0.6- to 6-pF ceramic piston trimmer capacitor (Johanson 5700 series or equiv).
- C3, C4, C5—200-pF ceramic chip capacitor.
- C6, C7—0.1-mF disc ceramic capacitor, 50 V or greater.
- C8—15-pF silver-mica capacitor.
- C9—500- to 1000-pF feedthrough capacitor.
- D1—16- to 30-V, 500-mW Zener diode (1N966B or equiv).
- D2—1N914, 1N4148 or any diode with ratings of at least 25 PIV at 50 mA or greater.
- J1, J2—Female chassis-mount Type-N connectors, PTFE dielectric (UG-58 or equiv).
- L1, L2—3t, #24 tinned wire, 0.110-inch ID spaced 1 wire diam.
- L3—5t, #24 tinned wire,  $\frac{3}{16}$ -inch ID, spaced 1 wire diam. or closer. Slightly larger diameter (0.010 inch) may be required with some FETs.
- L4, L6—1t #24 tinned wire, 1/8-inch ID.
- L5—4t #24 tinned wire,  $\frac{1}{8}$ -inch ID, spaced 1 wire diam.
- Q1—Mitsubishi MGF1402.
- R1—200- or 500- $\Omega$  cermet potentiometer (initially set to midrange).
- R2—62- $\Omega$ ,  $\frac{1}{4}$ -W resistor.
- R3—51- $\Omega$ ,  $\frac{1}{8}$ -W carbon composition resistor, 5% tolerance.
- RFC1—5t #26 enameled wire on a ferrite bead.
- U1—5-V, 100-mA 3-terminal regulator (LM78L05 or equiv. TO-92 package).

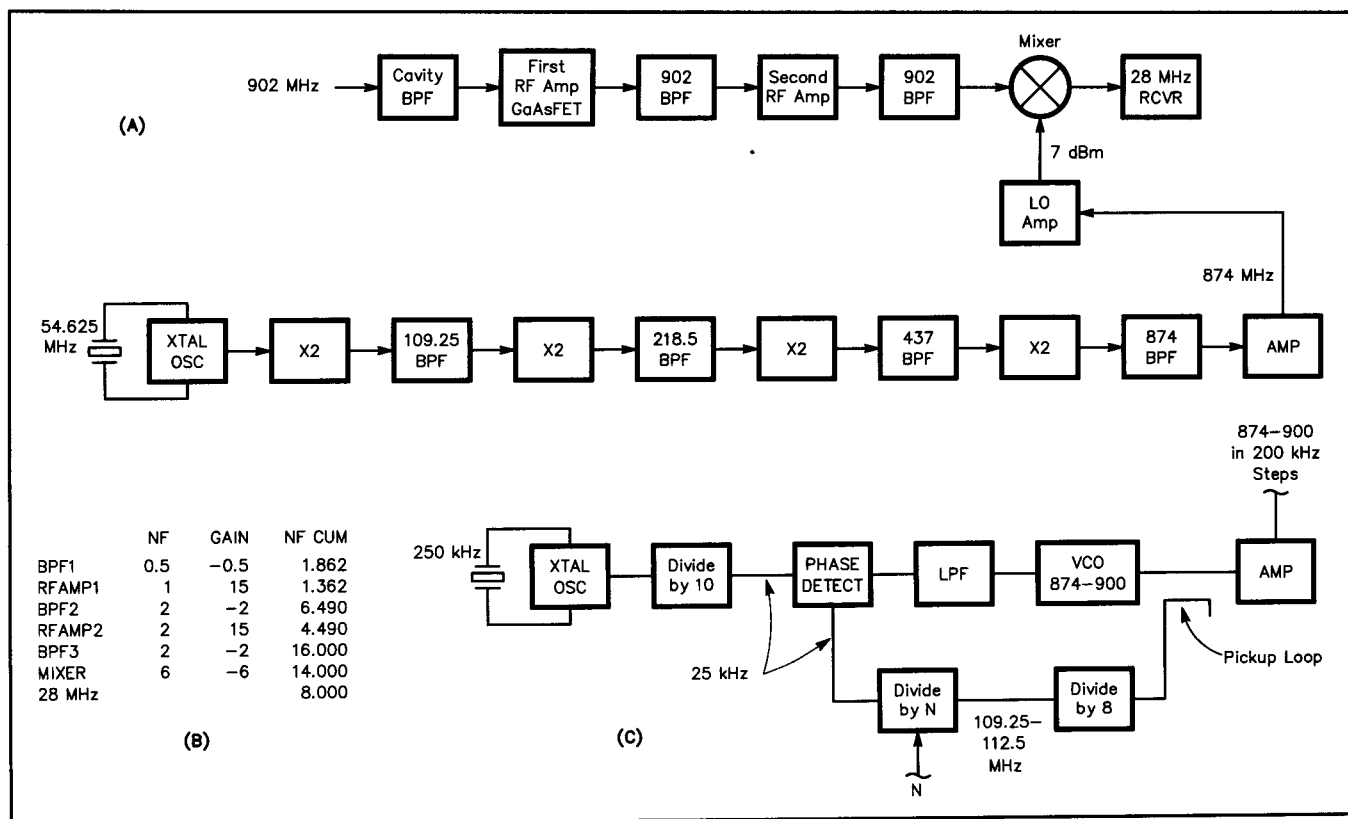

Fig 17.40—A down converter for the 902 to 928 MHz band. A: block diagram; B, cumulative noise figure of the signal path; C, alternative LO multiplier using a phase locked loop.

A wide variety of hybrid amplifiers, designed for the Cable TV industry, are available for the frequency range from 1 to 1200 MHz (for example, the Motorola CA series, in type 714x packages). These have gains from 15 to 35 dB, output 1-dB compression points from 22 to 30 dBm and noise figures from 4.5 to 8.5 dB. Such units are excellent alternatives to discrete home-brew circuits for many applications where very low noise figures are not needed. In small quantities they may be a bit expensive sometimes, but the total cost of a home-built circuit, including labor (even the amateur experimenter's time is not really "free") is often at least as great. Home-built circuits do, however, have very important educational value.

### UHF Design Aids

Circuit design and evaluation at the higher frequencies usually require some kind of minimal lab facilities, such as a signal generator, a calibrated noise generator and, hopefully, some kind of simple (or surplus) spectrum analyzer. This is true because circuit behavior and stability depend on a number of factors that are difficult to "guess at," and intuition is often unreliable. The ideal instrument is a vector network analyzer with all of the attach-

ments (such as an S-parameter measuring setup), but very few amateurs can afford this. Another very desirable thing would be a circuit design and analysis program for the personal computer. Software packages created especially for UHF and microwave circuit design are available. They tend to be somewhat expensive, but worthwhile for a serious designer. Inexpensive SPICE programs are a good compromise. Other public-domain programs for limited functions and uses (for example, Cal Tech's "Puff" program) are often available from various sources.

### A 902 to 928 MHz (33 cm) Receiver

Fig 17.40A is a block diagram of a 902-MHz down-converting receiver. A cavity resonator at the antenna input provides high selectivity with low loss. The first RF amplifier is a GaAsFET. Two additional 902-MHz band-pass microstrip filters and a BFR96 transistor provide more gain and image rejection (at RF-56 MHz) for the Mini Circuits SRA12 mixer. The output is at 28.0 MHz.

### Cumulative Noise Figure

Fig 17.40B shows the cumulative noise figure (NF) of the signal path, including the 28-MHz receiver. The 1.5-dB cumula-

tive NF of the input cavity and first-RF-amplifier combination, considered by itself, is degraded to 1.9 dB by the rest of the system following the first RF amplifier. The NF values of the various components for this example are reasonable, but may vary somewhat for actual hardware. Also, losses prior to the input, such as transmission-line losses (very important), are not included. They would be part of the complete receive-system analysis, however. It is common practice to place a low-noise preamp outdoors, right at the antenna, to overcome coax loss (and to permit use of inexpensive coax).

### Local Oscillator (LO) Design

The +7 dBm LO at 874 to 900 MHz is derived from a set of crystal oscillators and frequency multipliers, separated by band-pass filters. These filters prevent a wide assortment of spurious frequencies from appearing at the mixer LO port. They also enhance the ability of the doubler stage to generate the second harmonic. That is, they have a very low impedance at the input frequency, thereby causing a large current to flow at the fundamental frequency. This increases the nonlinearity of the circuit, which increases the second-harmonic component. The higher filter

**Fig 17.41—A low-noise preamplifier for 10 GHz, illustrating the methods used at microwaves. A: schematic. B: PC board layout. Use 15-mil 5880 Duroid, dielectric constant of 2.2 and a dissipation factor of 0.0011. C: A photograph of the completed preamp.**

**C1, C4**—1-pF ATC 100-A chip capacitors. C1 must be very low loss.  
**C2, C3**—1000-pF chip capacitors. (Not critical.) The ones from Mini Circuits work fine.

**F1, F2**—Pieces of copper foil used to tune the preamp.  
**J1, J2**—SMA jacks. Ideally these should be microstrip launchers. The pin should be flush against the board.

**L1, L2**—The 15-mil lead length going through the board to the ground plane.  
**R1, R2**—51- $\Omega$  chip resistors.  
**Z1-Z15**—Microstriplines etched on the PC board.

impedance at the second harmonic produces a large harmonic output.

For very narrow-bandwidth use, such as EME, the crystal oscillators are often oven controlled or otherwise temperature compensated. The entire LO chain must be of low-noise design and the mixer should have good isolation from LO port to RF port (to minimize noise transfer from LO to RF).

A phase-locked loop using GHz-range prescalers (as shown in Fig 17.40C) is an alternative to the multiplier chain. The divide by N block is a simplification; in

practice, an auxiliary dual-modulus divider in a “swallow count” loop would be involved in this segment.

The cascaded 902-MHz band-pass filters in the signal path should attenuate any image frequency noise (at RF–56 MHz) that might degrade the mixer noise figure.

#### Summary

This example is fairly typical of receiver design methods for the 500 to 3000 MHz range, where down conversion to an existing HF receiver is the most-convenient and

cost-effective approach for amateurs. At higher frequencies a double down conversion with a first IF of 200 MHz or so, to improve image rejection, might be necessary. Usually, though, the presence of strong signals at image frequencies is less likely. Image reducing mixers plus down conversion to 28 MHz is also coming into use, when strong interfering signals are not likely at the image frequency.

#### “No-Tune” Techniques

In recent years, a series of articles have

**Analysis of a 10.368 GHz communication link with SSB modulation:**

Free space path loss (FSPL) over a 50 mile line-of-sight path (S) at  $F = 10.368$  GHz:  
 $FSPL = 36.6 \text{ (dB)} + 20 \log F \text{ (MHz)} + 20 \log S \text{ (Mi)} = 36.6 + 80.3 + 34 = 150.9 \text{ dB}$

Effective isotropic radiated power (EIRP) from transmitter:  
 $EIRP \text{ (dBm)} = P_{XMIT} \text{ (dBm)} + \text{Antenna Gain (dBi)}$

The antenna is a 2 ft diameter (D) dish whose gain  $GA \text{ (dBi)}$  is:  
 $GA = 7.0 + 20 \log D \text{ (ft)} + 20 \log F \text{ (GHz)} = 7.0 + 6.0 + 20.32 = 33.3 \text{ dBi}$

Assume a transmission-line loss  $L_T$ , of 3 dB

The transmitter power  $P_T = 0.5 \text{ (mW PEP)} = -3 \text{ (dBm PEP)}$

$P_{XMIT} = P_T \text{ (dBm PEP)} - L_T \text{ (dB)} = -3 - 3 = -6 \text{ (dBm PEP)}$

$EIRP = P_{XMIT} + G_A = -6 + 33.3 = 27.3 \text{ (dBm PEP)}$

Using these numbers the received signal level is:

$P_{RCVD} = EIRP \text{ (dBm)} - \text{Path loss (dB)}$   
 $= 27.3 \text{ (dBm PEP)} - 150.9 \text{ (dB)} = -123.6 \text{ (dBm PEP)}$

Add to this a receive antenna gain of 17 dB. The received signal is then  $P_{RCVD} = -123.6 + 17 = -106.6 \text{ dBm}$

Now find the receiver's ability to receive the signal:

The antenna noise temperature  $T_A$  is 200 K. The receiver noise figure  $NF_R$  is 6 dB ( $FR=3.98$ , noise temperature  $T_R = 864.5 \text{ K}$ ) and its noise bandwidth (B) is 2400 Hz.

The feedline loss  $L_L$  is 3 dB ( $F=2.00$ , noise temperature  $T_L = 288.6 \text{ K}$ ). The system noise temperature is:

$T_S = T_A + T_L + (L_L) (T_R)$

$T_S = 200 + 288.6 + (2.0) (864.5) = 2217.6 \text{ K}$

$N_S = kT_S B = 1.38 \times 10^{-23} \times 2217.6 \times 2400 = 7.34 \times 10^{-17} \text{ W} = -131.3 \text{ dBm}$

This indicates that the PEP signal is  $-106.6 - (-131.3) = 24.7 \text{ dB}$  above the noise level. However, because the average power of speech, using a speech processor, is about 8 dB less than PEP, the average signal power is about 16.7 dB above the noise level.

To find the system noise factor  $F_S$  we note that the system noise is proportional to the system temperature  $T_S$  and the "generator" (antenna) noise is proportional to the antenna temperature  $T_A$ . Using the idea of a "system noise factor":  $F_S = T_S / T_A = 2217.6 / 200 = 11.09 = 10.45 \text{ dB}$ .

If the antenna temperature were 290 K the system noise figure would be 9.0 dB, which is precisely the sum of receiver and receiver coax noise figures ( $6.0 + 3.0$ ).

"get going" on microwaves using the material supplied in the articles. Complete kits are available from suppliers listed in the ARRL Address List in the **References** chapter. Microwave ham clubs and their publications are a good way to get started in microwave amateur technology.

Because of the frequencies involved, dimensions of microstrip circuitry must be very accurate. Dimensional stability and dielectric constant reliability of the boards must be very good.

**System Performance**

At microwaves, an estimation of system performance can often be performed using known data about the signal path terrain, atmosphere, transmitter and receivers systems. **Fig 17.42** shows a simplified example of how this works. This example is adapted from December 1980 *QST* (also see ARRL *UHF/Microwave Experimenter's Manual*, p 7-55). In the present context of receiver design we wish to establish an approximate goal for the receiver system, including the antenna and transmission line.

A more detailed analysis includes terrain variations, refraction effects, the Earth's curvature, diffraction effects and interactions with the atmosphere's chemical constituents and temperature gradients. *The ARRL UHF/Microwave Experimenter's Manual* is a good text for these matters.

In microwave work, where very low noise levels and low noise figures are encountered, experimenters like to use the "effective noise temperature" concept, rather than noise factor. The relationship between the two is given by

$$T_E = 290 (F - 1) \quad (7)$$

$T_E$  is a measure, in terms of temperature, of the "excess noise" of a component (such as an amplifier). A resistor at  $290 + T_E$  would have the same available noise power as the device (referred to the device's input) specified by  $T_E$ . For a lossy device (such as a lossy transmission line)  $T_E$  is given by  $T_E = 290 (L - 1)$ , where  $L$  is the loss factor (same as its noise factor). The cascade of noise temperatures is similar to the Friis formula for cascaded noise factors and its use is illustrated in **Fig 17.42**.

$$T_S = T_G + T_{E1} + T_{E2}/G_1 + T_{E3}/(G_1 G_2) + T_{E4}/(G_1 G_2 G_3) + \dots \quad (8)$$

where  $T_S$  is the system noise temperature (including the generator, which may be an antenna) and  $T_G$  is the temperature of the antenna.

The 290 number in the formulas for  $T_E$  is the standard ambient temperature

**Fig 17.42—Example of a 10-GHz system performance calculation. Noise temperature and noise factor of the receiver are considered in detail.**

appeared that emphasize simplicity of construction and adjustment. The use of printed-circuit microstrip filters that require little or no adjustment, along with IC or MMIC devices, or discrete transistors, in precise PC-board layouts that have been carefully worked out, make it much easier to "get going" on the higher frequencies. Several of the References at the end of this discussion show how these UHF and microwave units are designed and built (Refs 67, 68, 69, 70, 71). See also the projects at the end of this chapter.

**Microwave Receivers**

The world above 3 GHz is a vast territory with a special and complex technology and an "art form" that are well beyond the scope of this chapter. We will scratch the surface by describing a specific receiver for the 10-GHz frequency range and point out some of the important special features that are unique to this frequency range.

**A 10-GHz Preamplifier**

**Fig 17.41A** is a schematic and parts list,

B is a PC-board parts layout and C is a photograph for a 10-GHz preamp, designed by Zack Lau at ARRL HQ. With very careful design and packaging techniques a noise figure approaching the 1 to 1.5-dB range was achieved. This depends on an accurate 50-Ω generator impedance and noise matching the input using a microwave circuit-design program such as Touchstone or Harmonica. Note that microstrip capacitors, inductors and transmission-line segments are used almost exclusively. The circuit is built on a 15-mil Duroid PC board. In general, this kind of performance requires some elegant measurement equipment that few amateurs have. A detailed discussion appears in Ref 72; it is recommended reading. On the other hand, preamp noise figures in the 2 to 4-dB range are much easier to get (with simple test equipment) and are often satisfactory for terrestrial communication.

Articles written by those with expertise and the necessary lab facilities almost always include PC board patterns, parts lists and detailed instructions that are easily duplicated by readers. So it is possible to

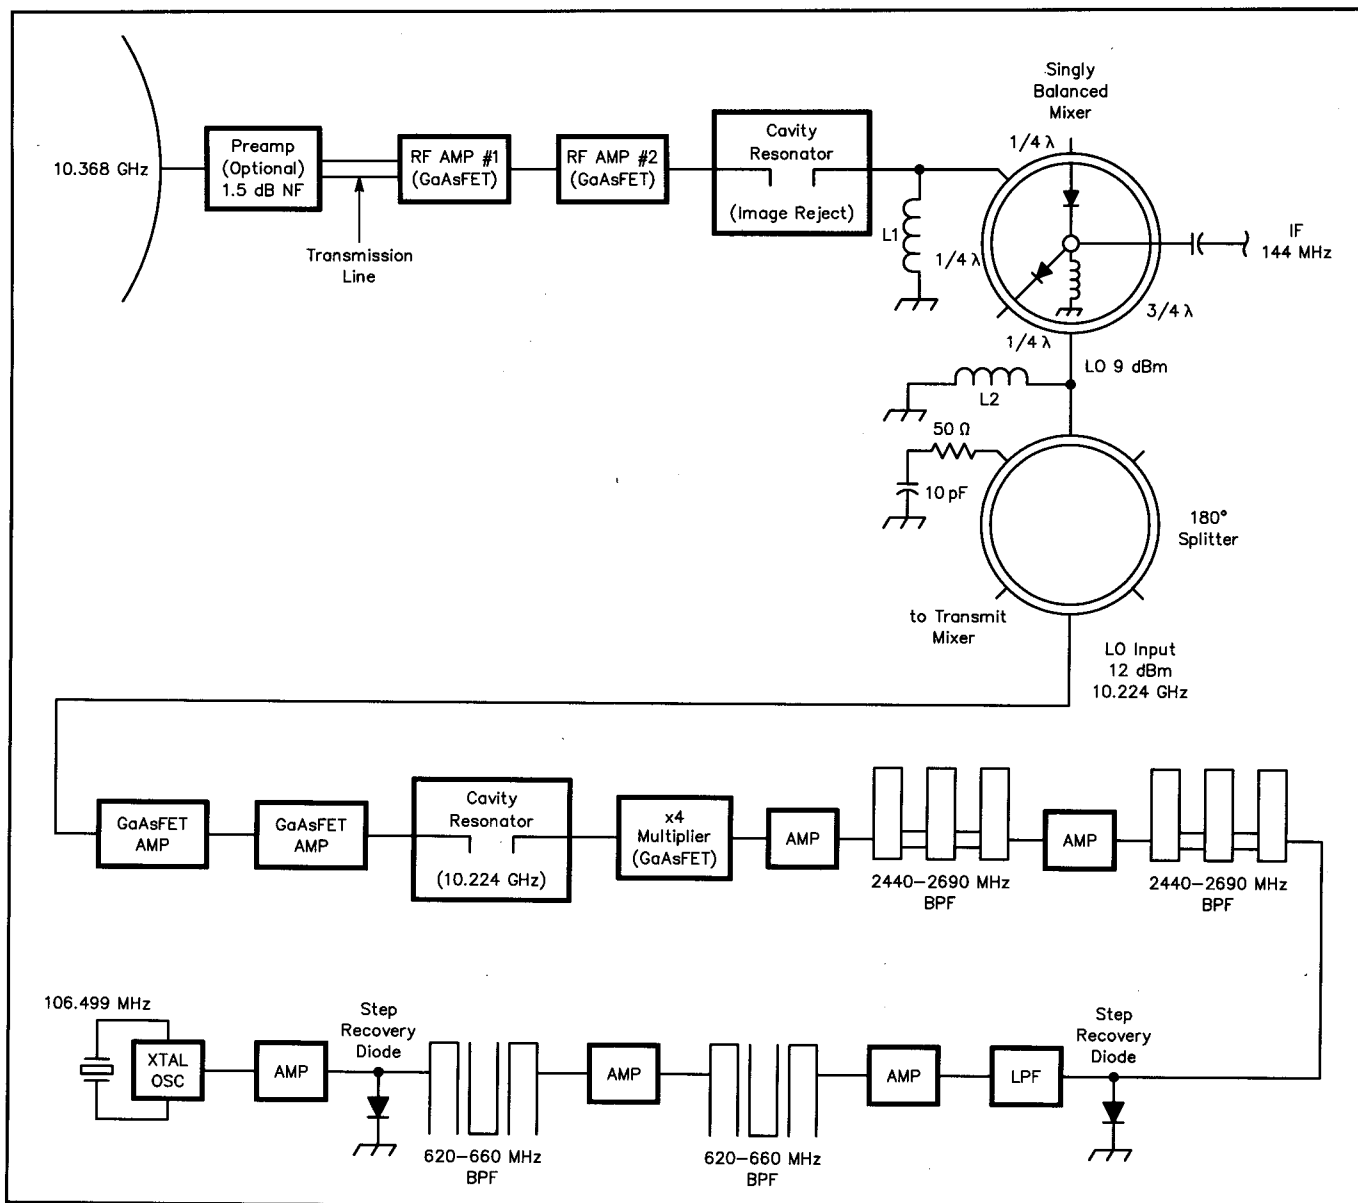

Fig 17.43—A block diagram of the microwave receiver discussed in the text.

(kelvins) at which the noise factor of a two-port transducer is defined and measured, according to an IEEE recommendation. So those formulas relate a noise factor  $F$ , measured at 290 K, to the temperature  $T_E$ . In general, though, it is perfectly correct to say that the ratio  $(S_i/N_i)/(S_o/N_o)$  can be thought of as the ratio of total system output noise to that system output noise attributed to the “generator” alone, regardless of the temperature of the equipment or the nature of the generator, which may be an antenna at some arbitrary temperature, for example. This ratio is, in fact, a special “system noise factor (or figure),  $F_S$ ” that need not be tied to any particular temperature such as 290 K. The use of the  $F_S$  notation avoids any confusion.

As the example of Fig 17.42 shows, the value of this system noise factor  $F_S$  is just the ratio of the total system temperature to the antenna temperature.

Having calculated a system noise temperature, the receive system noise floor (that is, the antenna input level of a signal that would exactly equal system noise, both observed at the receiver output) associated with that temperature is:

$$N = k T_S B_N \quad (9)$$

where

$$k = 1.38 \times 10^{-23} \text{ and} \\ B_N = \text{noise bandwidth.}$$

The system noise figure  $F_S$  is indicated in the example also. It is higher than the

sum of the receiver and coax noise figures.

The example includes a loss of 3 dB in the receiver transmission line. The formula for  $T_S$  in the example shows that this loss has a double effect on the system noise temperature, once in the second term (288.6) and again in the third term (2.0). If the receiver (or high-gain preamp with a 6 dB NF) were mounted at the antenna, the receive-system noise temperature would be reduced to 1064.5 K and a system noise figure,  $F_S$ , of 7.26 dB, a very substantial improvement. Thus, it is the common practice to mount a preamp at the antenna.

#### Microwave Receiver for 10 GHz

Ref 73 provides a good example of modern amateur experimenter techniques for the

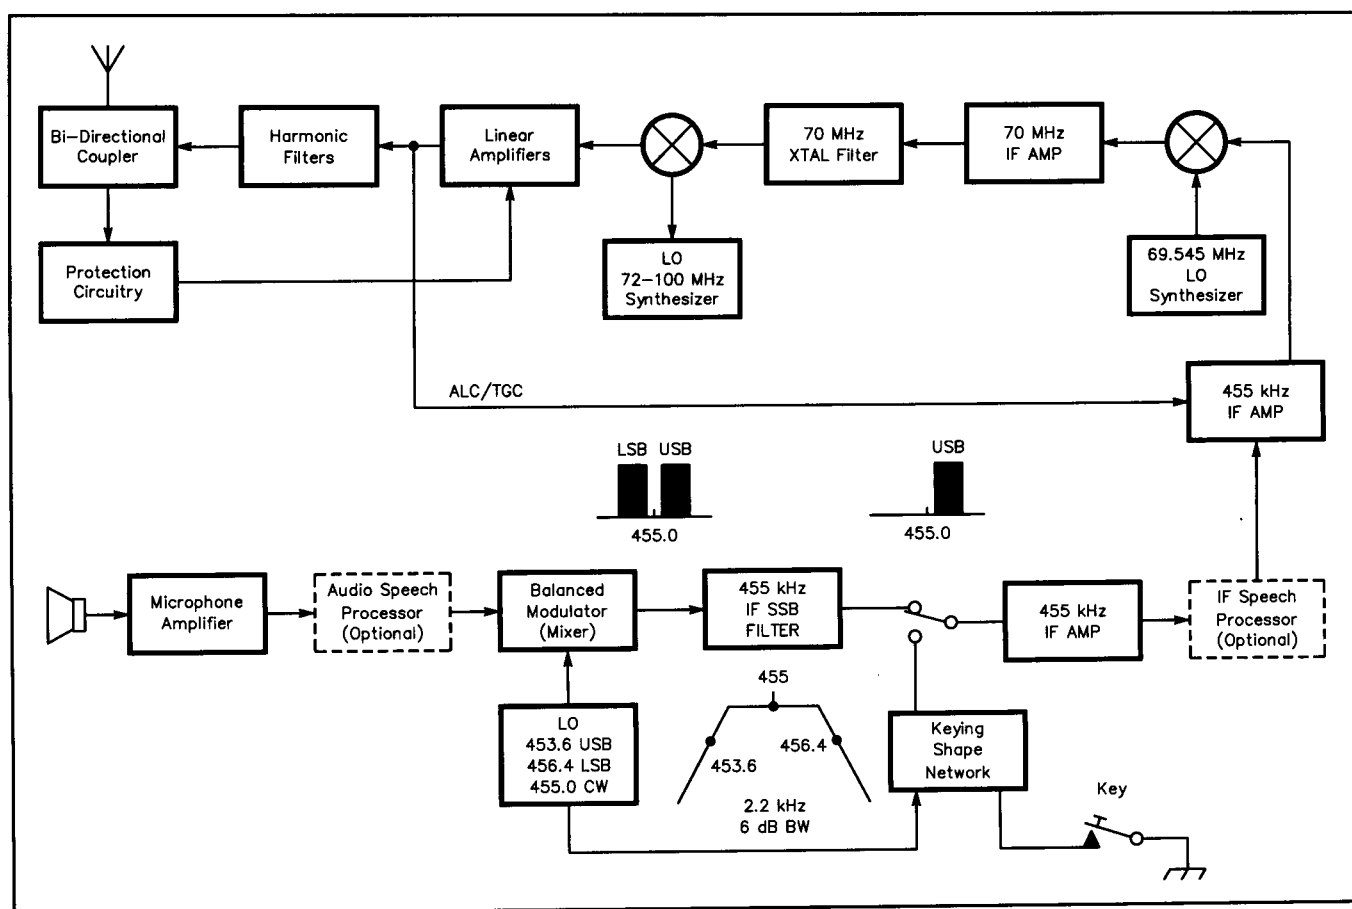

Fig 17.44—Block diagram of an up conversion SSB/CW transmitter. The various functions are discussed in the text.

10-GHz band. The intended use for the radio is narrowband CW and SSB work, which requires extremely good frequency stability in the LO. Here, we will discuss the receiver circuit (see also Ref 74).

### Block Diagram

Fig 17.43 is a block diagram of the receiver. Here are some important facets of the design.

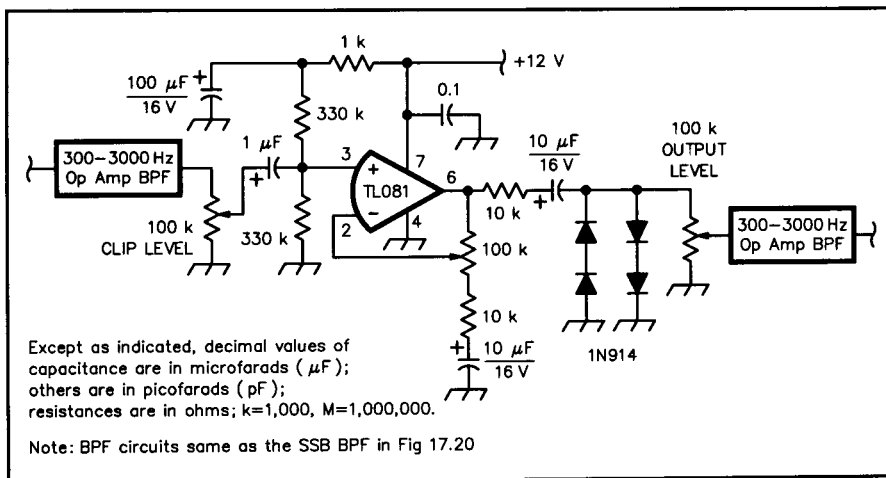

1. The antenna should have sufficient gain. At 10 GHz, gains of 30 dBi are not difficult to get, as the example of Fig 17.42 demonstrates. A 4-ft dish might be difficult to aim, however.
2. For best results a very low-noise preamp at the antenna reduces loss of system sensitivity when antenna temperature is low. For example, if the antenna temperature at a quiet direction of the sky is 50 K and the receiver noise figure is 4 dB (due in part to transmission-line loss), the system temperature is 488 K for a system noise figure of 9.9 dB. If the receiver noise figure is reduced to 1.5 dB by adding a preamp at the antenna the system temperature is reduced to 170 K for a system noise figure of 3.4 dB, which is a very big improvement.

3. After two stages of RF amplification using GaAsFETs, a probe-coupled cavity resonator attenuates noise at the mixer's image frequency, which is  $10.368 - 0.288 = 10.080$  GHz. An image reduction of 15 to 20 dB is enough to prevent image frequency noise generated by the RF amplifiers from affecting the mixer's noise figure.
4. The singly balanced diode mixer uses a "rat-race"  $180^\circ$  hybrid. Each terminal of the ring is  $1/4$  wavelength ( $90^\circ$ ) from its closest neighbors. So the anodes of the two diodes are  $180^\circ$  ( $1/2$  wavelength) apart with respect to the LO port, but in-phase with respect to the RF port. The inductors (L1, L2) connected to ground present a low impedance at the IF frequency. The mixer microstrip circuit is carefully "tweaked" to improve system performance. Use the better mixer in the transmitter.
5. The crystal oscillator is a fifth-overtone Butler circuit that is capable of high stability. The crystal frequency error and drift are multiplied 96 times ( $10.224 / 0.1065$ ), so for narrowband SSB or CW work it may be difficult to get on (and stay on) the "calling frequency" at 10.368

GHz. One acceptable (not perfect) solution might be to count the 106.5 MHz with a frequency counter whose internal clock is constantly compared with WWV. Adjust the 106.5 as required. At times there may be a small Doppler shift on the WWV signal. It may be necessary to switch to a different WWV frequency, or WWV's signals may not be strong enough. Surplus frequency standards of high quality are sometimes available. Many operators just "tune" over the expected range of uncertainty.

6. The frequency multiplier chain has numerous band-pass filters to "purify" the harmonics by reducing various frequency components that might affect the signal path and cause spurious responses. The final filter is a tuned cavity resonator that reduces spurs from previous stages. Oscillator phase noise amplitude is multiplied by 96.0 also, so the oscillator must have very good short term stability to prevent contamination of the desired signal.
7. A second hybrid splitter provides an LO output for the transmitter section of the radio. The 50- $\Omega$  resistor improves isolation between the two output ports.

**Fig 17.46—A simple audio speech clipper. The input signal is band pass filtered, amplified by 20 dB, clipped and band pass filtered again.**

power output, thereby wiping out some of the benefit of the speech processing. The square-wave effect is also reduced by band-pass filtering (300 to 3000 Hz) the input to the clipper as well as the output.

**Fig 17.46** is a circuit for a simple audio speech clipper. A CLIP LEVEL potentiometer before the clipper controls the amount of clipping and an OUTPUT LEVEL potentiometer controls the drive level to the balanced modulator. The correct adjustment of these potentiometers is done with a two-tone audio input or by talking into the microphone, rather than a single tone, because single tones don't exhibit the repeaking effect (Ref 48).

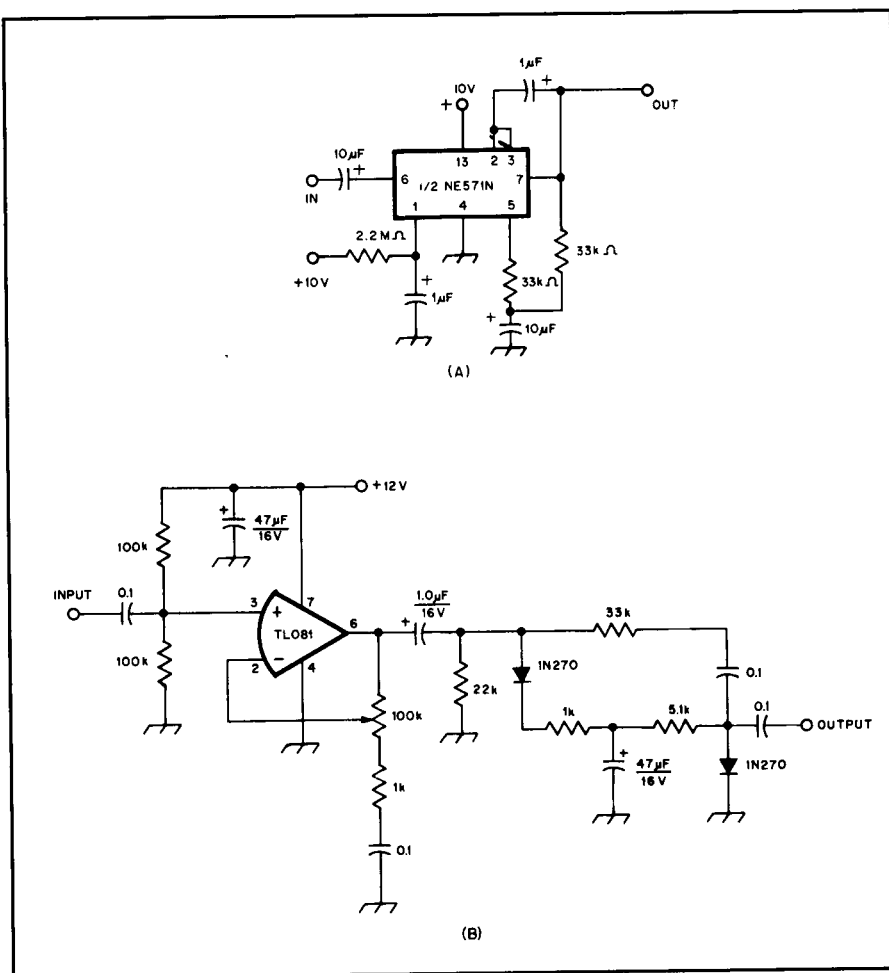

## Audio Speech Compression

Although it is desirable to keep the voice level as high as possible, it is difficult to maintain constant voice intensity when speaking into the microphone. To overcome this variable output level, it is possible to use an automatic gain control that follows the average variations in speech amplitude. This can be done by rectifying and filtering some of the audio output and applying the resultant dc to a control terminal in an early stage of the amplifier.

The circuit of **Fig 17.47A** works on this AGC principle. One section of a Signetics 571N IC is used. The other section can be connected as an expander to restore the dynamic range of received signals that have been compressed in transmission. Operational transconductance amplifiers such as the CA3080 are also well suited for speech compression.

When an audio AGC circuit derives control voltage from the output signal the system is a closed loop. If short attack time is necessary, the rectifier-filter bandwidth must be opened up to allow syllabic modulation of the control voltage. This allows some of the voice frequency signal to enter the control terminal, causing distortion and instability. Because the syllabic frequency and speech-tone frequencies have relatively small separation, the simpler feedback AGC systems compromise fidelity for fast response.

Problems with loop dynamics in audio AGC can be sidestepped by eliminating the loop and using a forward-acting system. The control voltage is derived from the input of the amplifier, rather than from the output. Eliminating the feedback loop allows unconditional stability, but the trade-off between response time and fidelity remains. Care must be taken to avoid excessive gain between the signal input and the control voltage output. Otherwise the transfer characteristic can reverse; that is, an increase in input level can cause a

**Fig 17.47—Typical solid-state compressor circuits. The circuit at A works on the AGC principle, while that at B is a forward-acting compressor.**

That is, the peak value tends to increase noticeably above its clipped value.

An SSB generator responds poorly to a square-wave audio signal. The Hilbert Transform effect, well known in mathematics, creates significant peaks in the

RF envelope. These peaks cause out-of-band splatter in the linear amplifiers unless Automatic Level Control (ALC, to be discussed later) cuts back on the RF gain. The peaks increase the peak-to-average ratio and the ALC reduces the average SSB

decrease in output. A simple forward-acting compressor is shown in Fig 17.47B.

An additional interesting method of speech compression involves the technology of "Homomorphic Signal Processing." This subject is covered prominently in digital signal processing textbooks (Ref 78). An excellent example of an analog instrument that performs this function is described in Ref 79.

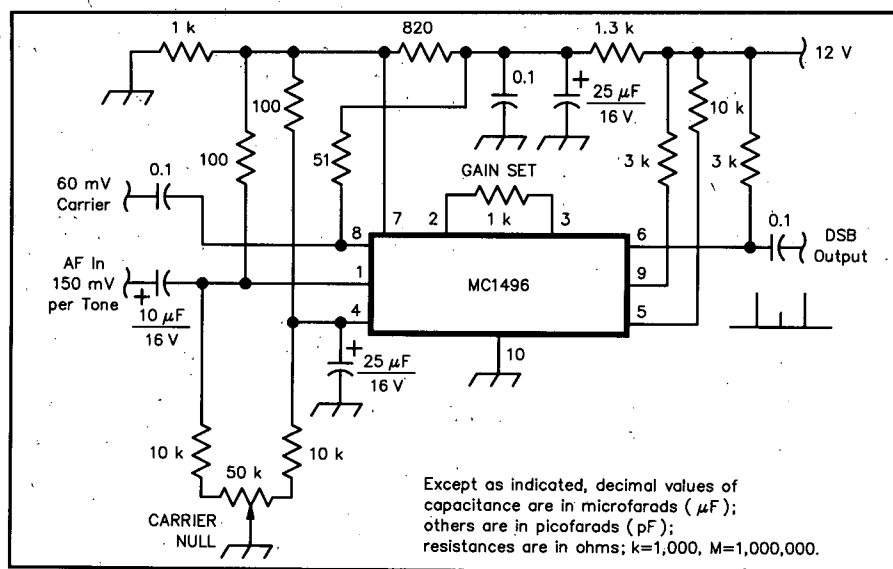

## Balanced Modulators

A balanced modulator is a mixer. A more complete discussion of balanced modulator design is provided in the **Mixers** chapter. Briefly, the IF frequency LO (455 kHz in the example of Fig 17.44) translates the audio frequencies up to a pair of IF frequencies, the LO plus the audio frequency and the LO minus the audio frequency. The balance from the LO port to the IF output causes the LO frequency to be suppressed by 30 to 40 dB. Adjustments are provided to improve the LO null.

The filter method of SSB generation uses an IF band-pass filter to pass one of the sidebands and block the other. In Fig 17.44 the filter is centered at 455.0 kHz. The LO is offset to 453.6 kHz or 456.4 kHz so that the upper sideband or the lower sideband (respectively) can pass through the filter. This creates a problem for the other LOs in the radio, because they must now be properly offset so that the final transmit output's carrier (suppressed) frequency coincides with the frequency readout on the front panel of the radio. Various schemes have been used to do this. One method uses two crystals for the 69.545-MHz LO that can be selected. In synthesized radios the programming of the microprocessor control moves the various LOs. Some synthesized radios use two IF filters at two different frequencies, one for USB and one for LSB, and a 455.0-kHz LO. These radios are often designed to transmit two independent sidebands (ISB, Ref 48).

In times past, balanced modulators using diodes, balancing potentiometers and numerous components spread out on a PC board were universally used. These days it doesn't make sense to use this approach. ICs and packaged diode mixers do a much better job and are less expensive. The most famous modulator IC, the MC1496, has been around for more than 15 years and is still one of the best and least expensive (Ref 80). Fig 17.48 is a typical balanced modulator circuit using the MC1496.

The data sheets for balanced modulators and mixers specify the maximum level of audio for a given LO level. Higher audio levels create excessive IMD. The IF filter

**Fig 17.48—An IC balanced modulator circuit using the MC1496. The resistor from pin 2 to pin 3 sets the conversion gain.**

after the modulator removes higher-order IMD products that are outside its passband but the in-band IMD products should be at least 40 dB below each of two equal test tones. Speech clipping (AF or IF) can degrade this to 10 dB or so, but in the absence of speech processing the signal should be clean, in-band.

## IF Filters

The desired IF filter response is shown in Fig 17.49A. The reduction of the carrier frequency is augmented by the filter response. It is common to specify that the filter response be down 20 dB at the carrier frequency. Rejection of the opposite sideband should (hopefully) be 60 dB, starting at 300 Hz below the carrier frequency, which is the 300-Hz point on the opposite sideband. The ultimate attenuation should be at least 70 dB. This would represent a very good specification for a high quality transmitter. The filter passband should be as flat as possible (ripple less than 1 dB or so).

Special filters, designated as USB or LSB, are designed with a steeper rolloff on the carrier frequency side, in order to improve rejection of the carrier and opposite sideband. Mechanical filters are available that do this. Crystal-ladder filters (see the **Filters** chapter) are called "single-sideband" filters because they also have this property. The steep skirt can be on the low side or the high side, depending on whether the crystals are across the signal path or in series with the signal path, respectively.

Filters require special attention to their terminations. The networks that interface

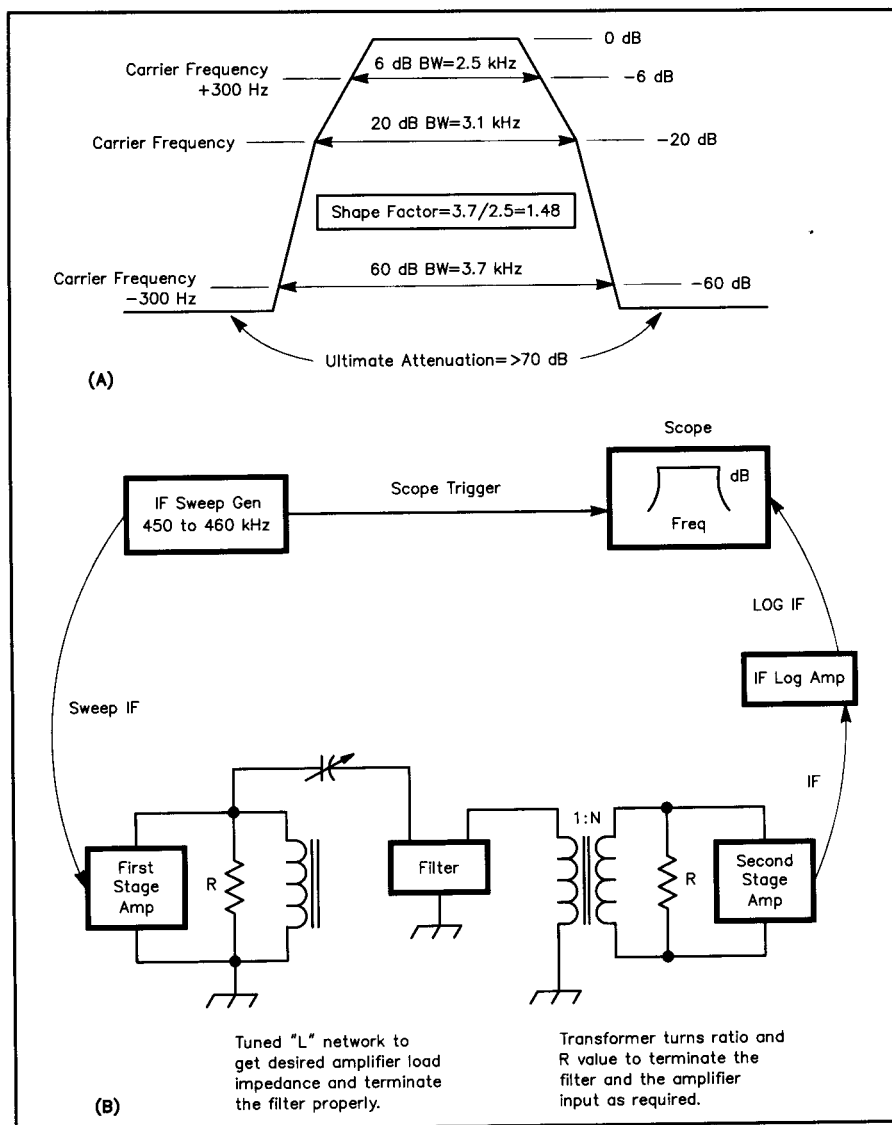

the filter with surrounding circuits should be accurate and stable over temperature. They should be easy to adjust. One very good way to adjust them is to build a narrowband sweep generator and look at the output IF envelope with a logarithmic amplifier, as indicated in Fig 17.49B. There are three goals: The driver stage must see the desired load impedance; the stage after the filter must see the desired source (generator) impedance and the filter must be properly terminated at both ends. Fig 17.49B shows two typical approaches (Ref 42). This kind of setup is a very good way to make sure the filters and other circuitry are working properly.

Finally, overdriven filters (such as crystal or mechanical filters) can become nonlinear and generate distortion. So it is necessary to heed the manufacturer's instructions. Magnetic core materials used in the tuning networks must be sufficiently linear at the signal levels encountered. They should be tested for IMD separately.

## IF Speech Clipper

Audio-clipper speech processors generate a considerable amount of in-band harmonics and IMD (involving different simultaneously occurring speech frequencies). The total distortion detracts somewhat from speech intelligibility. Other problems were mentioned in the section on audio processing. IF clippers overcome most of these problems, especially the Hilbert Transform problem (Refs 48, 77).

Fig 17.50A is a diagram of a 455-kHz IF clipper using high-frequency op amps. 20 dB of gain precedes the diode clippers. A second amplifier establishes the desired

**Fig 17.49—A: desired response of a SSB IF filter. B: one method of terminating a mechanical filter that allows easy and accurate tuning adjustment and also a possible test setup for performing the adjustments.**

output level. The clipping produces a wide band of IMD products close to the IF frequency. Harmonics of the IF frequency are generated that are easily rejected by subsequent selectivity. "Close-in" IMD distortion products are band limited by the 2.5-kHz-wide IF filter so that out-of-band splatter is eliminated. The in-band IMD products are at least 10 dB below the speech tones.

Fig 17.51 shows oscilloscope pictures of an IF clipped two-tone signal at various levels of clipping. The level of clipping in a radio can be estimated by comparing with these photos.

Listening tests verify that the IMD does not sound nearly as bad as harmonic distortion. In fact, processed speech sounds relatively clean and crisp. Tests also verify that speech intelligibility in a noise back-

ground is improved by 8 dB.

The repeaking effect from band-pass filtering the clipped IF signal occurs, and must be accounted for when adjusting the output level. A two-tone audio test signal or a speech signal should be used. The ALC circuitry (discussed later) will cut back the IF gain to prevent splattering in the power amplifiers. If the IF filter is of high quality and if subsequent amplifiers are "clean," the transmitted signal is of very high quality, very effective in noisy situations and often also in "pile-ups."

The extra IF gain implies that the IF signal entering the clipper must be free of noise, hum and spurious products. The cleanup filter also helps reduce the carrier frequency, which is outside the passband.

An electrically identical approach to

the IF clipper can be achieved at audio frequencies. If the audio signal is translated to, say 455 kHz, processed as described, and translated back to audio, all the desirable effects of IF clipping are retained. This output then plugs into the transmitter's microphone jack. Fig 17.50B shows the basic method. The mic amplifier and the MC1496 circuits have been previously shown and the clipper circuit is the same as in Fig 17.50A.

Another method, performed at audio, synthesizes mathematically the function of the IF clipper. This method is mentioned in Ref 48, and was an accessory for the Collins KWM380 transceiver.

The interesting operating principle in all of these examples is that the characteristics of the IF-clipped (or equivalent) speech signal do not change during frequency translation, even when translated down to audio and then back up to IF in a balanced modulator.

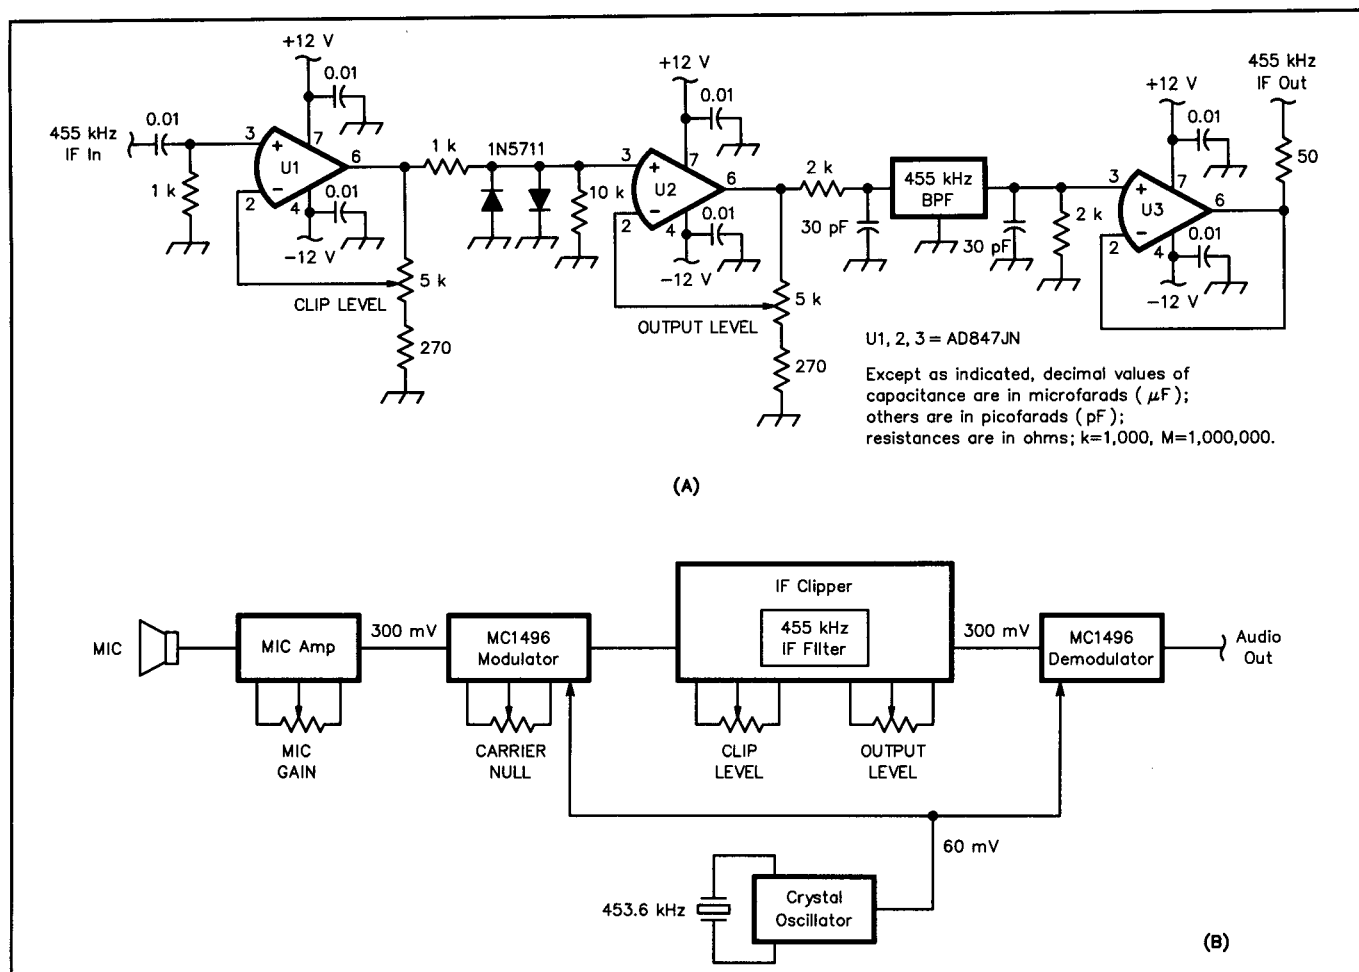

### IF Linearity and Noise

Fig 17.44 indicates that after the last SSB filter, whether it is just after the SSB modulator or after the IF clipper, subsequent BPFs are considerably wider. For example, the 70-MHz crystal filter may be 15 to 30 kHz wide. This means that there is a "gray region" in the transmitter just like the one that we saw in the up conversion receiver, where out-of-band IMD that is generated in the IF amplifiers and mixers can cause adjacent-channel interference.

A possible exception, not shown in Fig 17.44, is that there may be an intermediate IF in the 10-MHz region that also contains a narrow filter, as we saw in the triple-conversion receiver in Fig 17.36.

The implication is that special attention must be paid to the linearity of these circuits. It's the designer's job to make sure that distortion in this gray area is much less than distortion generated by the PA and also less than the phase noise generated by the final mixer. Recall also that the total IMD generated in the exciter stages is the resultant of several amplifier and mixer stages in cascade, therefore each element in the chain must have at least 40 to 50 dB IMD quality. The various drive levels should be chosen to guarantee this. This requirement for multistage linearity is one of the main technical and cost burdens of the SSB mode.

Of interest also in the gray region are white, additive thermal and excess noises originating in the first IF amplifier after the SSB filter and highly mag-

**Fig 17.50—IF speech clipping. A: an IF clipper circuit approach. B: the audio signal is translated to 455 kHz, processed, and translated back to audio.**

nified on their way to the output. This noise can be comparable to the phase noise level if the phase noise is low, as it would be in a high-quality radio. Recall also that phase noise is at its worst on modulation peaks, but additive noise may be (and often is) present even when there is no modulation. This is a frequent problem in colocated transmitting and receiving environments. Many transmitter designs do not have the benefit of the narrow filter at 70 MHz, so the amplified noise can extend over a much wider frequency range.

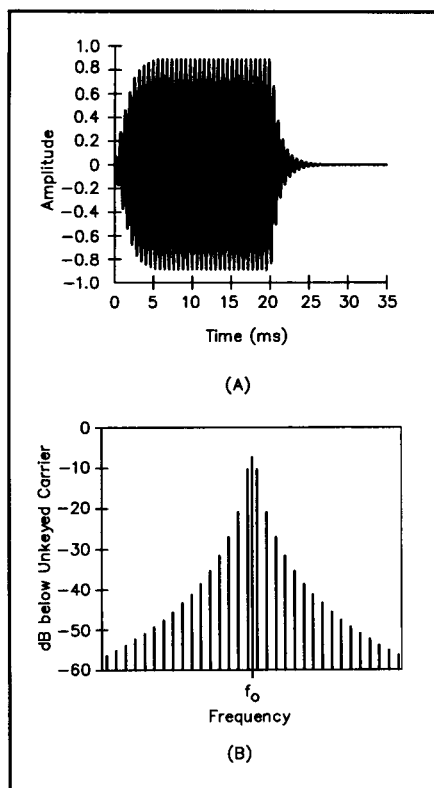

### CW Mode

Fig 17.44 shows that in the CW mode a carrier is generated at the center of the SSB filter passband. There are two ways to make this carrier available. One way is to unbalance the balanced modulator so that the LO can pass through. Each kind of balanced modulator circuit has its own method of doing this. The approach chosen in Fig 17.44 is to go around the modulator and the SSB filter.

**Fig 17.51—Two-tone envelope patterns with various degrees of RF clipping. All envelope patterns are formed using tones of 600 and 1000 Hz. At A, clipping threshold; B, 5 dB of clipping; C, 10 dB of clipping; D, 15 dB of clipping (from "RF Clippers for SSB," by W. Sabin, July 1967 QST, pp 13-18).**

A shaping network controls the envelope of the IF signal to accomplish two things: control the shape of the Morse code character in a way that limits wideband

**Fig 17.52—A: envelope, and B: spectrum of a 25-ms dot that has been shaped to 5 ms rise and fall times.**

spectrum emissions that can cause interference, and makes the Morse code signal easy and pleasant to copy.

### RF Envelope Shaping

On-off keying is a special kind of low-level amplitude modulation (a low-signal-level stage is turned on and off). It generates numerous sidebands around the carrier frequency whose amplitudes are influenced by the shapes of the RF envelope rise and fall intervals. Consider an unprocessed keying waveform, a string of equal-length rectangular RF pulses separated by equal-length “dead times.” Its spectrum consists of the carrier frequency, a pair of the usual modulation sidebands at the carrier frequency plus and minus the repetition rate of the pulses, and numerous other sidebands at multiples of the repetition rate. The higher frequency sidebands can create “key clicks” that extend many kHz either side of the carrier frequency.

Adjusting an exponentially shaped rise and fall time to about 5 ms (a value recommended by ARRL) controls key clicks, yet allows a wide range of practical keying speeds.

Fig 17.52A is a computer simulation of a single dot-space that is part of a continuous sequence, 20 ms on and 20 ms off (a

60 wpm rate), that has been shaped in this manner. This fast dot sequence is probably a “worst case” as far as Morse code interference is concerned. Fig 17.52B shows the line spectrum (Discrete Fourier Transform, DFT) of this periodic sequence. The carrier component is reduced because the on-off duty cycle is 50%, and some power is transferred from the carrier to the sidebands. (Note: This is a little different from ordinary AM, in which an additional source of power is used to create sidebands and the carrier remains constant.) The first pair of spectrum lines are  $\pm 25$  Hz from the carrier. These are the normal modulation sidebands, determined only by the keying rate ( $25 \text{ Hz} = 1/(40 \text{ ms})$ ). The subsequent pairs are odd-order sidebands starting at  $\pm 75$  Hz from the carrier (the symmetry of the on-off reduces even-order sidebands).

If the duration of the dot is held constant but the time between dots is greatly increased (the keying rate is greatly reduced) many more lines, much closer together and now including the even-order (50, 100, 150 Hz, and so on) sidebands, would appear in Fig 17.52B. But the general shape and also the bandwidth of the spectrum remain the same as shown. For example, a single, un-repeated dot would have essentially the same spectrum shape and width as in Fig 17.52B but would be a continuous spectrum (the Fourier Transform, FT) instead of the line spectrum (DFT) shown. In all cases the bandwidth of the interference, measured at the  $-20$  dB points, is approximately 150 Hz. Finally, a single “key-down-and-hold” or “key-up-and-hold” operation would produce a similar spectrum of brief duration (a single key click) due to the shaping of the leading or trailing edge.

The rolloff rate of the higher sidebands in the shaped pulse is much faster than for a rectangular pulse. The example shown could be improved further by making the transitions “sinusoidal.” The higher sidebands are still present but they are further reduced, as verified by computer simulations. This waveform (or other kinds of “windowing”) could be generated with DSP or with an op-amp state-variable analog computer in the Key Shape block of Fig 17.44. The linearity of the SSB amplifier chain will then preserve this envelope shape right up to the antenna.

### Keying Circuits

The circuit in Fig 17.53 is one example of an approach that will provide accurate control of the IF envelope. The PIN diodes are connected either to the signal source or to ground. They are turned on or off through U2 according to the exponential charging or discharging of the capacitor C1 through R1.

R1 connects to  $+12 \text{ V}$  or  $-12 \text{ V}$  through U1. Some experimentation with R1 and R2 will be necessary, depending on the IF drive level, to get the desired rise and fall characteristics. Look at the IF envelope on an oscilloscope while sending a string of dots. Try an input IF level of 100 mV. The transformers are optimized for the IF in use.

Another approach is to use gain controllable IC amplifiers of the type discussed in connection with receiver AGC. See, for example, Fig 17.31. The key-up “turnoff” must be complete to avoid “backwave,” residual output.

### Wideband Noise

In the block diagram of Fig 17.44 the last mixer and the amplifiers after it are wideband circuits that are limited only by the harmonic filters and by any selectivity that may be in the antenna system. Wideband phase noise transferred onto the transmitted modulation by the last LO can extend over a wide frequency range, therefore LO (almost always a synthesizer of some kind) cleanliness is always a matter of great concern (Ref 23).

The amplifiers after this mixer are also sources of wide-band “white” or additive noise. This noise can be transmitted even during times when there is no modulation, and it can be a source of local interference. To reduce this noise: use a high-level mixer with as much signal output as possible, and make the noise figure of the first amplifier stage after the mixer as low as possible.

Transmitters that are used in close proximity to receivers, such as on shipboard, are always designed to control wideband emissions of both additive noise and phase noise, referred to as “composite” noise.

### Transmit Mixer Spurious Signals

The last IF and the last mixer LO in Fig 17.44 are selected so that, as much as possible, harmonic IMD products are far enough away from the operating frequency that they fall outside the passband of the low-pass filters and are highly attenuated. This is difficult to accomplish over the transmitter’s entire frequency range. It helps to use a high-level mixer and a low enough signal level to minimize those products that are unavoidable. Low-order crossovers that cannot be sufficiently reduced are unacceptable, however; the designer must “go back to the drawing board.”

The References chapter gives information regarding FCC requirements for harmonic and spurious levels. The Filters chapter describes the design of harmonic filters.

### Automatic Level Control (ALC)

The purpose of ALC is to prevent the

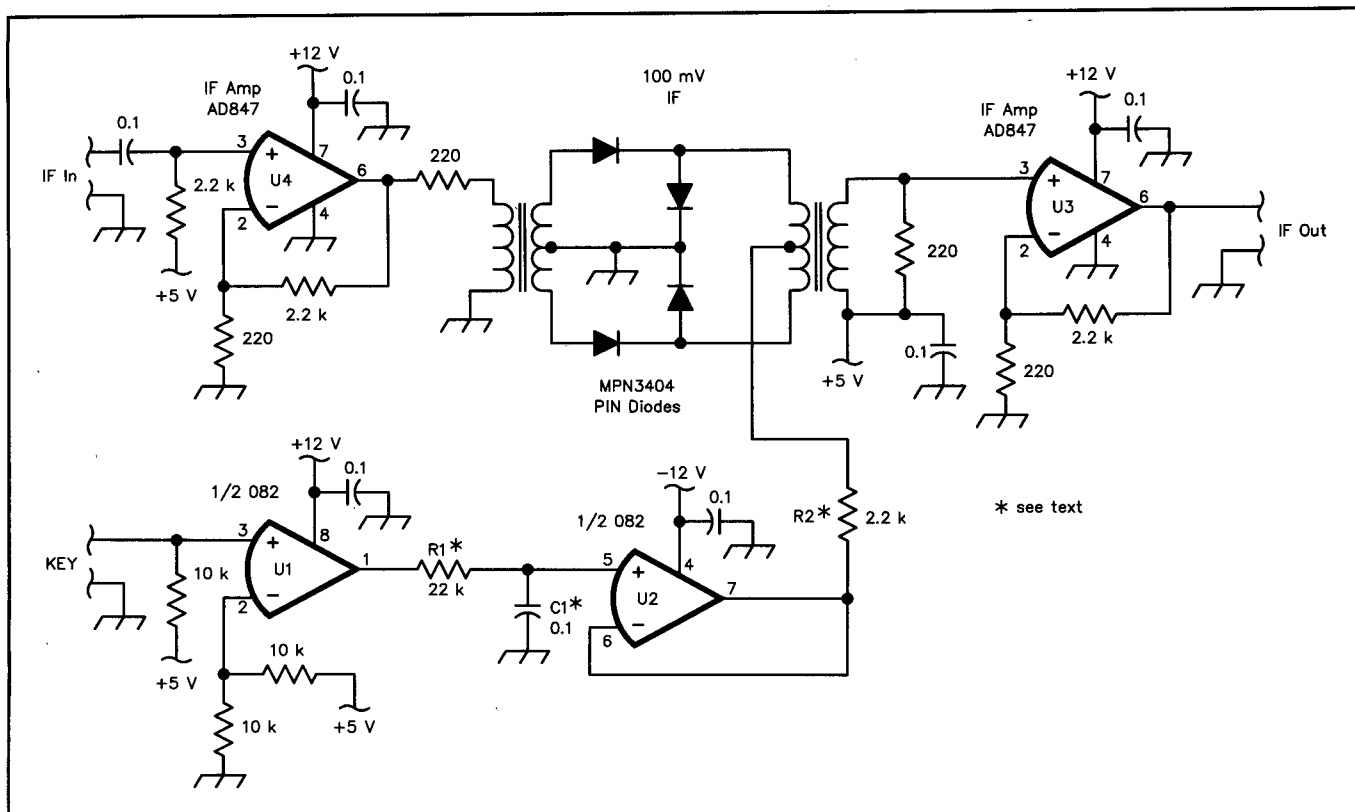

Fig 17.53—A keying circuit for the transmitter diagram in Fig 17.44.

various stages in the transmitter from being overdriven. Overdrive can generate too much out-of-band distortion or cause excessive power dissipation, either in the amplifiers or in the power supply. ALC does this by sampling the peak amplitude of the modulation (the envelope variations) of the output signal and then developing a dc gain-control voltage that is applied to an early amplifier stage, as suggested in Fig 17.44.

ALC is usually derived from the last stage in a transmitter. This ensures that this last stage will be protected from overload. However, other stages prior to the last stage may not be as well protected; they may generate excessive distortion. It is possible to derive a composite ALC from more than one stage in a way that would prevent this problem. But designers usually prefer to design earlier stages conservatively enough so that, given a temperature range and component tolerances, the last stage can be the one source of ALC. The gain control is applied to an early stage so that all stages are aided by the gain reduction.

#### Speech Processing with ALC

A fast response to the leading edge of the modulation is needed to prevent a transient overload. After a strong peak, the control voltage is "remembered" for some time as

the voltage in a capacitor. This voltage then decays partially through a resistor between peaks. An effective practice provides two capacitors and two time constants. One capacitor decays quickly with a time constant of, say 100 ms, the other with a time constant of several seconds. With this arrangement a small amount of speech processing, about 1 or 2 dB, can be obtained. (Explanation: The dB of improvement mentioned has to do with the improvement in speech intelligibility in a random noise background. This improvement is equivalent to what could be achieved if the transmit power were increased that same number of dB). The gain rises a little between peaks so that weaker speech components are enhanced. But immediately after a peak it takes awhile for the enhancement to take place, so weak components right after a strong peak are not enhanced very much. Fig 17.54A shows a complete ALC circuit that performs speech processing.

#### ALC in Solid-State Power Amplifiers

Fig 17.54B shows how a dual directional coupler can be used to provide ALC for a solid-state power amplifier (PA). The basic idea is to protect the PA transistors from excessive SWR and dissipation by monitoring both the forward power and the reflected power. The projects section of

this chapter includes a 50-W amplifier project; the protection circuitry is discussed in detail there. Thermal protection is also included.

#### Transmit Gain Control (TGC)

This is a widely used feature in commercial and military equipment. A calibrated "tune-up" test carrier of a certain known level is applied to the transmitter. The output carrier level is sampled, using a diode detector. The resulting dc voltage is used to set the gain of a low-level stage. This control voltage is digitized and stored in memory so that it is semipermanent. A new voltage may be generated and stored after each frequency change, or the stored value may be "fetched." A test signal is also used to do automatic antenna tuning. A dummy load is used to set the level and a low-level signal (a few mW) is used for the antenna tune-up.

#### Transmitter Output Load Impedance

The following logical processes are used to tune and load the final PA of a transmitter:

1. The RF input power requirement to the input terminal of the PA has been determined. That power level is applied to the input.

2. The desired load impedance of the plate/collector/drain of the PA has been determined, either graphically or by calculation, from the power to be delivered to the load, the dc power supply voltage and the ac voltage on the plate/collector/drain (see **Amplifiers** chapter).
3. The input impedance, looking toward the antenna, of the transmission line which is connected to the transmitter is adjusted by a network of some kind to its  $Z_0$  value (if it is not already equal to that value).
4. A network of some kind is designed, which transforms the transmission-line

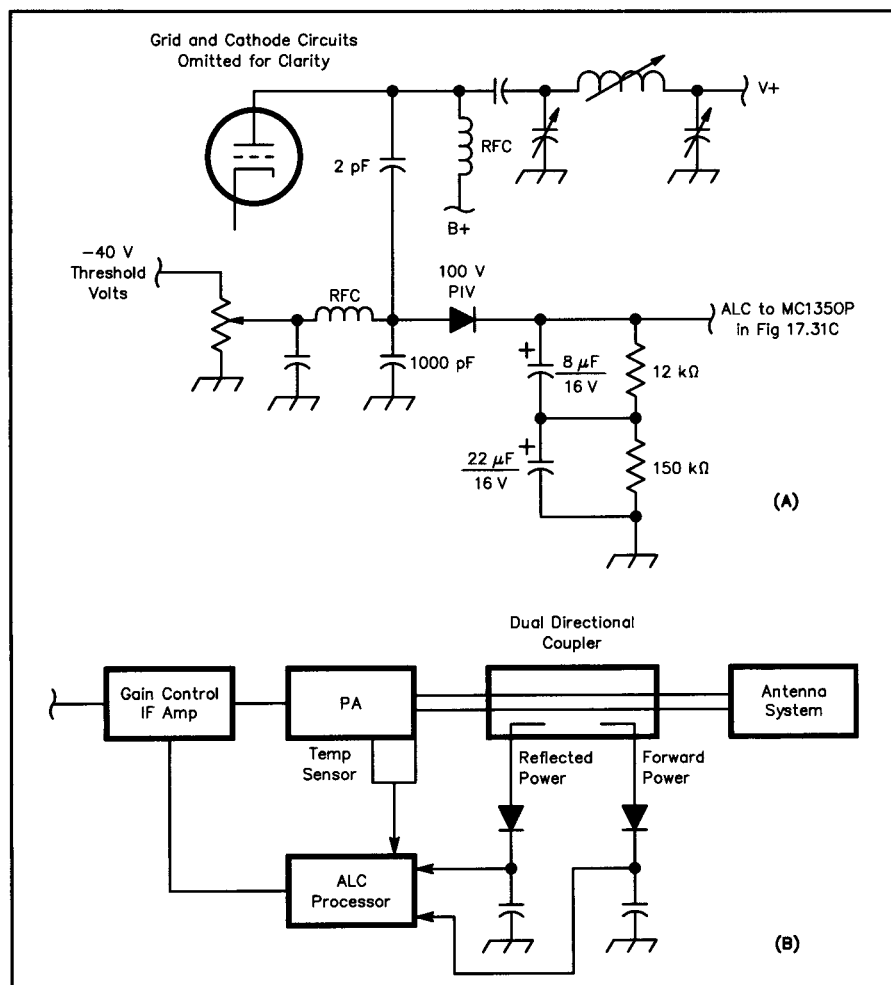

$Z_0$  to the impedance required in step 2. This may be a sharply tuned resonator with impedance transforming capability, or it may be a wideband transformer of some kind.

Under these conditions the PA is performing as intended. Note that a knowledge of the output impedance of the PA is not needed to get these results. That is, we are interested mostly in the actual power gain of the PA, which does not require a knowledge of the amplifier's output impedance.

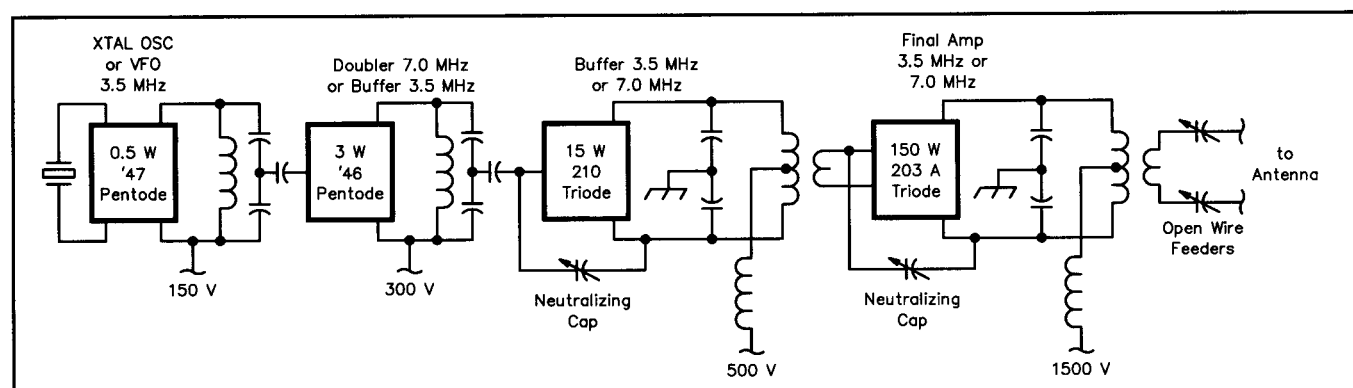

The output impedance, looking backward from the plate/collector/drain terminal of the network, in step 4, will have some influence on the selectivity of a resonant tuned circuit or the frequency response of a low-pass filter. This must (or should) be considered during the design process, but it is not needed during the "tune and load" process (Ref 81).

### A Classic Amateur Vacuum-Tube Transmitter

Cascaded stage transmitter designs became very popular after about 1930. Home-brew solid-state CW transmitters often use the same general idea today. **Fig 17.55** is a typical example. The first stage is an oscillator, which may be either crystal controlled or a variable frequency oscillator (VFO) of high stability. The oscillator is followed by a combination of buffer amplifiers and frequency multipliers, usually doublers, to arrive at the final frequency and power level. Mixer circuits and crystal-VFO "mix-master" frequency generator arrangements are not used, so spurious mixer products are not a problem. Each stage provides the power input that the next stage needs and each stage increases in size and power dissipation. The vacuum tube '47 crystal osc, '46 doubler, 210 ("five watter") buffer, 203A ("fifty watter") final (200 W input) was a famous CW "rig" during the mid 1930's.

**Fig 17.54—A: an ALC circuit with speech processing capability. B: protection method for a solid-state transmitter.**

**Fig 17.55—Example block diagram of MOPA transmitter, typical of the 1930s. Crystal control is shown, but VFOs replaced them during the 40s.**

HF CW DXers would usually have one favorite crystal that was just several Hz inside the band edge.

The process of frequency multiplication also multiplies the frequency drift, frequency/phase modulation and microphonic effects of the VFO. So for many years amateurs relied on crystal control, until they learned how to design very stable, low-noise VFOs. The frequency multiplier is an item worthy of discussion.

### Frequency Multipliers

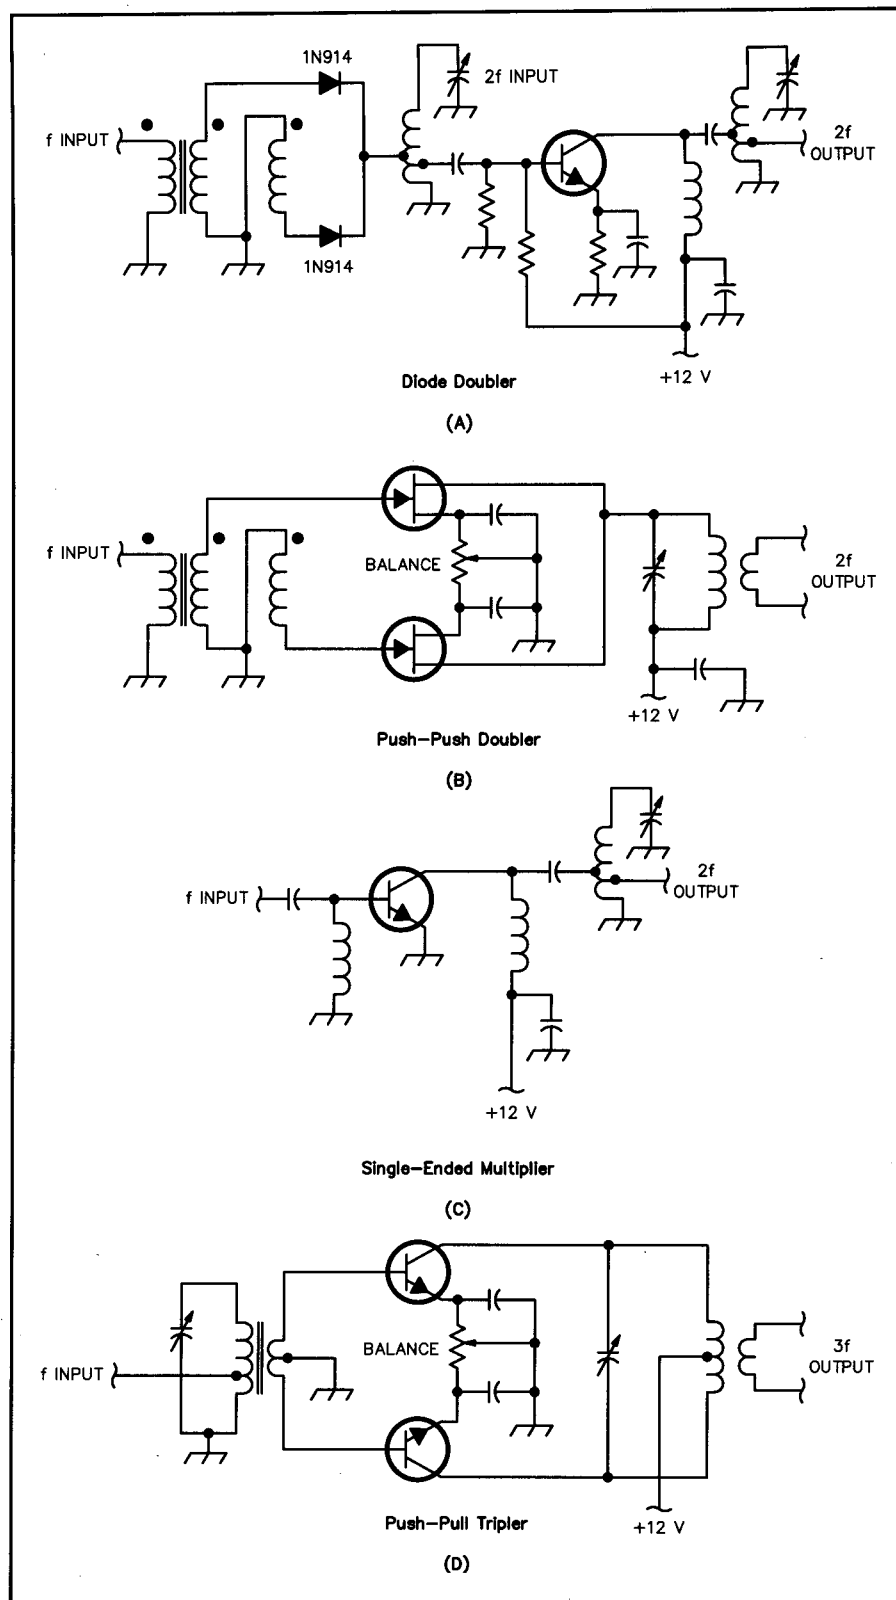

A passive multiplier using diodes is shown in Fig 17.56A. The full-wave rectifier circuit can be recognized, except that the dc component is shorted to ground. If the fundamental frequency ac input is 1.0 V RMS the second harmonic is 0.42 V RMS or 8 dB below the input, including some small diode losses. This value is found by calculating the Fourier Series coefficients for the full-wave-rectified sine wave, as shown in many textbooks.

Transistor and vacuum-tube frequency multipliers operate on the following principle: if a sine wave input causes the plate/collector/drain current to be distorted (not a sine wave) then harmonics of the input are generated. If an output resonant circuit is tuned to a harmonic the output at the harmonic is emphasized and other frequencies are attenuated. For a particular harmonic the current pulse should be distorted in a way that maximizes that harmonic. For example, for a doubler the current pulse should look like a half sine wave ( $180^\circ$  of conduction). A transistor with Class B bias would be a good choice. For a tripler use  $120^\circ$  of conduction (Class C).

An FET, biased at a certain point, is very nearly a "square law" device. That is, the drain-current change is proportional to the square of the gate-voltage change. It is then an efficient frequency doubler that also deemphasizes the fundamental.

A push-push doubler is shown in Fig 17.56B. The FETs are biased in the square-law region and the BALANCE potentiometer minimizes the fundamental frequency. Note that the gates are in push-pull and the drains are in parallel. This causes second harmonics to add in-phase at the output and fundamental components to cancel.

Fig 17.56C shows an example of a bipolar-transistor doubler. The efficiency of a doubler of this type is typically 50%, a tripler 33% and a quadrupler 25%. Harmonics other than the one to which the output tank is tuned will appear in the output unless effective band-pass filtering is applied. The collector tap on L1 is placed at the point that offers the best compromise between power out-

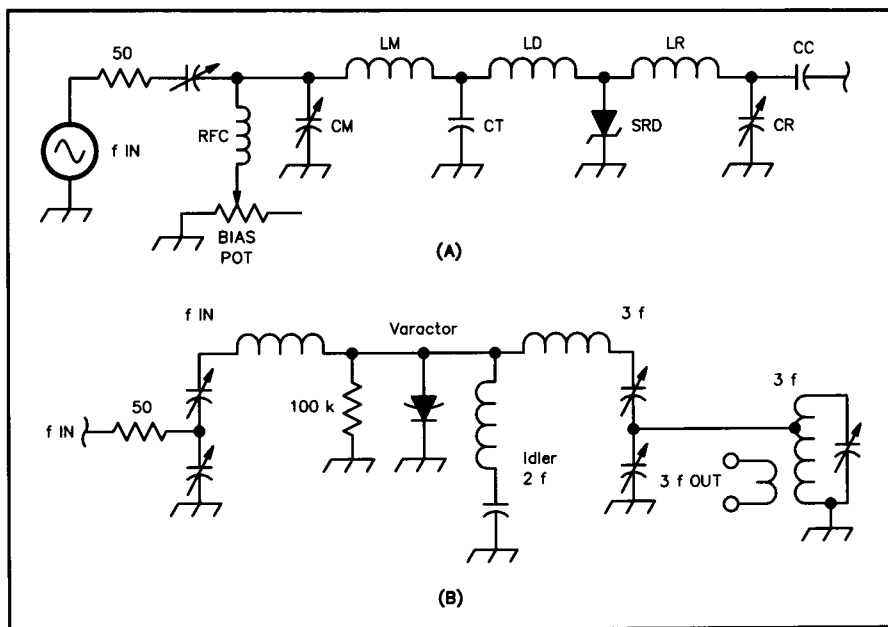

**Fig 17.56—A: diode doubler. B: push-push doubler using JFETs. C: single-ended multiplier using a BJT. D: push-pull tripler using BJTs.**

put and spectral purity.

A push-pull tripler is shown in Fig 17.56D. The input and output are both push-pull. The balance potentiometer

minimizes even harmonics. Note that the transistors have no bias voltage in the base circuit; this places the transistors in Class C for efficient third-harmonic production.

**Fig 17.57—Diode frequency multipliers. A: step-recovery diode multiplier. B: varactor diode multiplier.**

Choose an input drive level that maximizes harmonic output.

The step recovery diode (SRD) is an excellent device for harmonic generation, especially at microwave frequencies (Ref 25). The basic idea of the SRD is as follows: When the diode is forward conducting, a charge is stored in the diode's diffusion capacitance; and if the diode is quickly reverse-biased, the stored charge is very suddenly released into an LC harmonic-tuned circuit. The circuit is also called a "comb generator" because of the large number of harmonics that are generated. (The spectral display looks like a comb.) Phase-locked loops (PLLs) can be made to lock onto these harmonics. A typical low-cost SRD is the HP 5082-0180, found in the HP Microwave & RF Designer's Catalog. Fig 17.57A is a typical schematic. For more information regarding design details there are two References: Hewlett-Packard application note AN-920 and Ref 25.

The varactor diode can also be used as a multiplier. Fig 17.57B shows an example. This circuit depends on the fact that the capacitance of a varactor changes with the instantaneous value of the RF excitation voltage. This is a nonlinear process that generates harmonic currents through the diode. Power levels up to 25 W can be generated in this manner.

### Coupling Between Transmitter Stages

Most of the methods described here are also widely used in receiver circuits. Cor-

rect impedance matching between a stage and its load provides maximum transfer of power. The load can be an antenna or the next stage. The input impedance of the next stage is transformed to the value of load impedance that the preceding stage wants to "see" for proper operation. If the next stage is a bipolar transistor, determining the base input impedance can be difficult without adequate test equipment. Generally, when the drive power is 2 W or more the base impedance will be less than 10  $\Omega$  and often in the 1 to 2- $\Omega$  range. Under these conditions, some kinds of LC matching networks are difficult to adjust. It is desirable to use a network that can be easily adjusted over a wide range of impedances, where both L and C are variable. Sometimes a deliberate mismatch is preferred for stability or for accurate power-level control. This subject was discussed earlier in this chapter.

In the interest of stability, it is common practice to use low-Q networks between stages in a solid-state transmitter. Loaded Q values of five are common. The penalty for this is poor attenuation of harmonics and other spurious outputs. Conversely, vacuum-tube stages operate at relatively high-impedance levels in the grid and plate circuits. Loaded Q values of 15 are used. The rejection of spurs is greatly improved. In all cases the matching network is used to "absorb" circuit and tube or transistor reactances into the network, so that pure resistive impedance values can be achieved. The impedance values depend on frequency and power level, and tend to

be difficult to predict. So experimental methods, using wide-range networks, are usually preferred.

The interstage coupling method in Fig 17.58A is a common one for vacuum tubes. A low-value coupling capacitor goes to the grid. RFC1 and RFC2 have a very high impedance over the operating frequency range.

Band-pass coupling is shown in Fig 17.58B. C1 is selected to give a flat response over a frequency range, such as a ham band, and high attenuation outside the band. This response can be changed, though, by changes in the loading of the input and output terminals of the network. It works best between stages that have constant loading. Often, shunt resistors are added to improve the constancy of the response. As an alternative to the coupling capacitor, link coupling can be used at the "cold" end of each coil. Similar band-pass networks can be used in transistor circuits. The collector of the driver and the base of the next stage would be tapped down on their respective coils, to maintain the loaded Q and the selectivity.

A common form of transformer coupling is shown in Fig 17.58C. T1 is usually a toroid for frequencies up to 30 MHz. At higher frequencies, it is sometimes difficult to get accurate control of the impedance ratios, because fractions of a turn cannot be achieved. The collector tap sets the desired load impedance for the transistor and also improves the loaded Q. The impedance ratio from primary to secondary is approximately the square of the ratio of the number of turns at the primary tap point to the number of turns on the secondary. R1 (dotted) can be added to provide a more constant load and improve stability. R1 is usually in the range of 5 to 27  $\Omega$ .

A method for coupling between stages with a capacitive divider is shown in Fig 17.58D. The net value of C1 and C2 in series must be added to C3 to determine the value of L1 for resonance. The formula for the ratio of C2 to C1 is included. The reactance of C2 should be about 0.25 of the transistor input resistance. C2 also helps to discourage parasitic oscillations. The ferrite beads (950  $\mu$ ) reduce the Q of RFC1 at frequencies where it might be involved in an oscillation. The circuit in Fig 17.58E is more susceptible to instability.

When the impedance levels to be transformed are of the proper value to allow an integer turns ratio, two 4:1 impedance-ratio transformers can get a 16:1 impedance ratio as shown in Fig 17.58E. This transforms the 5- $\Omega$  base impedance to an 80- $\Omega$  collector load impedance. This ap-

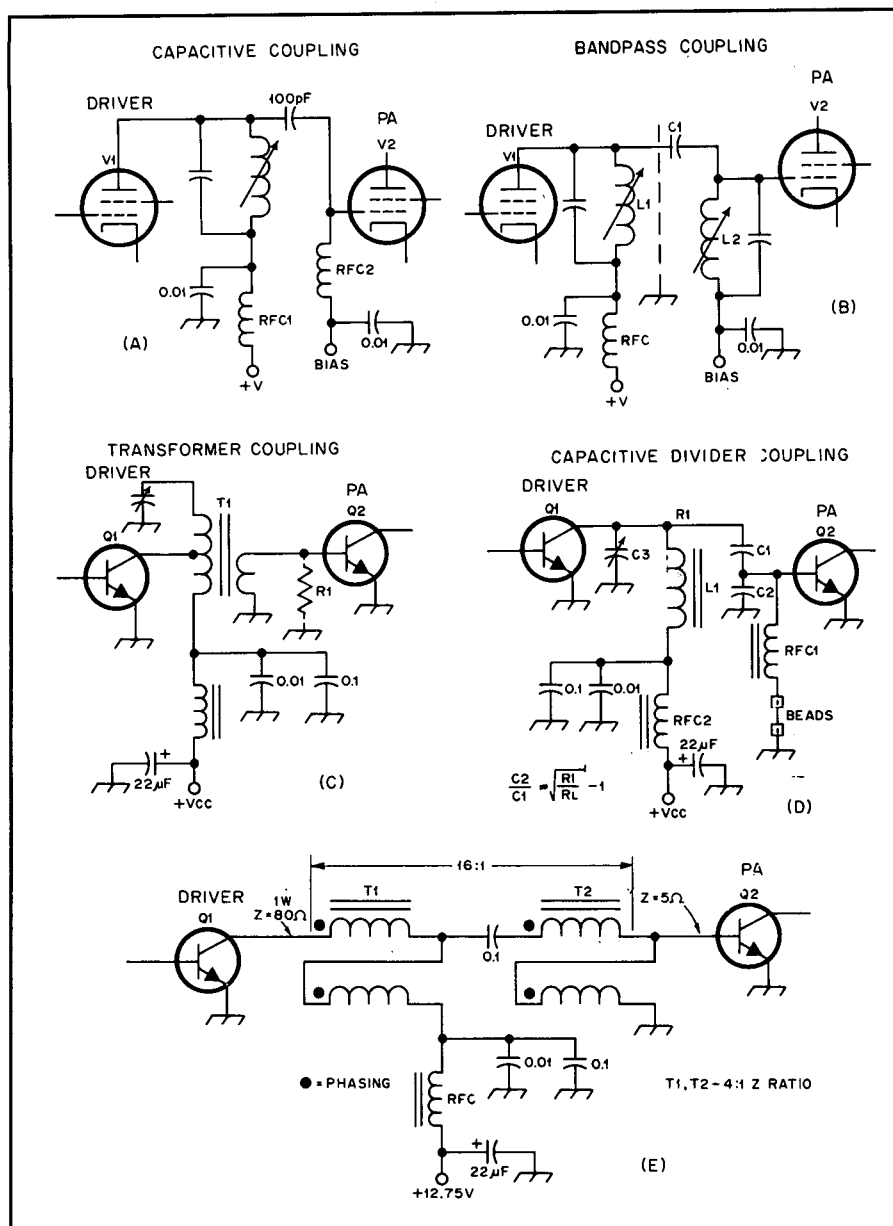

Fig 17.58—Five typical coupling methods for use between amplifier stages.

proach has no selectivity worth mentioning but is widely used in broadband amplifiers where selectivity is not needed or wanted.

### Network Equations

The three networks shown in Figs 17.59 through 17.61 provide practical solutions to many of the impedance-matching problems encountered by amateurs. In each figure, it is assumed that the desired impedance to the right of the network is higher than that to the left. If the opposite case is true, reverse the network, left to right.

These networks also assume that two resistance values ( $R_L$  and  $R_{out}$ ) are being "matched" by the network, and the

discussion proceeds along those lines. But as pointed out previously, the value of  $R_{out}$  is usually the desired value of transistor load resistance, which seldom corresponds exactly to the actual output impedance of the transistor. Still, the design method leads to correct answers. It provides the desired resistive load for the transistor output. It also absorbs the transistor output capacitance into the network.

Normally the output impedance of a transistor is given as a resistance  $R_{out}$  in parallel with a capacitance  $C_{out}$ . To use the design equations for these three networks the output impedance must first be converted from the parallel form to the series form  $R_s$  and  $C_s$ . These equivalent

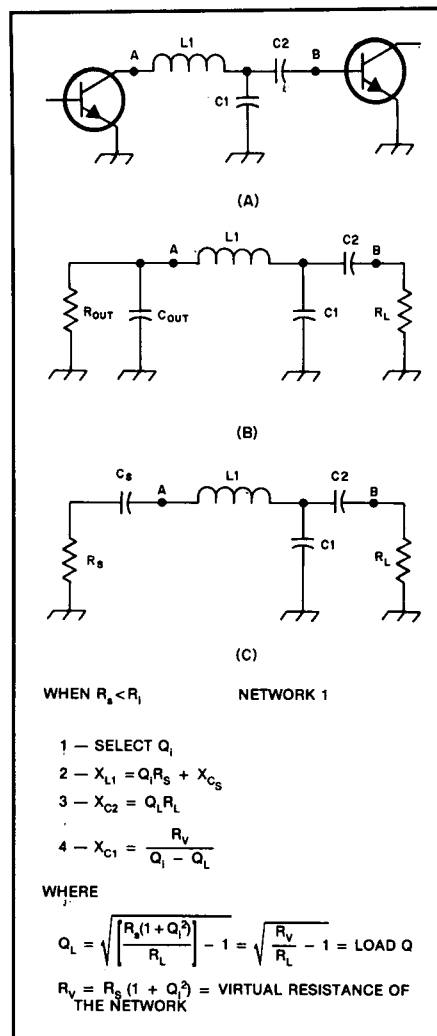

Fig 17.59—Circuit and mathematical solution for matching network number 1. Actual circuit (A), parallel equivalent (B) and series equivalent (C).

circuits and the equations for conversion are given in Fig 17.62. Often the output capacitance is small enough that it can be neglected. The resulting error is compensated by minor adjustments of the tunable components.

The low-pass T network in Fig 17.61 has the advantage of matching a wide range of impedances with practical component values. Some designers believe that this is the best network in terms of collector efficiency. The harmonic suppression provided by the T network varies with the transformation ratio and the loaded Q of the network. Stages feeding an antenna will need additional harmonic suppression. This is also true for Fig 17.59 and Fig 17.60. These three networks are covered in detail in Motorola Application Notes AN-267 and AN-721. There is also an excellent program, NBMATCH.BAS, on the software disk for *The ARRL UHF/*

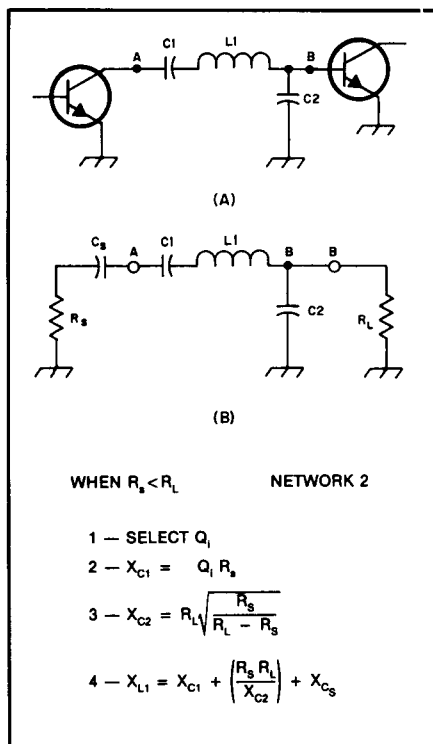

Fig 17.60—Circuit and design equations for matching network number 2. Actual circuit (A) and series equivalent (B).

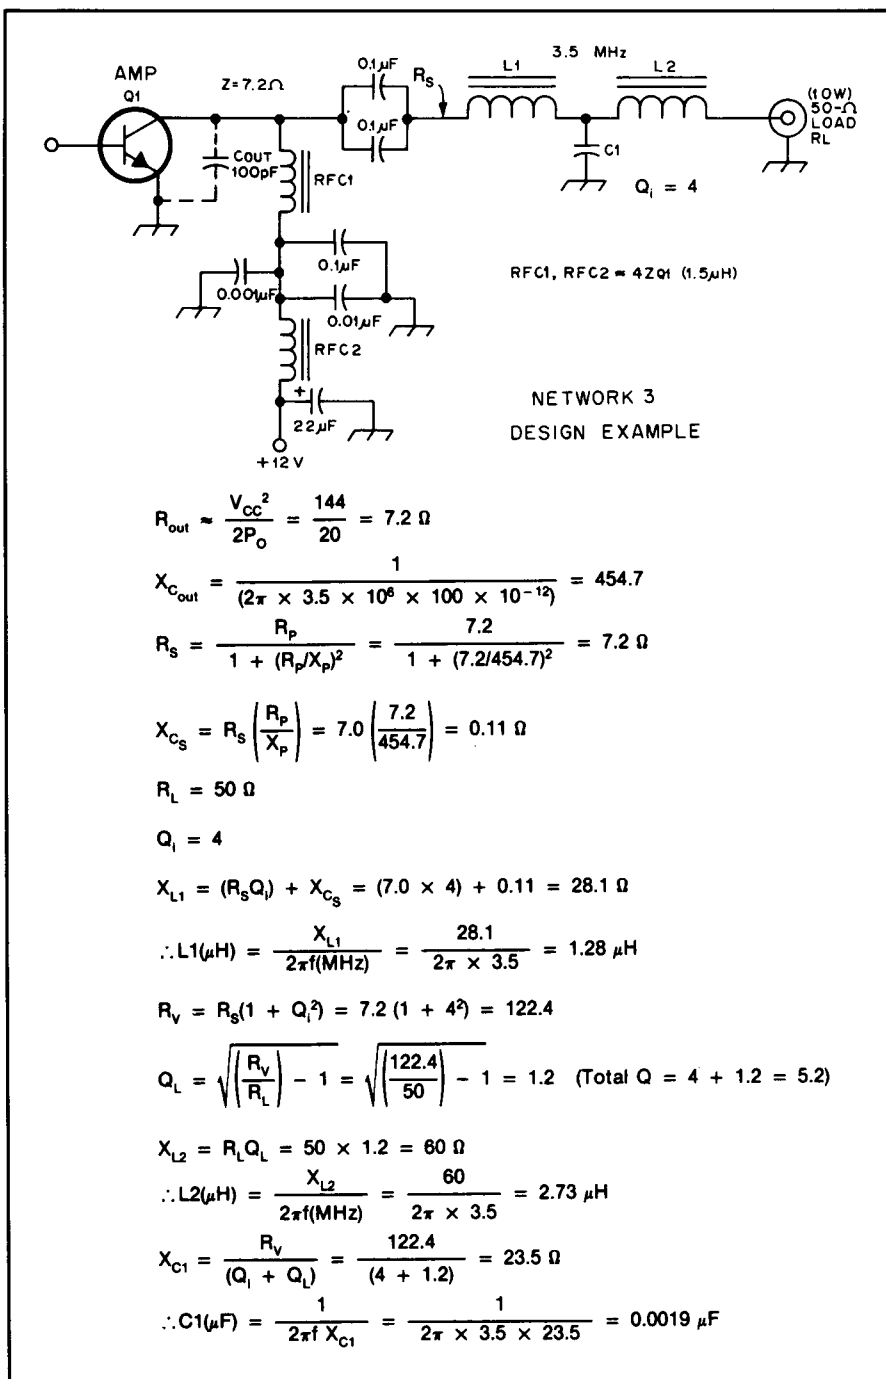

Fig 17.63—A practical example of network number 3 (Fig 17.61) and the solution to the network design.

#### Microwave Experimenter's Manual.

A design example for Fig 17.61 is given in Fig 17.63. The value of  $C_{out}$  is taken from the manufacturer's data sheet. If it is not available, small adjustments of the L and C values will make up for it. A computer simulation (using a SPICE program or ladder-network program such as ARRL's *MicroSmith*) would be an excellent way to get the circuit "working on paper"; it would also be good experience.

At lower frequencies the value of  $C_1$  will be large, so use fixed and variable capacitors in parallel.  $L_1$  and  $L_2$  can be wound on powdered-iron toroids. The procedures for selecting the size and permeability are discussed in an earlier chapter. There may be a little coupling between adjacent coils if they are not properly separated and at right angles to each other. This coupling can degrade harmonic reduction and affect tuning.

Some notes about toroid coils: Toroids do have a small amount of leakage flux, despite rumors to the contrary. Toroid coils are wound in the form of a helix (screw thread) around the circular length of the core. This means that there is a small component of the flux from each turn that is perpendicular to the circle of the toroid (parallel to the axis through the hole) and is therefore not adequately linked to all the other turns. This effect is responsible for a small leakage flux and the effect is called the "one-turn" effect, since the result is equivalent to one turn that is wound around the outer edge of the core and not through the hole. Also, the inductance of a toroid can be adjusted, despite rumors to the contrary. If the turns can be pressed

closer together or separated a little, inductance variations of a few percent are possible.

Continuing with the example, a grounded aluminum shield between adjacent coils can eliminate any significant capacitive or inductive (at high frequencies) coupling. These effects are most easily noticed if a network analyzer is available during the checkout procedure (how many of us are that lucky?), but spot checks with an attenuator ahead of a receiver that is tunable to the harmonics are also very helpful.

Transmission-line transformers were introduced briefly earlier in this chapter. Here we consider practical details for transmitter use and winding instructions. In transmitters, core heating and nonlinearity (from excessive voltage or current) determine the choice of core material, its permeability, wire size and the dimensions of the core. A detailed discussion of all of these factors is available in the second edition of ARRL's *Transmission Line Transformers*, by Jerry Sevick. Additional information is contained in the **Analog Theory** chapter of this *Handbook*.

The broadband transformers shown in Fig 17.64, Fig 17.65 and Fig 17.66 are suitable for use in low-level and high-level solid-state circuits. They can be used as matching devices between circuit modules and in antenna matching networks. For low-power levels and in receivers the cores are usually ferrites with permeabilities from 100 (30 MHz) to 2000 (0.1 MHz). Ferrites are usually preferred

because they result in smaller transformers than powdered-iron cores. Small physical size implies fewer turns, greater bandwidth (the length of the winding is a smaller fraction of a wavelength at higher frequencies) and more compact mechanical design. At higher frequencies materials with lower permeabilities are more efficient. For higher power levels, ferrites with permeabilities from 50 to 300 or in some cases powdered iron are better because the core heats less. Also involved in heating are wire losses, dielectric losses and hysteresis losses (in the core material). IMD and harmonic production in the cores are frequent problems in transmitters. The core size and permeability should be selected to minimize these problems at the signal levels in the equipment. IMD from cores is often noticed in high-signal-level receiver circuits as well.

Fig 17.64 shows two kinds of 4:1 transformers and a method (E) to series connect two of them for a 16:1 impedance ratio. The circuit at E is often used between a 50-Ω source and the base of an RF power transistor.

Two styles of 9:1 (impedance ratio) transformers are shown in Fig 17.65 A and C. They also are used at the inputs of transistor amplifiers and in collector/load circuits. The variable-ratio transformer in Fig 17.65E is excellent for obtaining many values of impedance transformation. It was developed by Jerry Sevick, W2FMI, for a ground-mounted vertical antenna.

Transformers for phase-reversal, 1:1-balun and hybrid-combiner/splitter use are

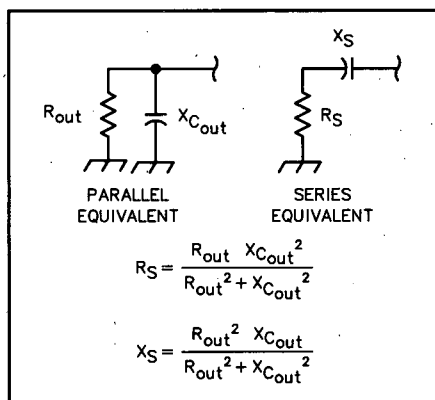

Fig 17.62—Parallel and series equivalent circuits and the formulas used for conversion.

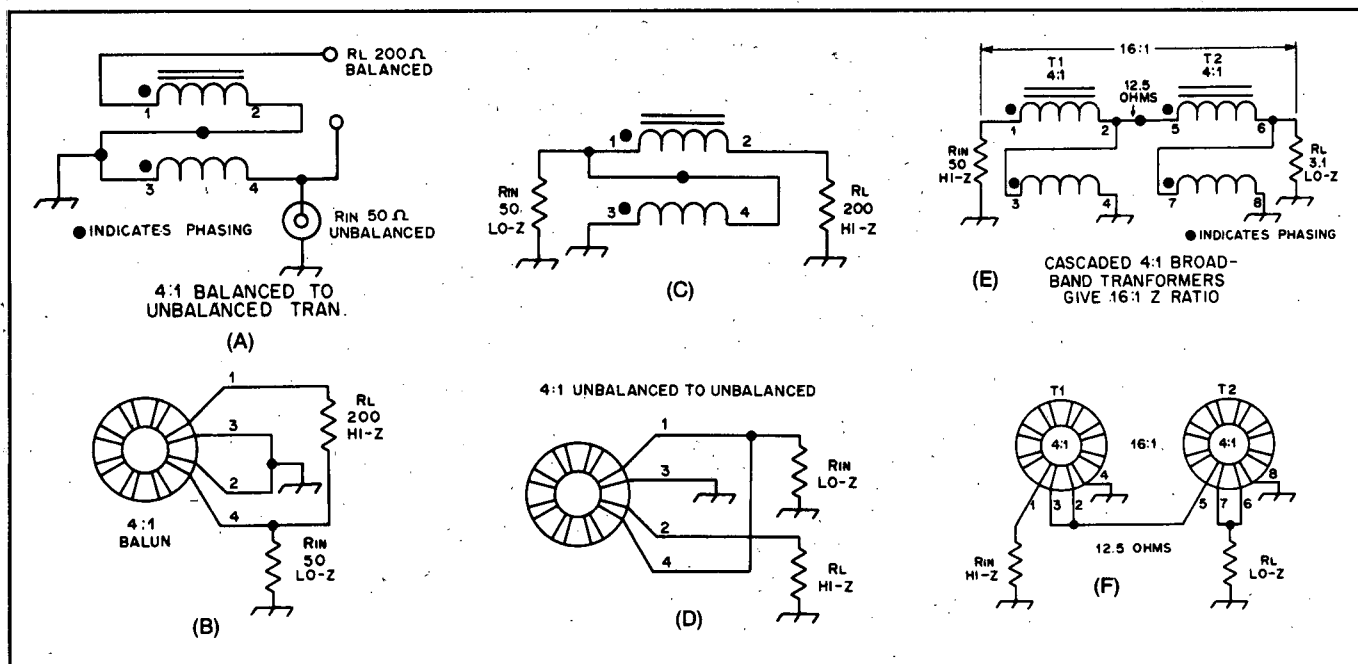

Fig 17.64—Circuit illustrations of 4:1 broadband transmission-line transformers.

Fig 17.65—Circuit examples of 9:1 broadband transmission-line transformers (A and C) and a variable-impedance transformer (E).

shown in Fig 17.66. This hybrid transformer was discussed earlier in this chapter.

### NBFM Transmitter Block Diagram

Fig 17.67 shows the phase-modulation method, also known as indirect FM. It is the most widely used approach to NBFM. Phase modulation is performed at a low IF, say 455 kHz. Prior to the phase modulator, speech filtering and processing are performed to achieve four goals:

1. Convert phase modulation to frequency modulation (see below),
2. Preemphasize higher speech frequencies for improved signal-to-noise ratio at the receive end,
3. Perform speech processing to emphasize the weaker speech components and
4. Adjust for the microphone's frequency

response and possibly also the operator's voice characteristics.

Multiplier stages move the signal to some desired higher IF and also multiply the frequency deviation to the desired final value. If the FM deviation generated in the 455-kHz modulator is 250 Hz, the deviation at 9.1 MHz is  $20 \times 250$ , or 5 kHz. A second conversion to the final output frequency is then performed. Prior to this final translation, IF band-pass filtering is performed in order to minimize adjacent-channel interference that might be caused by excessive frequency deviation. This filter needs good phase linearity to assure that the FM sidebands maintain the correct phase relationships. If this is not done, an AM component is introduced to the signal, which can cause nonlinear distortion problems in the PA stages. The final fre-

quency translation retains a constant value of FM deviation for any value of the output signal frequency.

The IF/RF amplifiers are Class C amplifiers because the signal in each amplifier contains, at any one instant, only a single value of instantaneous frequency and not multiple simultaneous frequencies as in SSB. These amplifiers are not sources of IMD, so they need not be "linear." The sidebands that appear in the output are a result only of the FM process (the Bessel functions).

In phase modulation, the frequency deviation is directly proportional to the frequency of the audio signal. To make the deviation independent of the audio frequency, an audio-frequency response that rolls off at 6 dB per octave is needed. An op-amp integrator circuit in the audio amplifier accomplishes this. This process converts phase modulation to frequency modulation. In addition, audio speech processing helps to maintain a constant value of speech amplitude, therefore constant IF deviation, with respect to audio speech levels. Also, preemphasis of the speech frequencies (6 dB per octave from 300 to 3000 Hz) is commonly used to improve the signal-to-noise ratio at the receive end. Analysis shows that this is especially effective in FM systems when the corresponding deemphasis is used at the receiver (Ref 82).

An IF limiter stage may be used to ensure that any amplitude changes created during the modulation process are removed. The indirect-FM method allows complete frequency synthesis to be used in all the transmitter LOs, so that the channelization of the output frequency is very accurate. The IF and RF amplifier stages are operated in a highly efficient Class-C mode, which is helpful in portable equipment operating on small internal batteries.

NBFM is more tolerant of frequency misalignments, between the transmitter and receiver, than is SSB. In commercial SSB communication systems, this problem is solved by transmitting a pilot carrier that is 10 or 12 dB below PEP. The receiver phase locks to this pilot carrier. The pilot carrier is also used for squelch and AGC purposes. A short-duration "memory" feature in the receiver bridges across brief pilot-carrier dropouts, caused by multipath nulls (Ref 83).

"Direct FM" frequency modulates a high-frequency (say, 9 MHz or so) crystal oscillator by varying the voltage on a varactor. The audio is preemphasized and processed ahead of the frequency modulator. The Transceivers section of this chapter describes such a system (see Fig 17.69).

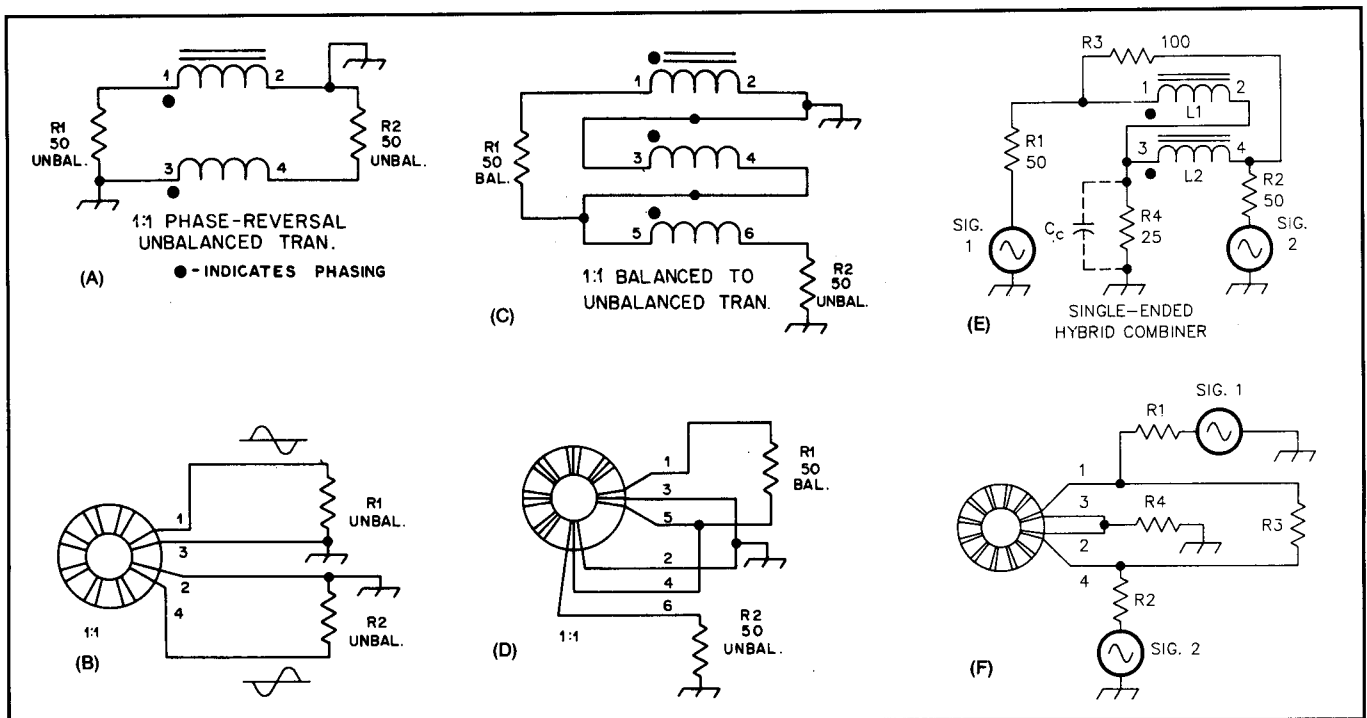

Fig 17.66—Assorted broadband transmission-line transformers.

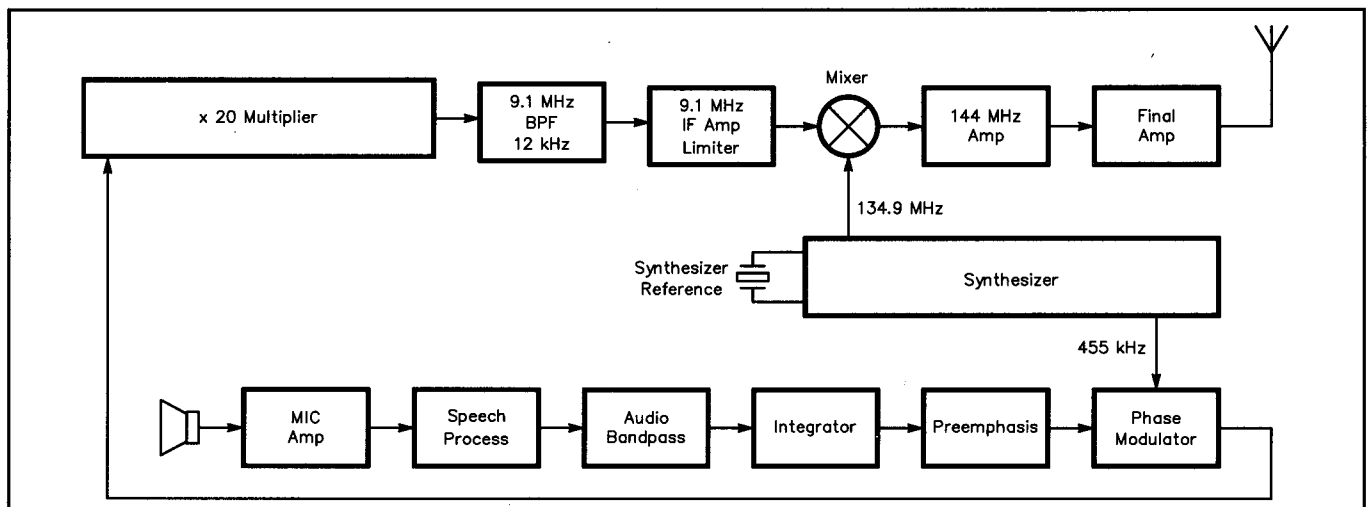

Fig 17.67—Block diagram of a VHF/UHF NBFM transmitter using the indirect FM (phase modulation) method.

## TRANSVERTERS

At VHF, UHF and microwave frequencies, transverters that interact with factory-made transceivers in the HF or VHF range are common and are often home-built. These units convert the transceiver transmit signal up to a higher frequency and convert the receive frequency down to the transceiver receive frequency. The resulting performance and signal quality at the higher frequencies are enhanced by the frequency stability and the signal processing capabilities of the transceiver. For example, SSB and narrowband CW from 1.2 to 10 GHz are

feasible, and becoming more popular. Some HF and VHF transceivers have special provisions such as connectors, signal-path switching and T/R switching that facilitate use with a transverter.

### VHF Transverters

The methods of individual circuit design for a transverter are not much different than methods that have already been described. The most informative approach would be to study carefully an actual project description. The Projects section of this chapter contains a very complete description of a 222-MHz transverter that is an excellent example of

transverter design. It is fairly easy to build and requires a minimum of test equipment for tune-up and adjustment. Much can be learned from this project, not only about transverter design but about VHF circuit and equipment design in general.

The interface between the transceiver and transverter requires some careful planning. For example, the transceiver power output must be compatible with the transverter's input requirements. This may require an attenuator or some modifications to a particular transverter or transceiver.

When receiving, the gain of the transverter must not be so large that the trans-

ceiver front-end is overdriven (system IMD is seriously degraded). On the other hand, the transverter gain must be high enough and its noise figure low enough so that the overall system noise figure is within a dB or so of the transverter's own noise figure. The formulas in this chapter for cascaded noise figure and cascaded third-order intercept points should be used during the design process to assure good system performance. The transceiver's performance should be either known or measured to assist in this effort.

### Microwave Transverters

The microwave receiver section of this chapter discussed a 10-GHz transverter project and gave references to the *QST* articles that give a detailed description. The reader is encouraged to refer to these articles and to review the previous material in this chapter.

### Other Information

The *ARRL UHF / Microwave Experimenter's Manual* and *ARRL's Microwave Projects* contain additional interesting and valuable descriptions of transverter and transponder requirements. See also Refs 67-71 in this chapter for valuable information on transverter projects and design.

## TRANSCIVERS

In recent years the transceiver has become the most popular type of purchased equipment among amateurs. The reasons for this popularity are:

1. It is economical to use LOs (especially synthesizers), IF amplifiers and filters, power supplies, DSP modules and microprocessor controls for both transmit and receive.
2. It is simpler to perform transmit-receive (T/R) switching functions smoothly and with the correct timing within the same piece of equipment.
3. It is convenient to set a receive frequency and the identical (or properly offset) transmit frequency simultaneously.

In addition, transceivers have acquired

very impressive arrays of operator aids that help the operator to communicate more easily and effectively.

The complex design, numerous features and the very compact packaging have made the transceiver essentially a "store bought" item that is extremely difficult for the individual amateur to duplicate at home. The complexity of the work done by teams of design specialists at the factories is incompatible with the technical backgrounds of nearly all individual amateur operators.

The result of this modern trend is that amateur home-built equipment tends to be simpler, with less power output and more specialized (one-band, QRP, CW only, direct conversion, no-tune, receive only, transmit only and so on). Or, the amateur designs and builds add-on devices such as antenna couplers, active adaptive filters, computer interfaces and such.

### Transceiver Example

As a way of providing a detailed, in-depth description of modern high-quality transceiver design, let's discuss one recent example, the Ten-Tec Omni VI, an HF ham-band-only solid-state 100 W (output) transceiver, shown in **Fig 17.68**. Ref 84 is a Product Review of this radio. Let's consider first the signal-path block diagram in **Fig 17.69**, one section at a time.

### Receiver Front End

The receive antenna can be either the same as the transmitting antenna or an auxiliary receive antenna. A 20-dB attenuator can be switched in as needed. A 1.6-MHz high-pass filter attenuates the broadcast band. A 9.0-MHz trap attenuates any very strong signals at 9.0 MHz that might create interference in the form of blocking or harmonic IMD, especially when tuned to the 10.1-MHz (30-m) or 7-MHz (40-m) bands.

A set of band-pass filters, one for each HF amateur band, eliminates image responses and other spurs in the first mixer. These filters are also used in the low-level transmit stages. A low-noise, high-dynamic-range, grounded-gate JFET RF amplifier with about 9 dB of gain precedes

the double balanced diode mixer, which uses 17 dBm of LO in a high-side mix.

### First IF

The first IF is 9.0 MHz. Because the LO is on the high side, there is a sideband inversion (USB becomes LSB and so on) after the first mixer. A grounded-gate, low-noise JFET amplifier terminates the first mixer in a resistive load and provides 6 dB of gain. This preamp helps to establish the receiver sensitivity (0.15  $\mu$ V) with minimum gain preceding the mixer.

The preamp is followed by a 15-kHz-wide two-pole filter, which is used for NBFM reception. It is also a roofing filter for the IF amplifier and the noise-blanker circuit that follow it.

The noise blanker gathers impulse energy from the 15-kHz filter, amplifies and rectifies it, and opens a balanced diode noise gate. The IF signal ahead of the gate is delayed slightly by a two-pole filter so that the IF noise pulse and the blanking pulse arrive at the gate at the same time (Ref 48).

The standard IF filter for SSB/CW has 8 poles, is centered at 9.0015 MHz and is 2.4 kHz wide at the -6 dB points. Following this filter, one optional 9.0-MHz filter with one of the following bandwidths can be installed: 1.8 kHz, 500 Hz, 250 Hz or a 500 Hz RTTY filter. The optional filter is in cascade with the standard filter, for improved ultimate attenuation.

### Passband Tuning Section

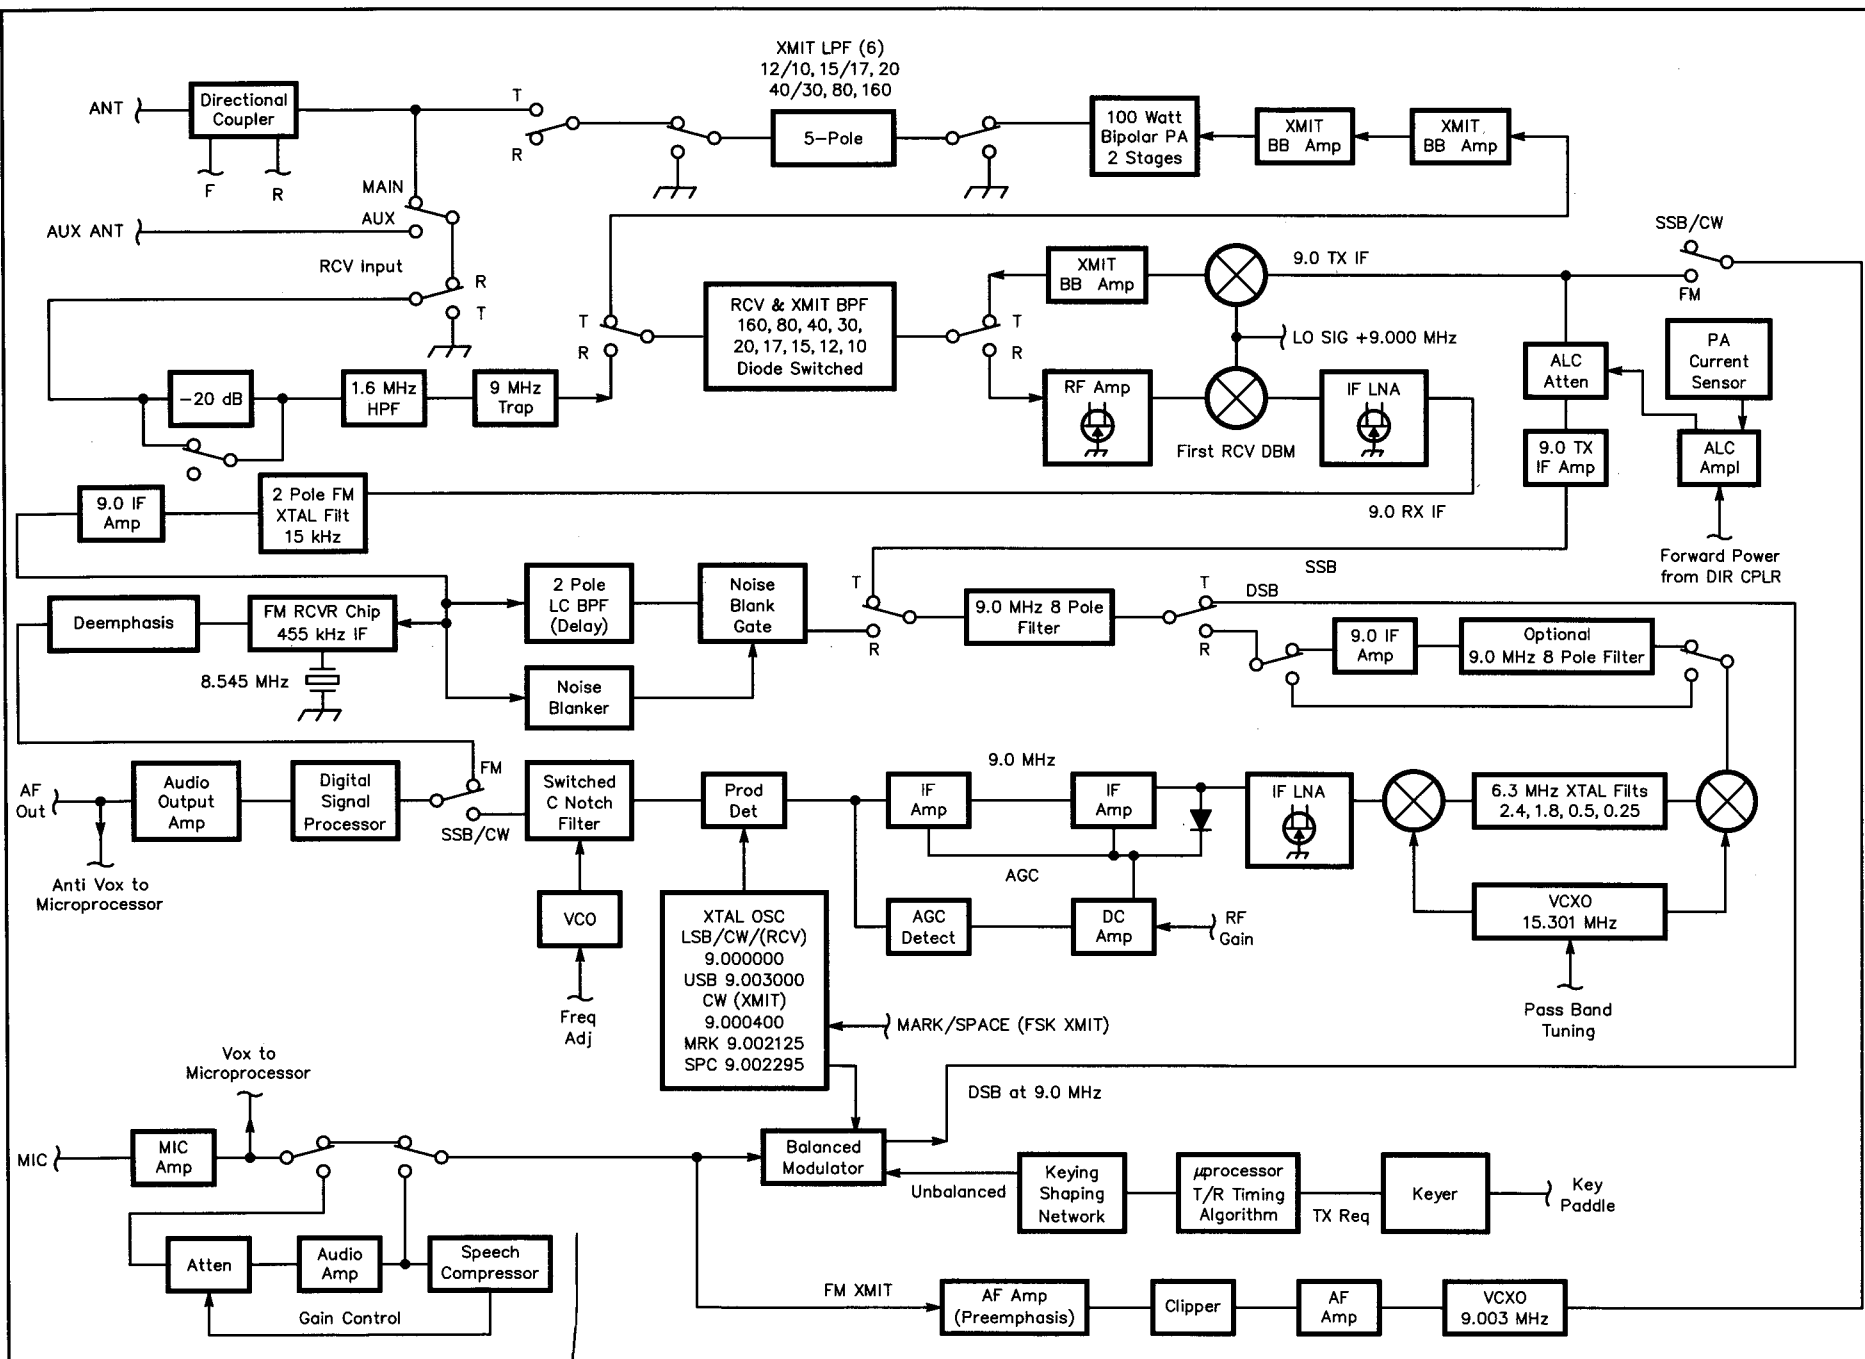

A mixer converts 9.0 MHz to 6.3 MHz and drives a standard 2.4 kHz wide filter. One of three optional filters, 1.8 kHz, 0.5 kHz (CW) or 250 Hz can be selected instead. A second mixer translates back to the 9.0-MHz frequency. A voltage tuned crystal oscillator at 15.301 MHz is the LO for both mixers. This choice of LO and the 6.3-MHz IF results in very low levels of harmonic IMD products that might cross over the signal frequency and cause spurious outputs. The passband can be tuned  $\pm 1.2$  kHz.

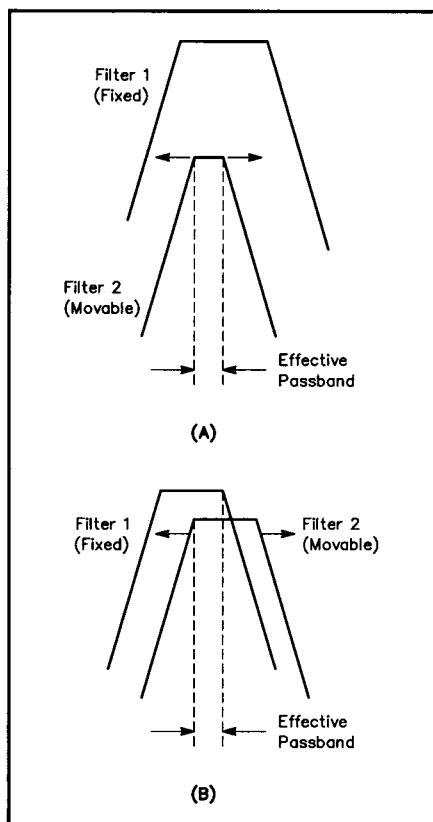

The composite passband is the intersection of the fixed 9.0-MHz passband and the tunable 6.3-MHz passband. If the first filter is wide and the second much narrower the passband width remains constant over most of the adjustment range. If both have the same bandwidth the resultant bandwidth narrows considerably as the second filter is adjusted. This can be especially helpful in CW mode. **Fig 17.70** shows how passband tuning works.

**Fig 17.68**—Photograph of Ten-Tec Omni VI HF transceiver.

**Fig 17.69**—Signal path block diagram, receive and transmit, for the Omni VI transceiver.

**Fig 17.70—Explanation of passband tuning. A: wide first filter and narrow second filter. B: two narrow filters.**

### IF Amplifiers after Passband Tuning

A low-noise grounded-gate JFET amplifier, with PIN-diode AGC, establishes a low noise figure and a low level of IF noise after the last IF filter. Two IC IF amplifiers (MC1350P) provide most of the receive IF gain. These three stages provide all of the AGC for the receiver. The AGC loop does not include the narrow-band IF filters. Two AGC recovery times (Fast and Slow) are available. AGC can be switched off for manual RF gain control as well. The AGC drives the S-meter, which is calibrated at 50  $\mu\text{V}$  for S9 and 0.8  $\mu\text{V}$  for S3.

### Product Detector

The IC product detector (CA3053E) uses LO frequencies of 9.000 MHz for LSB and CW (in receive only), 9.003 MHz for USB. When switching between USB and LSB, for a constant value of signal carrier frequency (such as 14.20000 MHz), the LO of the first mixer is moved 3.00 kHz in order to keep the signal within the passband of the IF SSB filters. More about this later.

### Audio Notch Filter

In the CW and digital modes, a switched-capacitor notch filter (MF5CN)

places a narrow notch in the audio band. The location of the notch is determined by the clock rate applied to the chip. This is determined by a VCO (CD4046BE) whose frequency is controlled by the front panel NOTCH control.

### NBFM Reception

After the 15 kHz wide IF filter at 9.0 MHz and before the noise blanker, the IF goes to the NBFM receiver chip (MC3371P). A mixer (8.545-MHz LO) converts it to 455 kHz. The signal goes through an off-chip ceramic band-pass filter, then goes back on-chip to the limiter stages and a quadrature detector. A received signal strength indicator (RSSI) output provides a dc voltage that is proportional to the dB level of the signal. This voltage goes to the front panel meter when in the NBFM mode. A squelch function (NBFM only) is controlled from a potentiometer on the front panel.

### Audio Digital Signal Processing (DSP)

The DSP is based on the Analog Devices ADSP 2105 processor. The DSP program is stored in an EPROM and loaded into the 2105's RAM on power-up.

DSP can be used in both SSB and CW. In USB or LSB (not CW or data) the DSP automatically locates and notches out one or several interfering carriers. In SSB or CW the manual audio notch filter described previously is also available, either as a notch filter or to reduce high frequency response (hiss filter). In the CW mode the DSP can be instructed to low-pass filter the audio with several corner-frequency values.

### Audio Output

The 1.5-W audio output uses a TDA2611 chip. Either FM audio or SSB/CW audio or, in transmit, a CW sidetone, can be fed to the speaker or headphones. The sidetone level (a software adjustment) is separate from the volume control. The audio output, after A/D conversion, is also fed to the Anti-VOX algorithm in the microprocessor.

### Transmit Block Diagram

Now, let's look at the path from microphone or key to the antenna, one stage at a time.

### Microphone Amplifier

The suggested microphone is 200  $\Omega$  to 50 k $\Omega$  at 5 mV (–62 dB). A polarizing voltage for electret mics is provided. The Mic Amp drives the balanced modulator, either directly or through the speech compressor. It also supplies VOX information to the microprocessor, via an A/D converter. The microprocessor software sets VOX hang time and sensitivity, as well as the Anti-VOX, via the keypad. Timing and delays for

T/R switching are also in the software.

### Speech Processor

The audio speech processor is a compressor, as discussed in a previous section of this chapter. A dc voltage that is proportional to the amount of compression is sent to the front panel meter so that compression can be set to the proper level. Clipper diodes limit any fast transients that might overdrive the signal path momentarily.

### Balanced Modulator

The balanced modulator generates a double-sideband, suppressed carrier IF at 9.0 MHz. The LO is that used for the receive product detector. There is a carrier nulling adjustment. In CW and FSK modes, the modulator is unbalanced to let the LO pass through. For CW, a keying shaping circuit provides an adjustable 1 to 5 ms rise and fall time for the RF envelope. A built-in iambic keyer (Curtis style A or B) is adjustable from 10 to 50 wpm. An external key or keyer can also be plugged in.

### IF Filter

The standard 9.0015 MHz, 2.4 kHz-wide 8-pole filter (also used in receive) removes either the lower or upper sideband. The output is amplified at 9.0 MHz.

### ALC

The forward-power measurement from the PA output directional coupler is used for ALC, which is applied at the output of the first 9.0-MHz IF amplifier by a PIN diode attenuator. A front panel LED lights when ALC is operating. An additional circuit monitors dc current in the PA and cuts back on RF drive if the PA current exceeds 22 A.

### Output Mixer

This mixer translates to the output signal frequency. The same LO frequency is used for each transmit mode (USB/LSB) and the same 3.00000-kHz frequency shift is used to assure that the frequency readout is always correct.

### Band-pass Filters

The mixer output contains the image, at 9.0 plus LO and low values of harmonics and harmonic IMD products. A band-pass filter for each ham band, the same ones used in receive, eliminates all out of band products from the transmitter output.

### PAs

Four stages of amplification, culminating in push-pull bipolar MRF458s in Class AB, supply 100 W output, CW or PEP from 160 to 10 m. Temperature sensing of the transistors in the last two stages helps to prevent

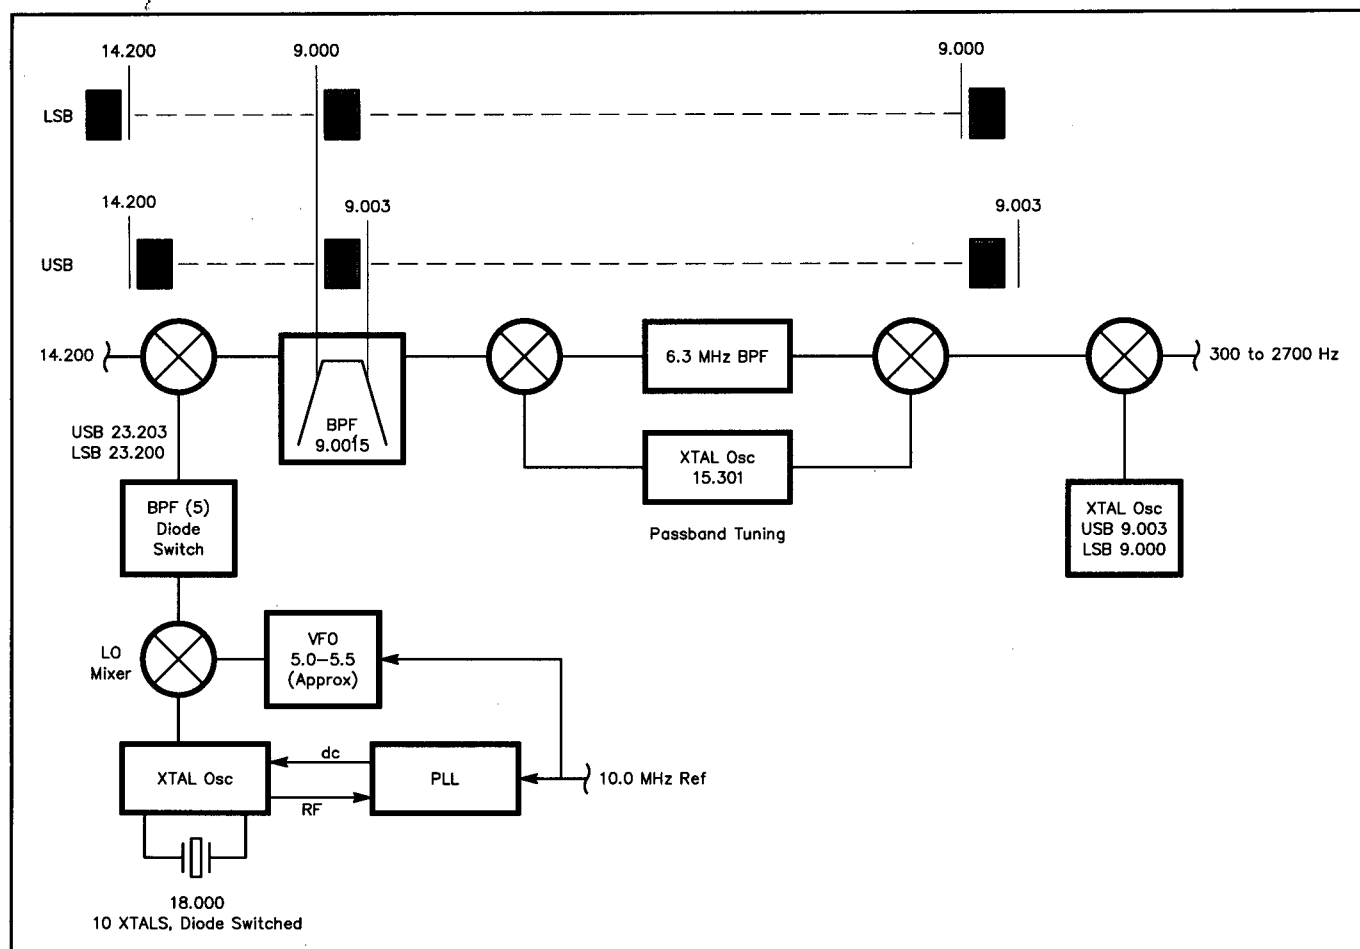

Fig 17.71—LO frequency management in USB and LSB.

thermal damage. Full output can be maintained, key down, for 20 minutes. Forced air heat-sink cooling allows unlimited on-time.

### LO Frequency Management

The LO goals are to achieve low levels of phase noise, high levels of frequency stability and at the same time keep equipment cost within the reach of as many amateurs as possible. As part one of the LO analysis we look at the method used to adjust the LOs in order to keep the speech spectrum of a USB or LSB signal within the 9.0-MHz IF filter passband. This method is somewhat typical for many equipment designs. Refer to Fig 17.71.

#### First Mixer and Product Detector

An SSB signal whose carrier frequency is at 14.20000 MHz, which may be LSB or USB, is translated so that the modulation (300 to 2700 Hz) in either case falls within the passband of the 9.0015-MHz 8-pole crystal filter. For a USB signal this is accomplished by increasing the first LO 3 kHz, as indicated. Since the LO is on the high side of the signal frequency there is a sideband “inversion” at the first mixer. The

passband tuning module does not change this relationship. At the product detector, the LO is increased 3 kHz in USB so that it is the same as the carrier (suppressed) frequency of the IF signal. Note that the designators “USB” or “LSB” at the product detector LO refer to the antenna signal, not the IF signal. The jog of the first mixer LO is accomplished partly within the crystal oscillator and partly within the VFO. The microprocessor sends the frequency instructions to both of these oscillators. Despite the frequency offsets, the digital readout displays the correct carrier frequency, in this example 14.20000 MHz. And, of course, the same procedures apply to the transmit mode.

Another interesting idea involves the first LO mixer. The 18-MHz crystal and the VFO are added to get 23.0 to 23.5 MHz, for the 20-m band. But the output of the LO mixer also contains the difference, 12.5 to 13.0 MHz, which is just right for the 80-m band. For the 20-m band one BPF selects 23.0 to 23.5 MHz. For the 80-m band the 12.5 to 13.0-MHz BPF is selected. A problem occurs, though, because now the direction of frequency tuning is reversed, from high to low. The microprocessor corrects this by

reversing the direction of the tuning knob (an optical encoder). Other “book keeping” is performed so that the operation is transparent to the operator. A similar trick is used on the 17-m band and the 28.5 to 29.0-MHz segment of the 10-m band.

#### CW-Mode LO Frequencies

In CW mode the “transceiver problem” shows up. See Fig 17.72 for a discussion of this problem. If the received carrier is on exactly 14.00000 MHz and if we want to transmit our carrier on that same exact frequency then the transmitter and the receiver are both “zero beat” at 14.00000 MHz. In receive we would have to retune the receiver, say up 700 Hz, to get an audible 700-Hz beat note. But then when we transmit we are no longer on 14.0000 MHz but are at 14.00070 MHz. We would then have to reset to 14.00000 when we transmit.

The transceiver’s microprocessor performs all of these operations automatically. Fig 17.72 shows that in receive the first-LO frequency is increased 700 Hz. This puts the first IF at 9.0007 MHz, which is inside the passband of the 9.0 MHz IF filter. The BFO is at 9.0000 MHz and an audio beat note at

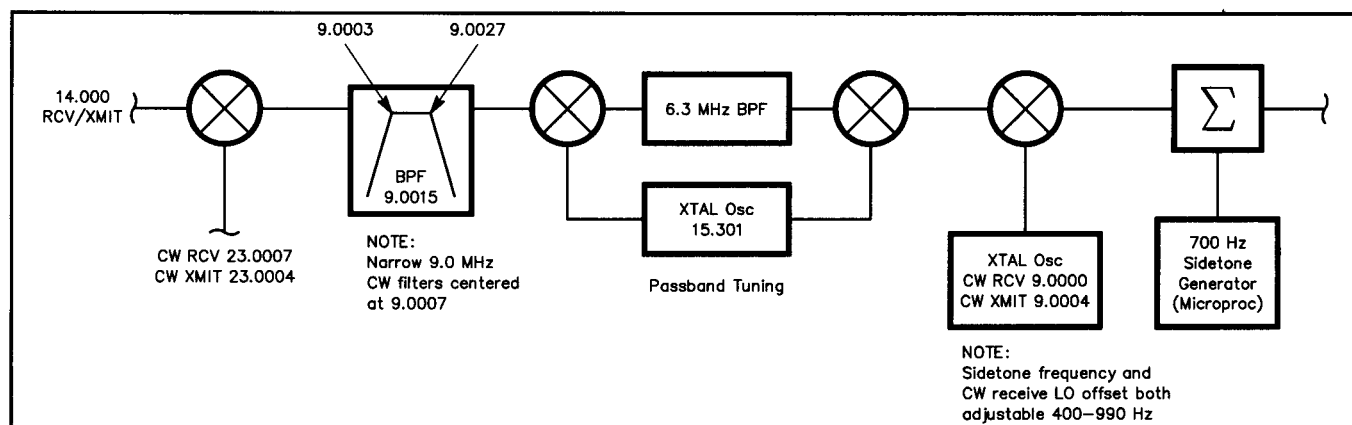

Fig 17.72—LO management in the CW receive and transmit modes.

700 Hz is produced. This 700-Hz pitch is compared to a 700-Hz audio oscillator (from the microprocessor). When the two pitches coincide the signal frequency display of our transceiver coincides almost exactly with the frequency of the received signal. The digital frequency display reads “14.00000” at all times. The value of the 700-Hz reference beat can be adjusted between 400 and 950 Hz by the user. The receive LO shift matches that value.

When the optional 500/250 Hz CW 9.0 MHz IF filters are used, these are centered at 9.0007 MHz. These filters are used in receive but not in transmit.

When we transmit, the transmit frequency is that which the frequency display indicates, 14.00000 MHz. However, there is a slight problem. The 9.0-MHz transmit IF must be increased slightly to get the speech signal within the passband of the 9.0 MHz IF filter. The transmit BFO is therefore at 9.0004 MHz. The mixer LO is also moved up 400 Hz so that the transmit output frequency will be exactly 14.0000 MHz.

In addition to the above actions, the RIT (receive incremental tuning) and the XIT (transmit incremental tuning) knobs permit up to  $\pm 9.9$  kHz of independent control of the receive and transmit frequencies, relative to the main frequency readout.

### Local Oscillators

Fig 17.71 indicates that the crystal oscillator for the first mixer is phase locked. Each of the 10 crystals is locked to a 100-kHz reference inside the PLL chip. This reference is derived from a 10-MHz system reference.

Let’s go into some detail regarding the very interesting 5.0 to 5.5 MHz VFO circuitry. Fig 17.73 is a block diagram.

The VCO output, 200 to 220 MHz, is divided by 40 to get 5.0 to 5.5 MHz. The reference frequency for the PLL loop is 10 kHz, so each increment of the final output is 10 kHz / 40, which is 250 Hz. Phase noise in the PLL is also divided by 40, which is

equivalent to 32 dB ( $20 \times \log(40)$ ).

To get 10-Hz steps at the output, the voltage-tuned crystal oscillator at 39.94 MHz is tuned in 200-Hz steps (the division ratio from oscillator to final output is 20 instead of 40 because of the frequency doubler). To get 200-Hz steps in this oscillator, serial data from the microprocessor is fed into a latch. This data is sent from a RAM lookup table that has the correct values to get the 200-Hz increments very accurately. The outputs of the latch are fed into an R/2R ladder (D/A conversion) and the dc voltage tunes the VCXO. Adjustment potentiometers calibrate the tuning range of the oscillator over 5000 Hz in 200-Hz increments. At the final output, this tuning range fills in the 10-Hz steps between the 250-Hz increments of the PLL. Although this circuit is not phase locked to a reference (it’s an open-loop), the resulting frequency steps are very accurate, especially after the division by 20. This economical approach reduces the complexity and cost of the VFO considerably, but performs extremely well (very low levels of phase noise and frequency drift).

### CW Break-In (Fast QSK) Keying

The radio is capable of break-in keying at rates up to 45 wpm when it is in the FAST QSK mode. This mode is also used for AMTOR FSK. Fig 17.74 explains the action and the timing involved in this T/R switching. The sequence of events is as follows:

1. The key is pressed.
2. A Transmit Request is sent to the microprocessor.
3. The microprocessor changes the LO and BFO to their transmit frequencies.
4. After a 0.25-ms delay a Transmit Out logic level is sent to a jack on the rear panel.
5. The Transmit Out signal is jumpered to the TRANSMIT ENABLE jack. If an external Fast QSK PA is being used, an additional short delay is introduced while it is being switched to the transmit mode.

6. The Transmit Enable signal starts the keying-waveform circuit, which ramps up in 1 to 5 ms (adjustable by the operator).
7. Near the bottom of this ramp, the “T” (transmit B+) voltage goes high and the “R” (receive B+) voltage goes low. The T/R reed relay (very fast) at the Omni VI PA output switches to transmit.
8. The shaped keying waveform goes to the balanced modulator and the RF envelope builds up. There is a very brief delay from balanced modulator to Omni VI output. The T/R relay is switched before the RF arrives.
9. The key is opened.
10. The Transmit Out and Transmit Enable lines go high.
11. The keying waveform ramps down. RF ramps down to zero.
12. After 5 ms (a fixed delay set by the microprocessor) “T” goes low and “R” goes high and the microprocessor returns the LO and BFO to their receive frequencies.

### Slow QSK

In the Slow QSK mode the action is as described above. The radio reverts quickly to the receive mode. However, the receive audio is muted until the end of an extended (adjustable) delay time.

There is also a relay in the Omni VI that can be used to T/R switch a conventional (not Fast QSK) external PA. This option is selected from the operator’s menu and is available only in the Slow QSK mode. The relay is held closed for the duration of the delay time in the slow QSK mode. When using this option the operator must ensure that the external PA switches fast enough on the first “key-down” so that it is not “hot switched” or that the first dot is missed. Many older PAs do not respond well at high keying rates. If the PA is slow, we can still use the Fast QSK mode with the Omni VI (“barefoot”) and the PA will be bypassed because the optional

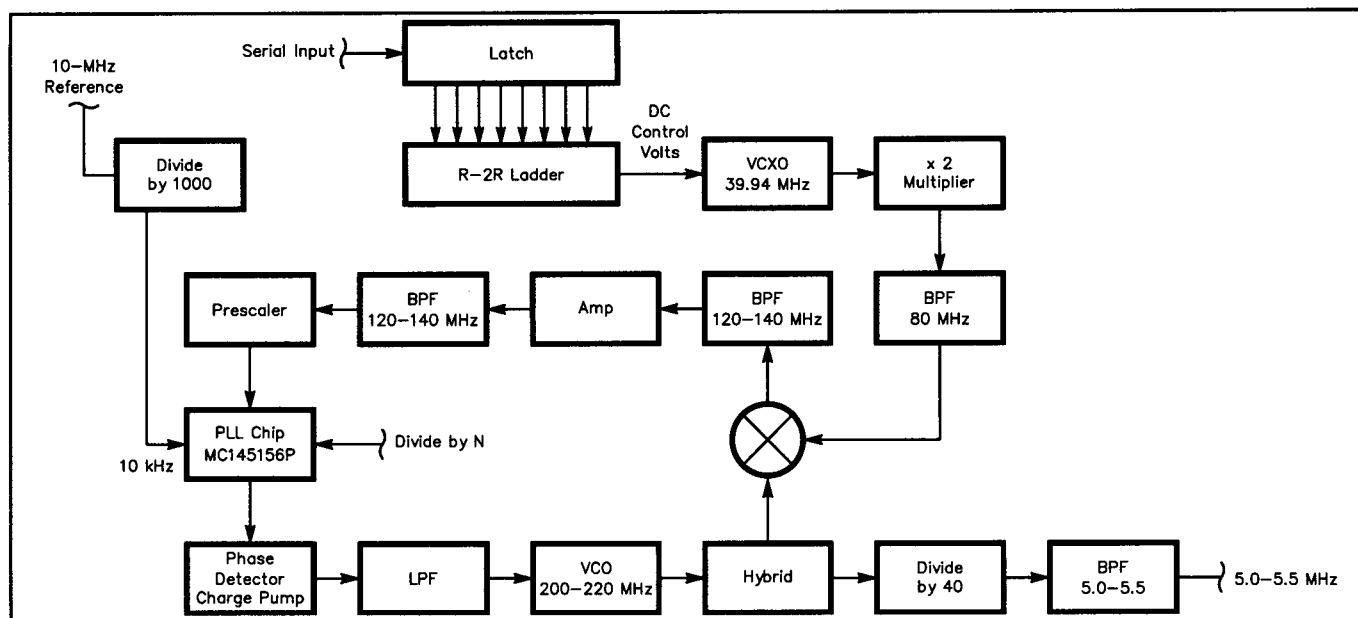

Fig 17.73—Block diagram of the VFO.

relay is not energized in the Fast QSK mode.

## VOX

In SSB mode, VOX and PTT perform the same functions and in the same manner as the CW Slow QSK described above. The VOX hang-time adjustment is separate from the CW hang-time adjustment. A MUTE jack allows manual switching (foot switch, and so on) to enable the transmit mode without applying RF. The key or the VOX then subsequently applies RF to the system. This arrangement helps if the external PA has slow T/R switching.

## Operating Features

Modern transceivers have, over the years, acquired a large ensemble of operator's aids that have become very popular. Here are some descriptions of them:

### Key Pad

The front panel key pad is the means for configuring a wide assortment of operating preferences and for selecting bands and modes.

### Frequency Change

1. Use the tuning knob. The tuning rate can be programmed to 5.12, 2.56, 1.71, 1.28, 1.02 or 0.85 kHz per revolution. The knob has adjustable drag.
2. UP and DOWN arrows give 100 kHz per step.
3. Band selection buttons.
4. Keyboard entry of an exact frequency.

### Mode Selection

1. **Tune:** puts the rig in CW mode, key down,

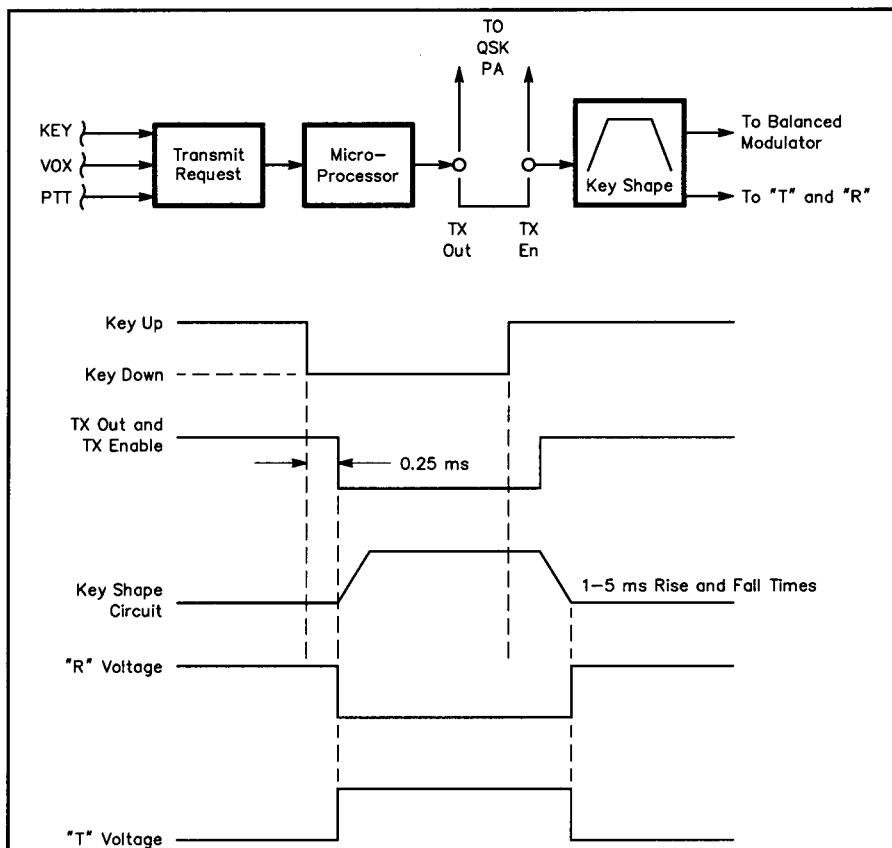

Fig 17.74—Fast QSK operation of the Omni VI transceiver.

- for various "tune-up" operations.
2. **CW:** An optional DSP low-pass filter can be selected. Cutoff frequencies of 600, 800, 1000, 1200 or 1400 Hz can be designated. A SPOT function generates a 700-Hz audio sidetone that can be

used for precise frequency setting (the received signal pitch matches the 700-Hz tone). The pitch of the sidetone can be adjusted from 400 to 950 Hz. Audio level is adjustable also. FAST QSK and SLOW QSK are available as previously

described. Cascaded CW filters are available, with passband tuning of one of the filters. CW filter options: 500/250 Hz at 6.3 MHz IF and 500 Hz at 9.0-MHz IF.

3. **USB or LSB:** Standard SSB IF bandwidth is 2.4 kHz (two 8-pole filters in cascade). The second filter can be passband-tuned  $\pm 1.2$  kHz. Additional IF filters with 1.8-kHz BW are available.
4. **FSK and AFSK:** Special FSK filter for receive. AMTOR operation with FAST QSK capability. AFSK generator can be plugged into microphone jack.
5. **FM:** 15-kHz IF filters at 9.0 MHz and 455 kHz. Quadrature detection, RSSI output and squelch. Adjustable transmit deviation. FM transmit uses the direct method, as shown in Fig 17.69.
6. **VOX:** VOX sensitivity and hang time adjustable via the key pad. Anti-VOX level adjustable.

#### **Time of Day Clock**

There is a digital readout on front panel.

#### **Built-In Iambic Keyer**

Curtis type A or B, front panel speed knob. Adjustable dot-dash ratio. Also external key or keyer.

#### **Dimmer**

Adjusts brightness of front panel display.

#### **Dual VFOs**

Select A or B. Independent frequency, mode, RIT and filter choices stored for each VFO. Used for split-frequency operation.

#### **Receiver Incremental Tuning (RIT)**

Each VFO has its own stored RIT value.

#### **Frequency Offset Display**

RIT value adjusted with knob. RIT can be toggled on and off, or cleared to zero.

#### **Transmitter Incremental Tuning (XIT)**

Same comments as RIT. Simultaneous RIT and XIT.

#### **Cross-Band and Cross-Mode Operation**

For cross-band operation, use PTT for SSB and manual switch for CW.

#### **Scratch-Pad Memory**

Stores a displayed frequency. Restores that frequency to the VFO on command.

#### **Band Register**

Allows toggling between two frequencies on each band.

#### **Memory Store**

Store 100 values of frequency, band,

mode, filter, RIT, XIT. Memory channels can be recalled by channel number (key pad), "scrolling" the memory channels or "memory tune" using the main tuning knob.

#### **Band Scan**

Automatically scan between two frequencies within a band. Scan rate is adjustable.

#### **Lock**

Locks the main tuning dial.

#### **User Option Menu**

Enables configuration of the radio via the keypad.

#### **Meter**

Select between receive signal strength (on SSB/CW or NBFM), speech processor level, forward power, SWR and PA dc current.

#### **AGC**

Fast, slow, off and manual RF gain control.

#### **FM Squelch Adjust**

#### **Passband Tuning Knob**

#### **Notch**

Automatically notch out several heterodynes on SSB/FM or manually notch on CW/digital modes. Adjustable low-pass filter in CW mode.

#### **Antenna Switch**

Auxiliary antenna may be selected in receive mode.

#### **Interface Port**

25-pin D connector for interface to personal computer.

### **OTHER TRANSCEIVERS**

Other transceivers vary in cost, complexity and features. The one just described is certainly one of the best, at a reasonable price. For reviews of other transceivers (to see the differences in cost, features and performance specs) refer to the Product Reviews in *QST* and ARRL's *Radio Buyer's Sourcebook* series. For example, see Refs 85, 86, 87, 88.

Let's look quickly at a more expensive transceiver, to get some feel for other options and design approaches at higher prices.

#### **The Kenwood TS-950SDX**

This radio has a "subreceiver," containing an SSB filter and a 500-Hz CW filter. Simultaneous reception on both receivers is possible. Both receivers can be tuned

independently.

A stored-message memory allows automatic transmission of short CW messages.

It performs harmonic sampling and DSP at a 100-kHz IF. Digital detection is followed by digital filtering. The 100-kHz IF also has a voltage-tuned notch filter. SSB is generated by a DSP phasing method.

The synthesizer uses a DDS that can tune in 1-Hz steps. The receiver covers from 100 kHz to 30 MHz. The radio uses up conversion to a first IF of 73 MHz, followed by IFs at 8.8 MHz, 455 kHz and 100 kHz.

The PA uses FET technology. A cooling fan is provided. The radio also contains a built-in automatic antenna tuner with memory retention of tuner settings.

## A REGENERATIVE RECEIVER FOR BEGINNERS

A modern version of the classic regenerative receiver is shown in **Fig 17.75**. This project was designed and built by Charles Kitchin, N1TEV. This kind of receiver is easy (and fun) to build and has been used by many generations of hams to learn radio basics. It provides good general-coverage reception of the short-wave bands from 1.6 to 25 MHz, which includes the 80, 40, 30, 20, 17, 15 and 12-m ham bands. It offers good sensitivity and selectivity and is very portable, powered by two 9-V batteries. It has provision for operating on an external ac supply and can be user modified to provide any desired band spread on the amateur bands. A low-cost frequency counter may be added for a display. The circuit is designed to use series connected (64  $\Omega$ ) Sony "Walkman" stereo headphones, which are commonly available. A 50-ft length of wire run to a nearby tree will suffice as the antenna.

### Circuit Description

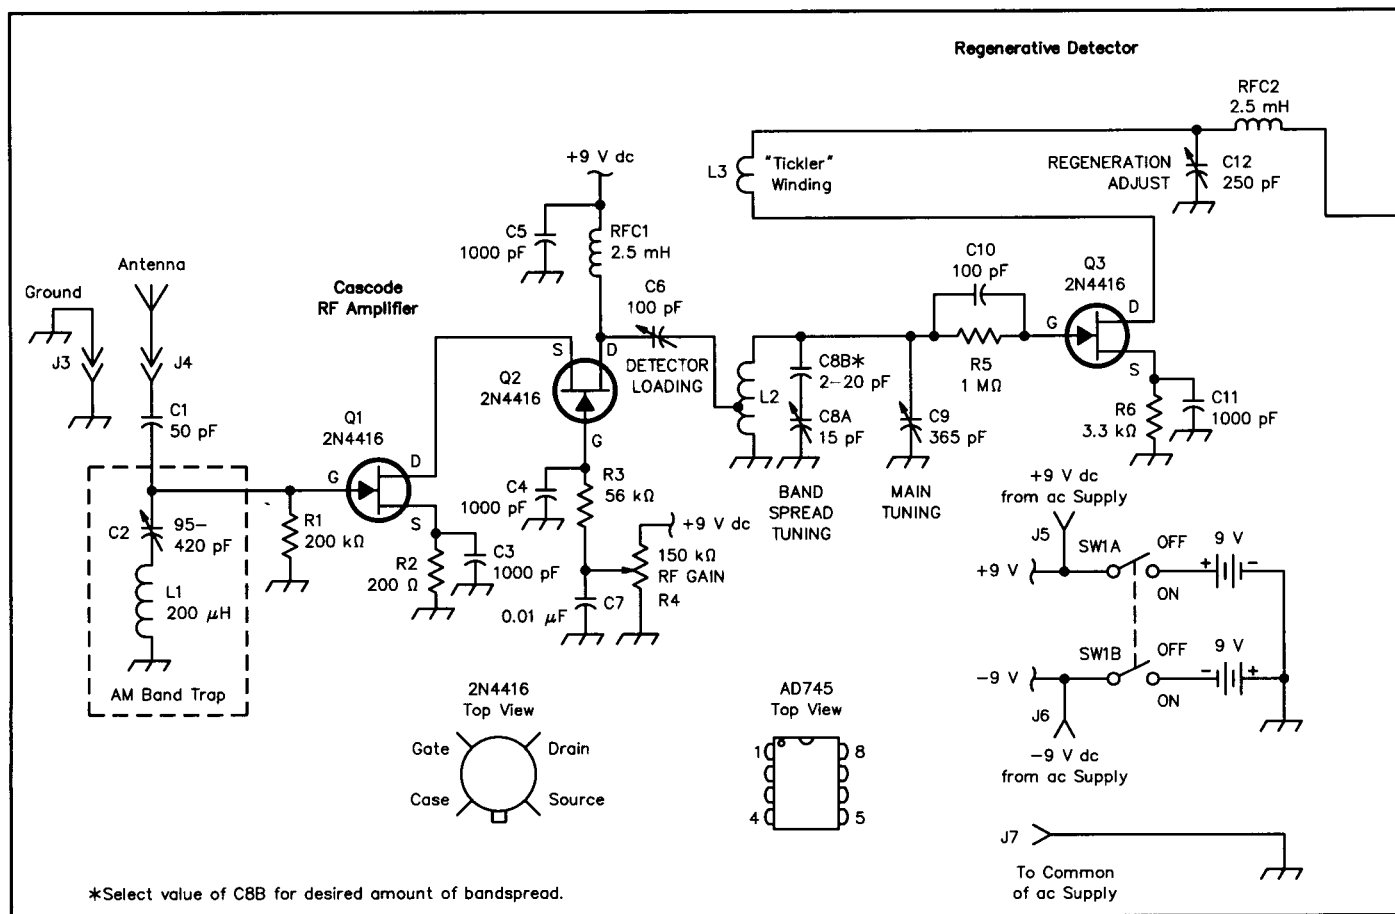

The heart of this circuit is JFET Q3,

which operates as a regenerative detector (see **Fig 17.76**). The circuit is basically an “Armstrong” oscillator that is user adjusted to operate just below the threshold of oscillation for AM signals, and just above for CW and SSB. The input signal (tuned by L2, C8, and C9), is amplified by Q3. Tickler coil L3 provides regenerative (in-phase) feedback so that the input signal is amplified over and over, providing very high gain in a single stage. In addition to increasing the gain, regeneration also greatly increases the selectivity or “Q” of the circuit. C12 controls the amount of regeneration. C6 allows the user to adjust the detector loading so that the signal is not detuned as regeneration is increased. This allows razor sharp regeneration adjustment without premature oscillation. The detector operating voltage is regulated by a Zener diode, D1, which helps keep the detector oscillation frequency from drifting when receiving SSB or CW transmissions.

The detector is preceded by an RF stage that provides gain and, more importantly, isolates the detector from the antenna, pre-

**Fig 17.75—Photos of the prototype regenerative receiver.**

venting its oscillations from interfering with other receivers in the area. An optional AM band trap can be tuned to reject interference from any nearby AM broadcast stations.

The audio stage uses an Analog Devices AD745 op amp that replaces the usual two stages of audio amplification and an output transformer. This op amp has enough output current capability to directly drive series connected "Walkman" type head-

phones to high levels with low distortion, and yet it only draws 8 mA from the batteries.

### Construction Details

The prototype receiver was built on a wooden chassis. This makes construction much easier, reduces loading effects caused by placing metal objects too close to the main tuning coil, and provides a nice looking receiver. The base is a piece of

$\frac{3}{4} \times 10 \times 6$ -inch poplar. The sides and back are  $\frac{1}{4}$ -inch plywood. The two side pieces are  $6\frac{1}{4} \times 5\frac{1}{4}$  inches. The back panel is  $10 \times 4$  inches and is braced to the base with a  $10 \times 1\frac{1}{2} \times \frac{3}{4}$ -inch piece of poplar and wood screws.

The front panel is the black-wrinkle finished steel U-shaped top from a  $10 \times 5\frac{1}{4} \times 3\frac{1}{2}$ -inch metal cabinet. If desired, the front panel can also be made of plywood as long as the metal frames

**Fig 17.76—A regenerative receiver for beginners.** Part Suppliers: OSE = Ocean State Electronics; AES = Antique Electronics Supply; FRS = Fair Radio Sales; NE = Newark Electronics; RS = Radio Shack. Look at the ARRL Address List in the References chapter for current addresses (OSE, AES, FRS). NE and RS are chain stores, look for them in your local yellow pages.

C1—50-pF mica capacitor.  
C2—95-420-pF mica trimmer capacitor (RS# 272-1336).  
C3, C4, C5, C11—1000-pF mica capacitor.  
C6—100-pF air variable capacitor.  
C7, C17, C18—0.01- $\mu$ F disc ceramic capacitor.  
C8A\*—15-pF air variable capacitor.  
C8B—Small mica capacitor to set desired band spread: 2-20-pF.  
C9\*—10-365-pF air-variable capacitor.  
C10—100-pF mica capacitor.  
C12\*—250-pF air-variable capacitor.  
C13—10- $\mu$ F, 16-V tantalum or

electrolytic capacitor.  
C14—0.1- $\mu$ F disc ceramic or Mylar capacitor.  
C15, C16—33- $\mu$ F, 16-V tantalum or electrolytic capacitor.  
D1—1N4736A 6.8-V Zener diode (OSE).  
J1—Phono jack.  
J2—Stereo headphone jack—note that the common terminal is not connected.  
J3, J4—Five-way binding posts for antenna and ground connections, J5, J6, J7—Banana jacks.  
L1—200- $\mu$ H RFC (OSE).  
L2, L3—Plug-in coils (see Fig 17.77 for winding data).

Q1-Q3—2N4416 Motorola VHF N-channel JFET (NE).  
R1—200-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R2—200- $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R3—56-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R4—150-k $\Omega$  potentiometer.  
R5—1-M $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R6—3.3-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R7—1.5-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R8—100-k $\Omega$  potentiometer.  
R9—1-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R10—330-k $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R11—680- $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
R12—51- $\Omega$   $\frac{1}{8}$ -W 5% carbon composition resistor.  
RFC1, RFC2—J. W. Miller #70F253A 2.5-mH RF choke (OSE).  
S1—DPST toggle switch.  
U1—Analog Devices AD745JN low-noise op amp (NE).

### Miscellaneous:

Vernier dial (OSE) or vernier reduction drive (OSE) (FRS) or use "Jackson" drive.

Vector #4112-4 plug board (NE) or low-cost  $4\frac{1}{2} \times 6$ -inch standard and copper clad board (RS).

\*C6, C8, C9, and C12—available from (AES),(OSE),(FRS).

### Measured Parameters

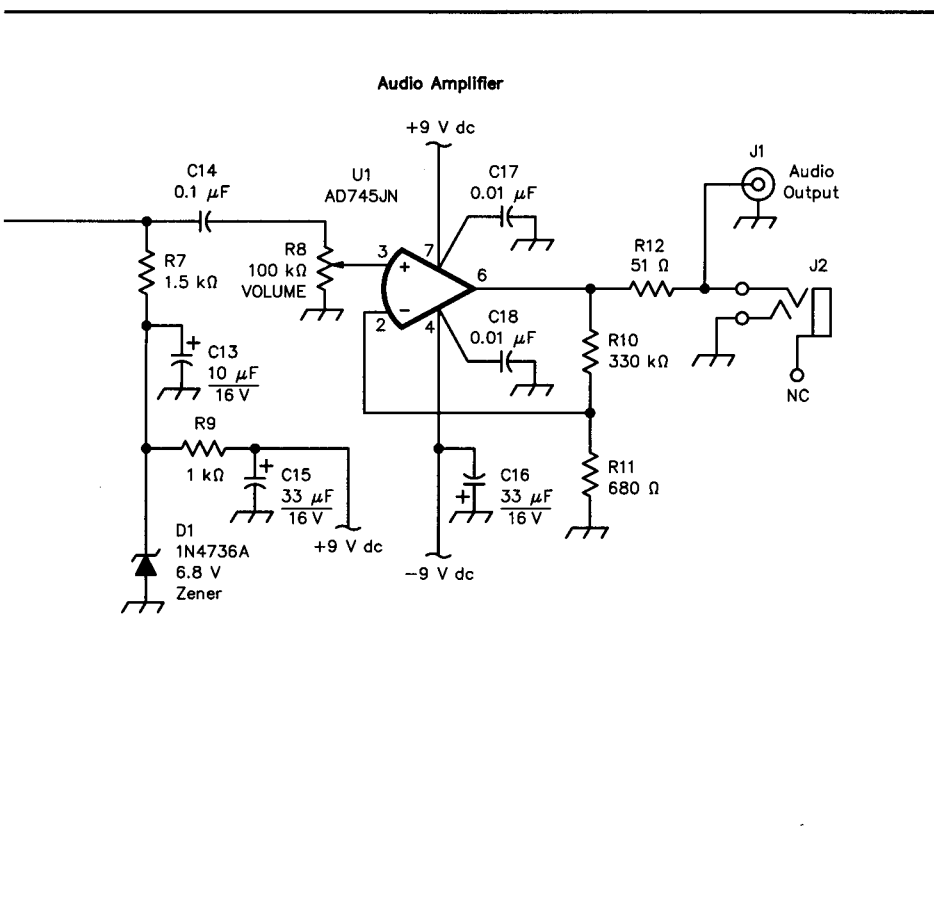

50- $\Omega$  input termination, Sensitivity (discernible 1-kHz audio output for 100% modulated RF input level)

### Sensitivity:

CW & SSB (detector oscillating) 0.3  $\mu$ V  
AM (detector not oscillating) 1  $\mu$ V.

### Selectivity:

Variable, depending on setting of C6 from approximately 10 kHz to a few hundred Hz at critical regeneration.

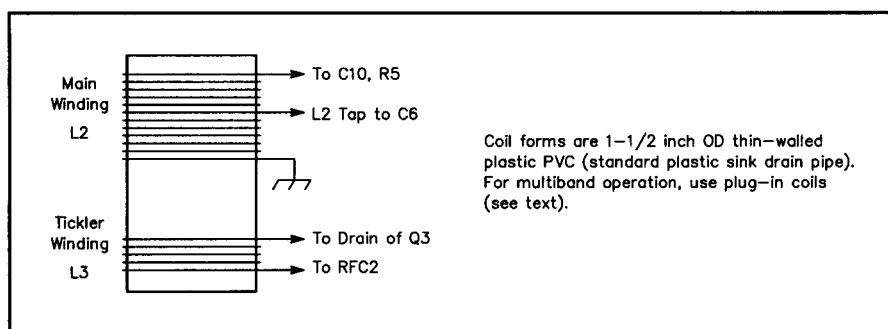

Fig 17.77—Details and winding data for L2/L3.

#### Coil Data for the Regenerative Receiver

Turns required for use with a 10 to 365-pF tuning capacitor, #20 enameled wire and a 1½-inch OD coil form.

Frequency Range (MHz)	L3 turns (μH)	L2 turns (μH)	L2 tap turns (% of L2)
1.6 to 5.5	8(3.9)	30(30.0)	10(30%)
3 to 12	4(1.1)	13(8.6)	4(31%)
8 to 25	2(0.3)	5(1.7)	1(20%)

of the tuning and regeneration capacitors and the shaft of the volume control are grounded to the circuit board through short leads.

The circuit was built on a Vector 4112-4 predrilled fiberglass breadboard with a metal ground plane on one side. The board was cut to 5¼×4½ inches. All ground leads are short and made directly to the ground plane, which is on top.

The detector and RF stages are located on the left side of the board, the main tuning capacitor, C9, is screwed directly onto the top center of the board (grounding it directly), and the audio amplifier section is located on the right-hand side. Wiring is point to point, using the shortest leads possible. The metal front panel is grounded.

It is a good idea to build receiver circuits *backwards*. That is, audio stage first, then detector, then RF stage. Test each stage to be sure it functions before you start the next. Note that the headphone jack common terminal is not connected, so don't mount the jack through a grounded panel. In the receiver shown, the jack was mounted through the right-hand wooden side panel. The audio output jack is mounted just above it.

An optional RF shield was used between the detector and RF stages. It consists of a 5¾×3¼-inch double sided PC board mounted vertically with both foils soldered to the ground plane of the main board (thus making a double shield). A small one-inch-square window was cut at the bottom edge of the shield to pass wiring between the stages. The ground lug of the RF GAIN control is

soldered to the RF shield to hold the control in place. This control could also be placed on the front or side panels of the receiver and connected to the RF section using shielded wire.

The REGENERATION ADJUST control, C12, is located on the top-left side of the front panel with the DETECTOR LOADING capacitor directly below it. Because the DETECTOR LOADING capacitor must be isolated from ground, a small piece of insulated board was attached to the capacitor frame. This allows it to be screwed down onto the wooden base. The shaft of the loading capacitor passes through an oversized hole in the front panel.

The shaft of the MAIN TUNING capacitor is attached to a vernier dial. This receiver uses a vintage 4-inch "velvet vernier" dial (from the 1930s), which was purchased at a local hamfest. Although smaller and of lesser quality, new vernier dials can be purchased from several suppliers as can the vernier drive mechanism itself (without the front plate and knob—see parts list). The VOLUME control is located at the top right-hand side of the front panel; the BAND-SPREAD TUNING capacitor, C8A, is located below it. C8B is a small fixed capacitor selected to provide the desired band spread. For general-coverage use, the vernier dial should be used on the main tuning capacitor. For maximum bandspread on the amateur bands, use the vernier on the band spread capacitor and a large knob for the main tuning. In all cases, plastic knobs are best for all the controls; they prevent hand capacitance effects.

On the back panel, two five-way binding posts provide ANTENNA and GROUND connections and three banana jacks allow connection of an optional ac power supply. The ON/OFF switch, HEADPHONE jack and AUDIO OUTPUT jack are mounted on the right-side panel.

This receiver can use a single fixed coil form for L2 and L3 to cover a single range of frequencies or it can use plug in coils to cover several bands (Fig 17.77). For fixed coils, standard 1½-inch thin-wall PVC pipe (plastic sink drain pipe) is easy to find, and it works well. Use #20 enameled wire to wind both L2 and L3 in the *same* direction. To avoid detuning effects, wind L3 on the bottom (ground end) of L2, with a ¼" space between windings as shown in the figure.

When winding the coils on a PVC form, first drill two small holes at the beginning of each winding. Next, feed the wire into the pipe through the first hole and out again through the second. Tie a knot at the point in the wire where it enters the form—this will hold the wire securely. Wind the coil tightly onto the form. When you reach the proper number of turns on L2, where the tap is placed, simply sand off a small amount of insulation from the wire and solder a lead to it. When the winding is finished, drill two more holes and tie a knot at the end to hold the coil in place. Be sure to leave enough extra wire at both ends of the winding to make connections, and clean the ends of the leads before soldering. Plug-in coil forms may be purchased from Antique Electronics Supply (see the **References** chapter Address List).

Plugs for the coils may be easily made from the bases of 4, 5, 6 or 8-pin vacuum tubes (tube bases can be purchased, or old tubes can be "cannibalized" by removing the glass envelope and "innards"). After winding the coil, push a tube base inside the PVC coil form, drill a couple of holes through both, and fasten them together with small machine screws and nuts. Four-pin tube bases fit perfectly into 1½-inch PVC. Others, such as common octal bases, may need a couple wraps of electrical tape for a snug fit. When using four-pin bases, a separate banana plug and jack can serve as the fifth pin that connects the L2 tap to C6. You can also make plug-in coils by attaching standard chassis connector plugs to plastic pill-bottle coil forms: Drill a small hole through the center of the plug and the bottom center of the pill bottle. Again, hold the two together with small machine screws and nuts.

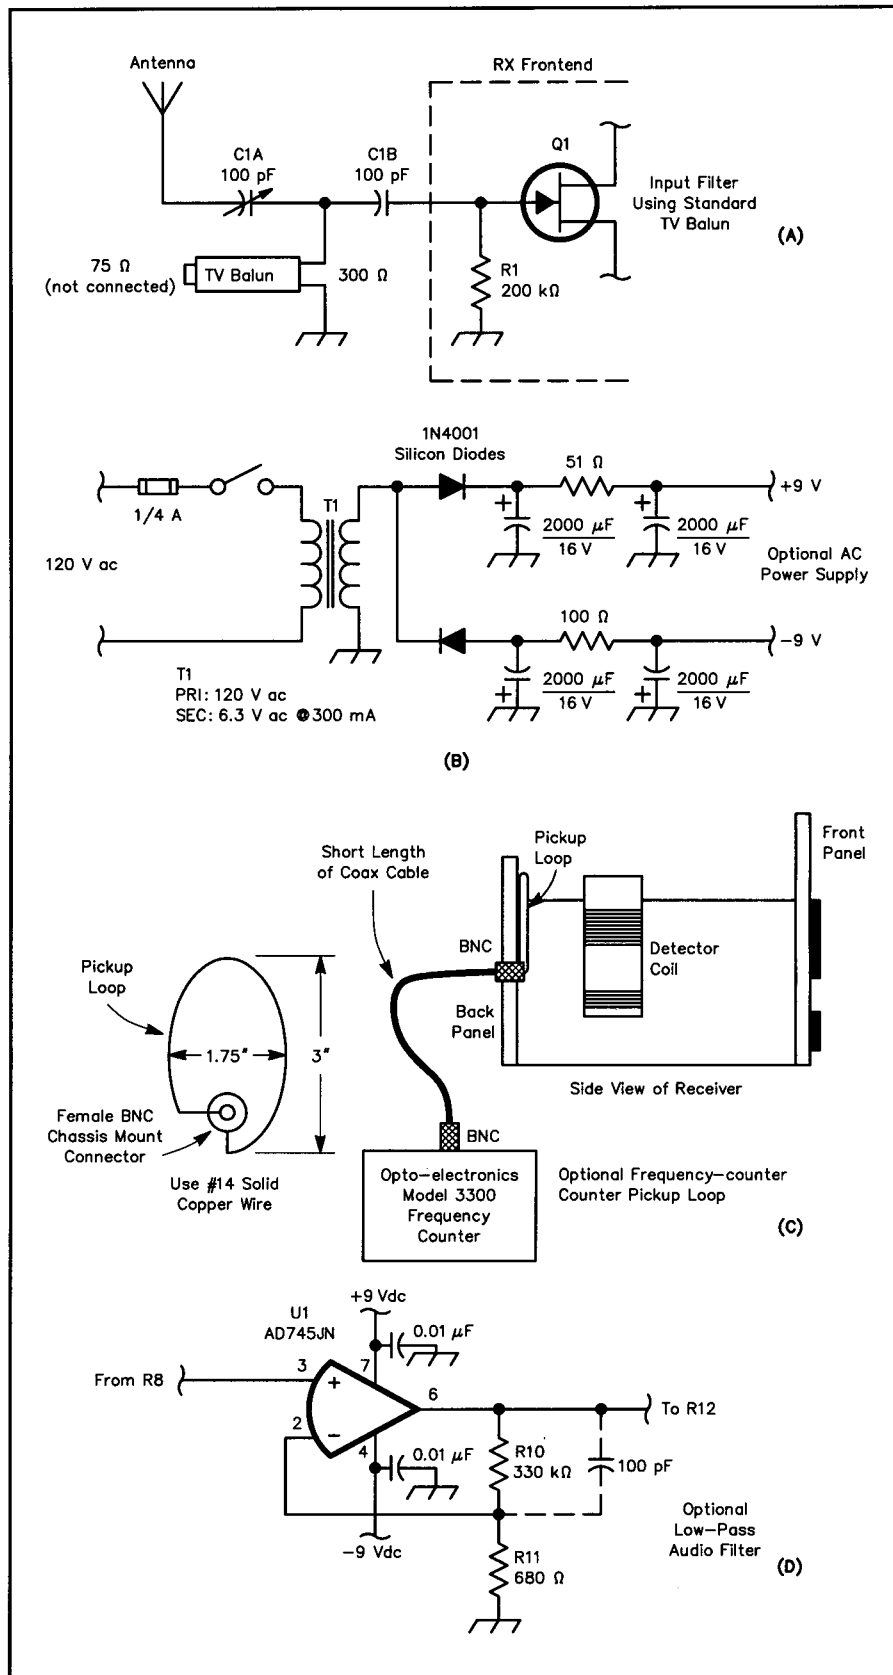

With any plug-in coil, run the wires from each winding inside the coil form and solder them to one of the pins on the plug, ensuring that all the coils are wired exactly the same. The completed coil form then plugs into a companion socket that is screwed to the wooden base. Be sure to locate the coil at least one inch away from any metal object.

### Circuit Testing

Test the audio stage by installing the batteries, plugging the headphones into J2, turning the VOLUME control half way up and placing your finger on the center terminal (wiper) of the control. If you hear a buzz (the buzz is power-line noise picked up by your body), it's working. Test the detector by setting C6 for minimum capacitance and then slowly increase the capacitance of the REGENERATION control, C12, until the detector oscillates, producing a hiss or squeal in the headphones. If the detector does not oscillate, carefully check the wiring for errors. If the wiring seems okay, try swapping the wires to the tickler winding, L3. Once the detector is oscillating, temporarily connect an antenna to the input (Q2) side of C6 and tune in a strong station that doesn't fade. Adjust C6 and C12 for best reception.

Test the RF stage by connecting the antenna to C1 and adjusting the RF GAIN control, R4, for maximum volume. If the received station now comes in weaker than it did using just the detector, recheck the RF-stage wiring. If a strong AM broadcast station is being received, it will be necessary to install the optional AM band trap; adjust C2 to tune out the offending station. An alternative to the AM trap is a low-pass filter (built from a standard TV balun transformer—see Fig 17.78) to restrict reception below 5 MHz. If the balun is used, make C1 a variable capacitor and adjust it for best sensitivity. The balun is cheaper and easier to find than the 200- $\mu$ H choke used for the AM trap, but the receiver's sensitivity will be reduced and it will not cover the 80 and 160-m bands.

In the time honored tradition of Amateur Radio, simply experiment with the number of turns on coil L2 to get the exact range of frequencies desired. That is, simply add turns to lower the range of reception frequencies or remove turns to raise it. Accordingly, 150 or 250-pF variable capacitors can be substituted for the 365-pF main tuner and likewise, 1 or 2-inch coil forms can be used instead of the 1 1/2-inch diameter specified, as long as the number of turns on L2 and L3 are changed to provide the desired range of frequencies and degree of regeneration.

**Fig 17.78—Optional modifications for the regenerative receiver. A shows a 5-MHz high-pass filter that uses a TV balun as an inductor. This filter is less expensive than the AM broadcast trap, but it lessens sensitivity and prevents reception of the 160 and 80-m ham bands. B is an ac power supply; keep the supply isolated from the receiver (see text). The pickup loop at C couples some of the detector signal to a frequency counter for use as a display. D is an audio low-pass filter.**

(Calculated inductance values for the coils are given in Fig 17.77.)

If you build the optional ac power supply (Fig 17.78), be sure to build it on a separate wooden board and use a long three-wire cable (telephone wire works well)—2 ft long, or more, to physically isolate the power supply from the receiver. If you use an external supply other than that shown, be sure that it is well filtered. Other options include a low-pass filter to reduce the audio bandwidth and a pickup loop to drive a frequency counter display. (The display will only work when the detector is oscillating.)

### Tuning Tips

Use two hands when operating the receiver, one for tuning, the other to adjust regeneration. For maximum sensitivity,

the regeneration level needs to be maintained at a point just below (for AM signals) or just above (for CW and SSB) the threshold of oscillation. When the detector is oscillating, as when receiving SSB or CW transmissions, it will tend to lock onto the center of strong RF signals and prevent or "block" tuning to either side of the carrier—this can make SSB difficult to receive. To avoid blocking, set the detector loading control for less capacitance and increase the level of regeneration. Very high sensitivity can be achieved, for receiving very weak AM signals, by operating the detector just above oscillation and zero beating the carrier. This is known as "autodyne" reception.

The correct adjustment of the DETECTOR

LOADING capacitor, C6, is critical to the operation of this receiver because it decouples the detector from the RF stage and permits very high selectivity, which helps to separate stations on a crowded band. Its adjustment is a trade-off: less coupling (less capacitance) reduces the loading and provides higher selectivity but it also reduces the signal level coming from the RF stage and therefore the receiver's sensitivity.

Space limitations do not permit us to show a companion super regenerative receiver for the VHF and UHF bands. If you're interested, look at "The Lost Technology of Super Regeneration" by Charles Kitchin in the fall 1994 *Communications Quarterly*.

## THE R2: AN IMAGE-REJECTING D-C RECEIVER

Direct-conversion (D-C) receivers are capable of outstanding performance. This receiver (see Fig 17.79) was designed and built by Rick Campbell, KK7B; and originally appeared in the January 1993 *QST*. It has been used from 25 kHz to 6 GHz with excellent results. It works well and sounds good because it combines several desirable traits:

- high third-order, two-tone dynamic range;

- moderate noise figure;
- low distortion from antenna to speaker leads; and
- 60 dB of output signal-to-noise ratio.

Some D-C receivers are significantly flawed in that they have no opposite-sideband rejection. This flaw can cause real problems: On crowded HF bands, the opposite sideband is almost always occupied by an interfering signal or two. On VHF

and microwaves, the noise in the opposite sideband reduces the signal-to-noise ratio by up to 3 dB.<sup>1</sup>

There are two ways to get rid of the opposite sideband: (1) a narrow filter before the down converter; or (2) an image-reject mixer. A fixed-frequency D-C receiver preceded by a narrow filter and tunable converter is a conventional superhet. The image-reject mixer is less familiar (see Fig 17.80).

For many years, the difficulty of accurate phase control has made the filter method of image rejection dominant. Today, the required phase and amplitude tolerances are easy to obtain with modern components. A properly designed phasing exciter has fewer adjustments (and fewer spurs) than a filter rig!

### The Design

This radio is based on a wealth of excellent technical material at hand, in particular the outstanding papers by Oppelt.<sup>2,3</sup> The goal was to add single-signal capability to an earlier design (called the "R1")

**Fig 17.79—A simple modular 40-m CW QRP transceiver built around an R2 board. R2 is built in the box on the lower left; the LO phase-shift network from Fig 17.85A is in the small box connected to rear of R2 with BNC connectors. A 7-MHz VFO is in the larger box on the right. Resting atop R2 is a 1-W CW transmitter with low-pass filter and break-in circuitry. The transmitter and VFO were borrowed from other published projects (see text). (photos by Kirk Kleinschmidt, NT0Z)**

without degrading its otherwise outstanding performance.<sup>4</sup>

Fig 17.81 is the block diagram of the "R2" receiver. The phasing image rejection is performed by an RF splitter, a second mixer, diplexer and audio preamp, and an audio phase-shift network and summer using a pair of quad op amps. For maximum flexibility, the

90° phase-shift network for the LO is off the board. The complete schematic is shown in Fig 17.82. All of the parts fit comfortably on a 3×5-inch double-sided PC board.<sup>5</sup>

#### Circuit Details

The first component the input signal sees is the RF input splitter. A Toko

TK2518 is cheap (\$2), small, and available from Digi-Key (see the Address List in the **References** chapter).<sup>6</sup> It is rated from 20 MHz to 600 MHz, but when tried on 40 m it worked. A Mini-Circuits PSC2-1 splitter worked fine as well, but it is a lot more expensive (\$12). A homebrew alternative for operation below 20 MHz, is shown in Fig 17.83.

After the splitter, the input signals are multiplied with the 90°-out-of-phase LOs, filtered and amplified in a pair of identical channels. They are referred to as the I channel (for "In phase") and the Q channel (for "Quadrature," a fancy word for "90° out of phase"). Amplitude and phase-shift errors in the I and

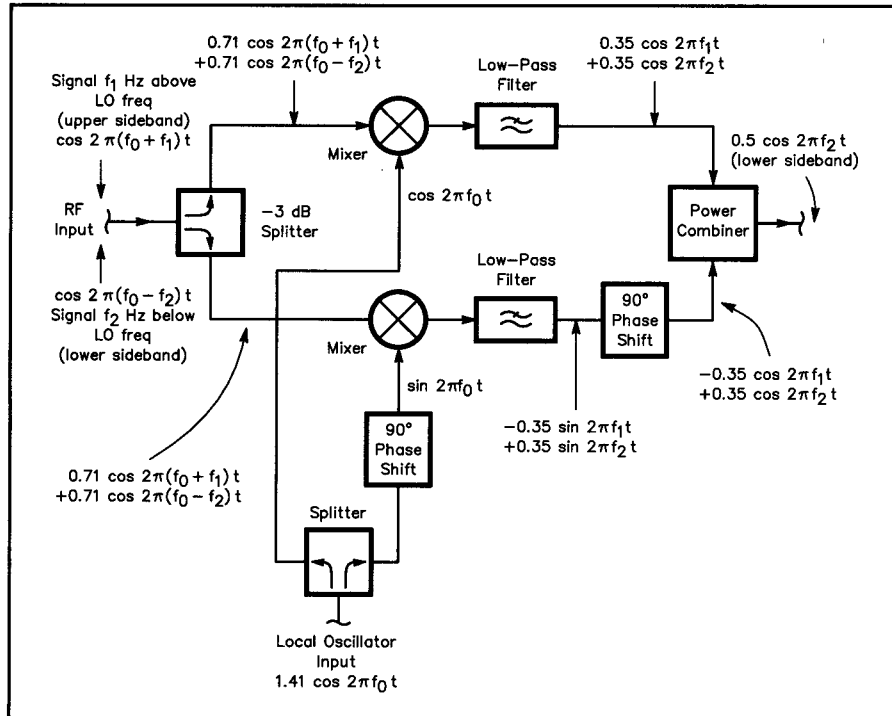

Fig 17.80—Block diagram of an image-reject mixer. The sines and cosines represent the local oscillator signal and signals above and below the LO frequency. Signals above the LO frequency cancel at the output, while signals below the LO frequency add.

<sup>4</sup> R. Campbell, "High-Performance Direct-Conversion Receivers," *QST*, Aug 1992, pp 19-28. This article provides a good discussion of D-C receiver techniques.

<sup>5</sup> An etching template/part-overlay package for a single-sided version of the R2 PC board is available from the ARRL for an SASE. Address your request for the CAMPBELL R2 BOARD TEMPLATE to Technical Department Secretary at ARRL HQ. Double-sided etched boards were once available from the author, but he can no longer supply them. Boards may be available from a commercial supplier in the future. If that happens, the information will be added to the template package.

<sup>6</sup> One source for SBL-1 mixers is Oak Hills Research. XICON 1% polyester film capacitors used in the audio phase-shift network are available from Mouser Electronics. All other parts are available from Digi-Key. For current addresses look at the Address List in the **References** chapter.

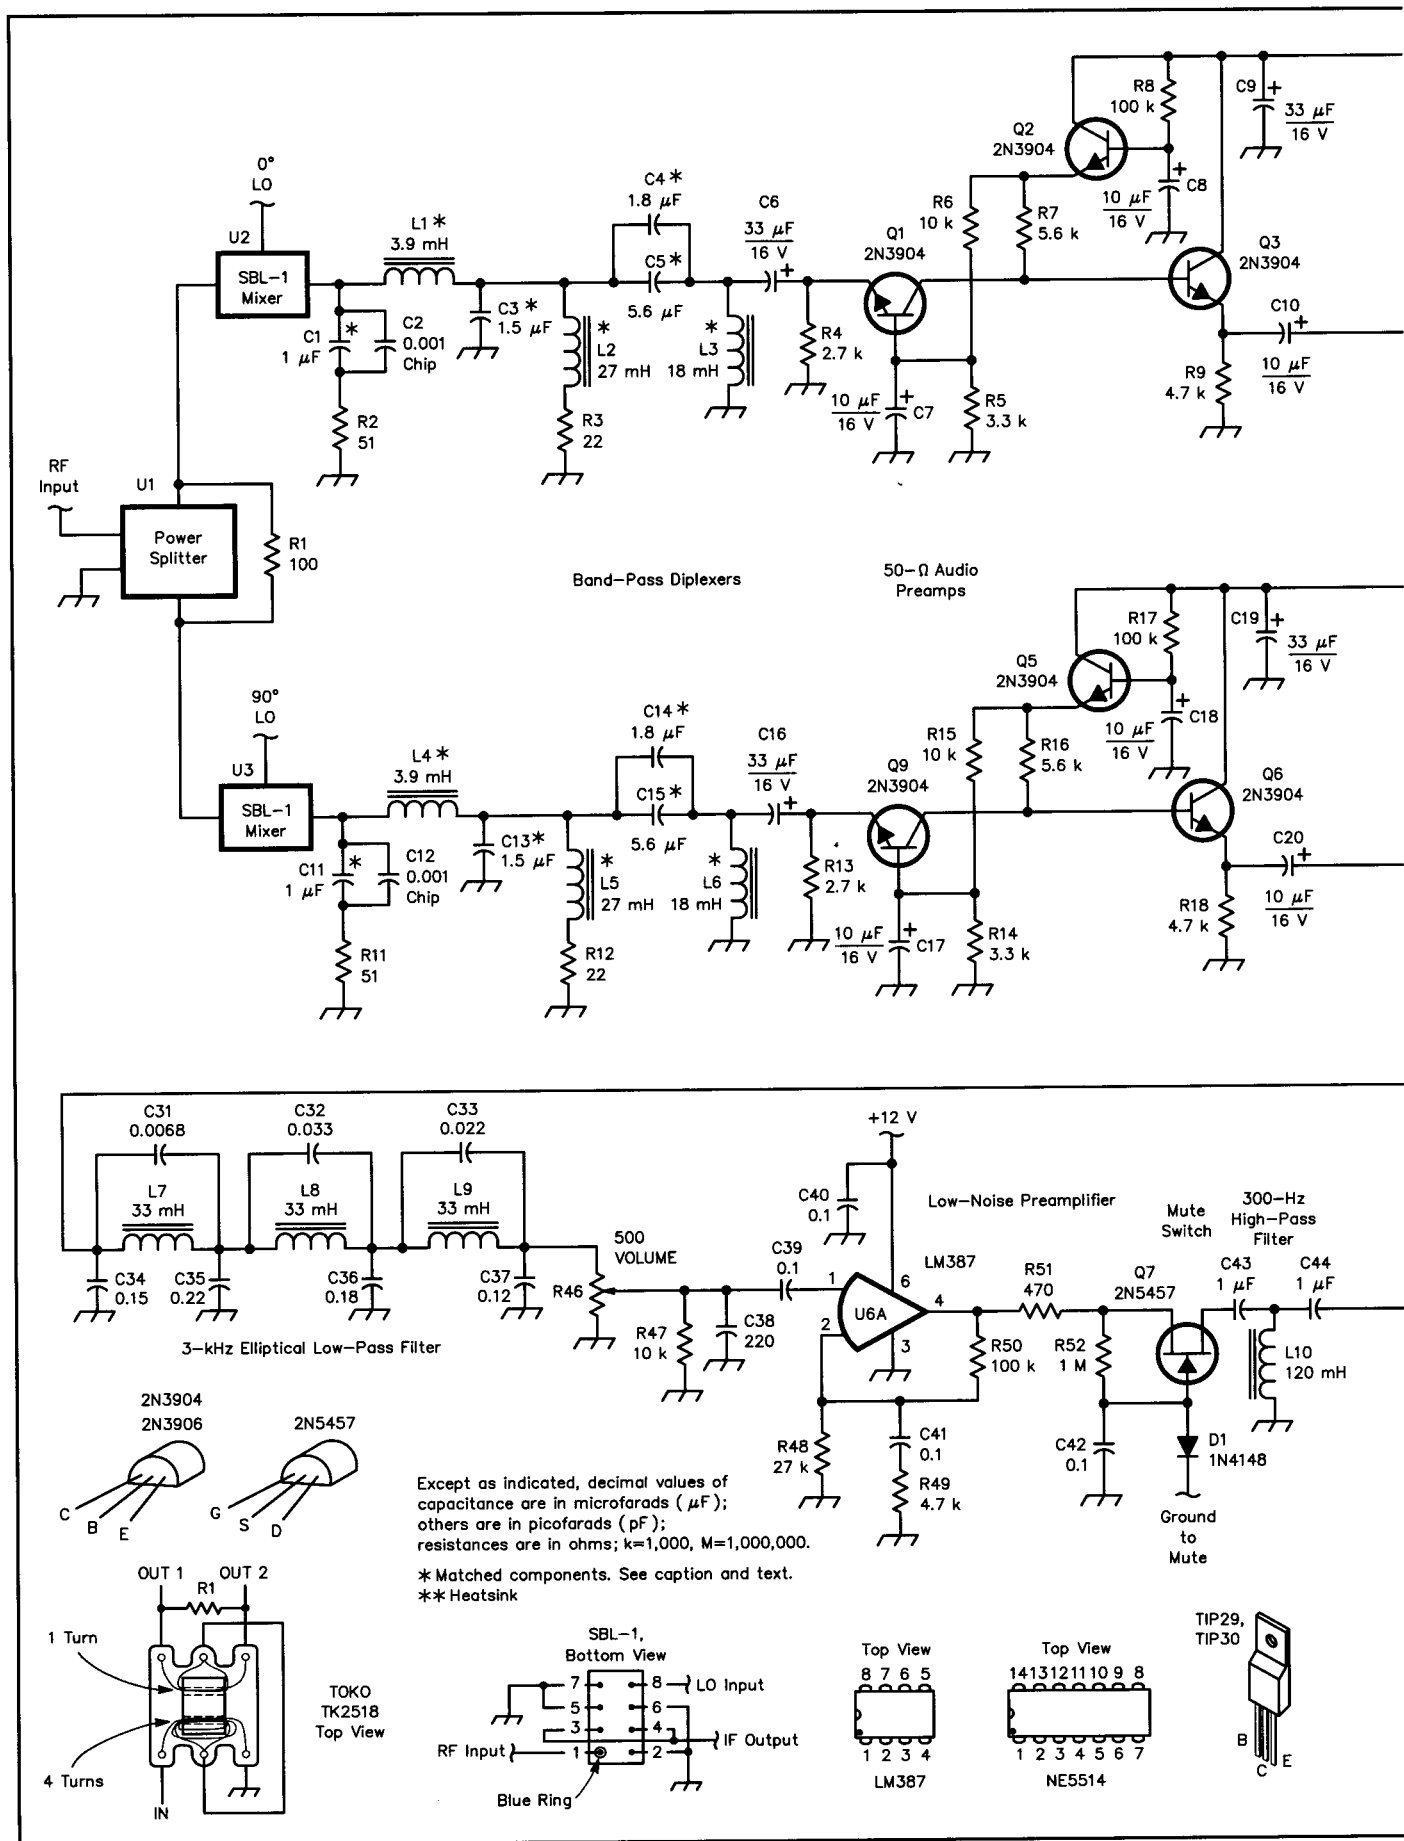

Fig 17.81—Block diagram of the R2 single-signal direct-conversion receiver. The sections inside the dashed lines are included on the original R1 board. Added are an RF splitter, second mixer, diplexer and low-noise preamp, an audio phase-shift network and a summer.

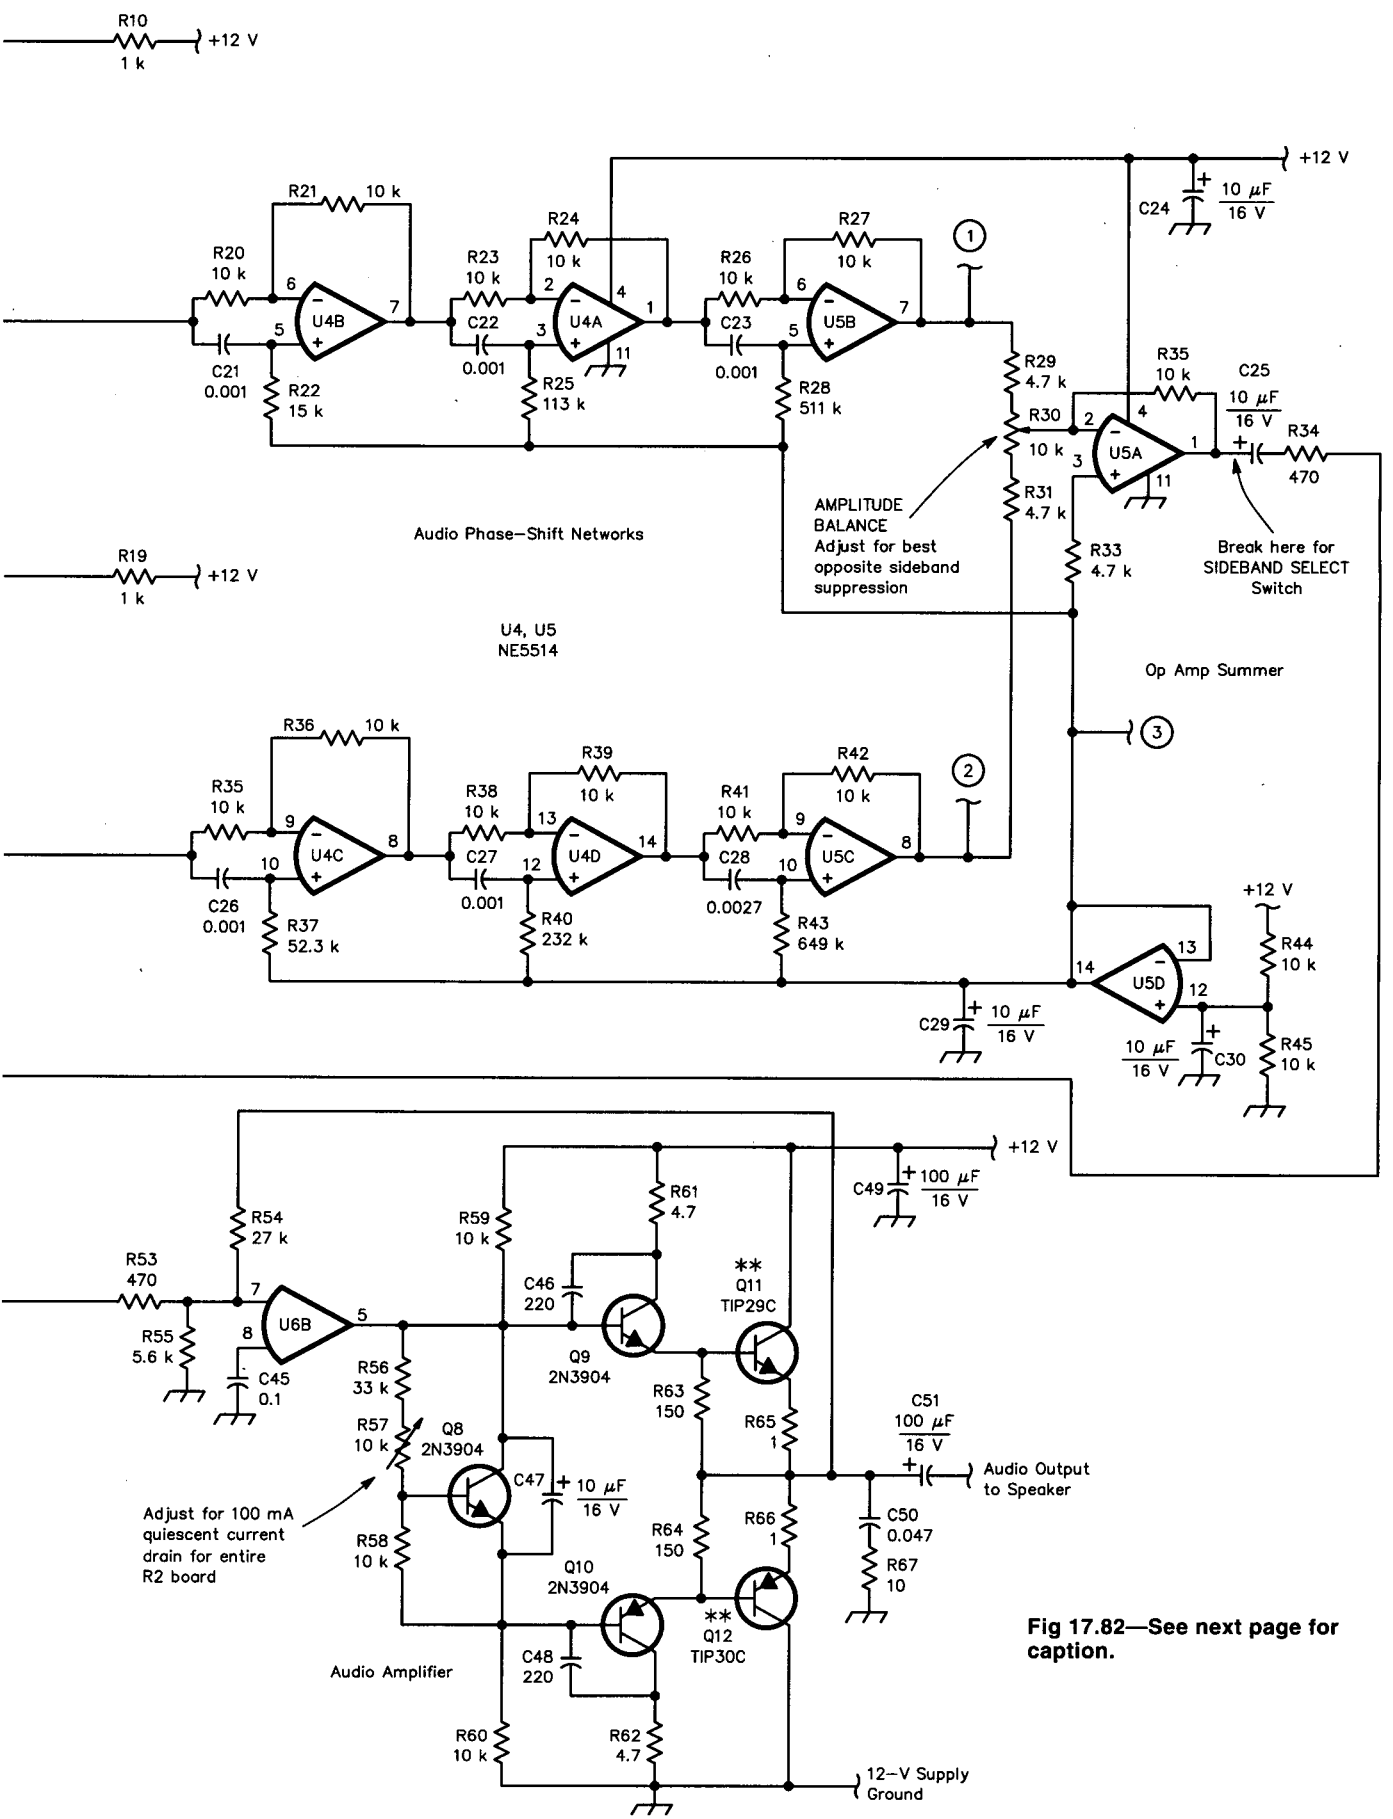

Fig 17.82—See next page for caption.

**Fig 17.82 (see previous two pages)—**The local oscillator, LO phase-shift network and front-end filter are located off the board. The resistors in the audio phase-shift networks (R20-R28 and R35-R43) are 1%-tolerance metal-film units. Other resistors are 5%-tolerance carbon-film or composition units. Inductors are Toko 10RB series fixed inductors. Polarized capacitors are aluminum electrolytics rated at 16 V dc. The capacitors in the audio phase-shift networks (C21 to C23 and C26 to C28) are 1%-tolerance XICON polyester-film units available from Mouser (see text). The capacitors in the diplexers (C1, C3-C5, C11, C13-C15) and 300-Hz high-pass filter (C43, C44) are Panasonic type ECQ-E(F) 100-V, 10%-tolerance miniature metalized polyester film units. C32-C37 in the low-pass filter are Panasonic V-series 50-V, 5%-tolerance metalized film capacitors; C31 is a 50-V Panasonic P-series polypropylene capacitor. C38, C46 and C48 are disc-ceramic capacitors. The other capacitors can be metalized polyester or ceramic-disc capacitors. See Note 6 for part sources. Off-board connections 1 through 3 and the **SIDEBAND SELECT** note refer to Fig 17.84.

C2, C12—0.001- $\mu$ F chip capacitor.

These parts are necessary only if the board is used at VHF or UHF.

R30—10-k $\Omega$  single-turn PC-board-mount control (Panasonic MAG14 or equivalent).

R53—500- $\Omega$  audio-taper control.

R57—10-k $\Omega$  single-turn PC-board-mount control (Panasonic MAG14 or equivalent).

U1—Toko TK-2518 power splitter (this part is called a balun transformer in the Digi-Key catalog). See text.

U2, U3—Mini-Circuits SBL-1 double balanced mixer. Other mixers may be substituted if higher dynamic range is needed or other frequency ranges are desired.

**Fig 17.83—**This home-brew in-phase splitter is an alternative to the commercial RF power splitter (U1) of Fig 17.82.

Q channels must be carefully controlled. If there is a difference in the conversion loss of the two mixers or the gain of an audio preamp, it can be compensated by adjusting the **AMPLITUDE BALANCE** potentiometer (R30).

If the amplitude difference is a function of frequency, however, R30 can only correct for at a single audio frequency. Since the diplexer network between the mixer IF port and the audio preamp in each channel has an amplitude and phase characteristic that varies rapidly with frequency over the audio range, it is necessary to carefully select the components marked with asterisks in the schematic. Each component needs to be within 1% of the value of its counterpart in the other channel. The matched pairs may vary from the schematic value by up to 10% with no significant change in performance, *but they must be within 1% of each other*. Ten sets of the marked parts were matched with an RLC bridge, yielding four sets matched to within 1%.

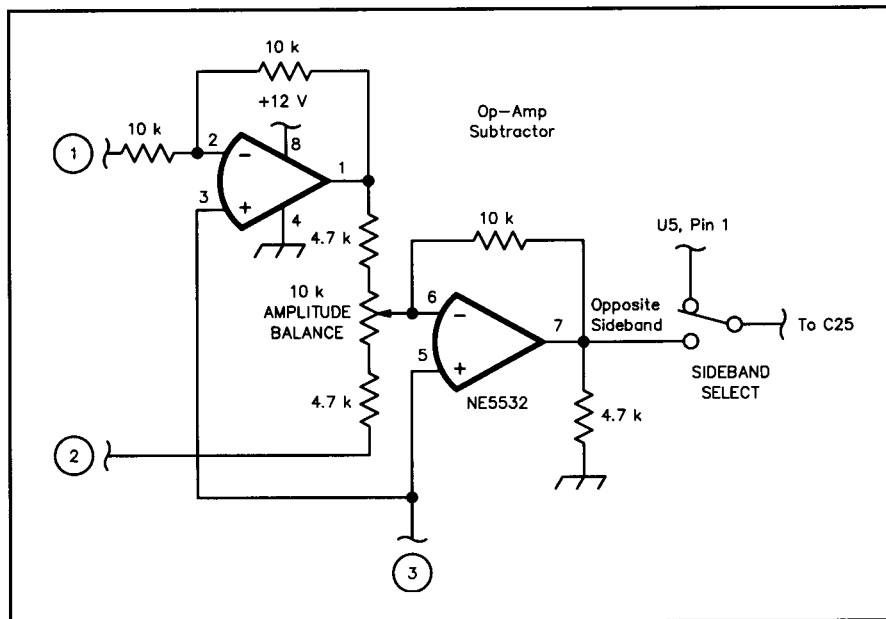

In an ideal world with ideal components, it would be possible to have identical I and Q channels, a perfect 90° audio-phase-shift network, and thereby obtain infinite opposite-sideband suppression. Oppelt has done an excellent study of the errors introduced using real components (see Note 2). To paraphrase his many pages of analysis, it is trivial to build a receiver with 20 dB of opposite-sideband suppression, easy to get 30 dB, not too tough to obtain 40 dB, a real stretch to reach 50 dB, and quite likely im-

possible to hit 60 dB.

In order to achieve easy reproducibility and decent performance with off-the-shelf components, this receiver is designed for the "not-too-tough" 40 dB rejection. The phase-shift network is similar to one used by Breed, but it uses the third-order coefficients calculated by Oppelt (see Note 3). In the audio phase-shift network, R20 through R28, R35 through R43, C21 through C23 and C26 through C28 must be within 1% of the schematic value. The first prototype used hand selected components, but all subsequent versions have used off-the-shelf 1% resistors and capacitors. There is no performance difference.

The phase-shift network and combiner can handle fairly large signals without distortion. The design goal was to have the preamplifier distort before the phase-shift network. If distortion occurs between the RF splitter and op-amp summer, the distortion products will not have the proper phase relationship, and they will not be suppressed in the opposite sideband. The result: Strong signals have worse opposite-sideband suppression than weak signals! This would be an unhappy circumstance indeed, but it has not been a problem at input signal levels well up into the millivolt range.

If you want to select the upper or lower sideband for reception, the best approach is to add the op-amp subtractor circuit shown in Fig 17.84, with its own **AMPLITUDE BALANCE** pot. Then sideband selection is simply a matter of connecting the volume control to the appropriate sideband output with an

**Fig 17.84—**This subtractor circuit may be used to switch between sidebands or for simultaneous reception of both sidebands (see text). All connections go to the main schematic, Fig 17.82.

SPDT SIDEBAND SELECT switch. An independent filter and audio output stage could be added if ISB reception is desired.

Many other audio-phase-shift networks may be used in place of the op-amp version shown here. The I and Q channel signals may be digitized at the points marked  $\times$  in the schematic, and all of the phase shifting, combining and filtering operations performed in DSP hardware and software. That will probably be the preferred receiver architecture for any band and any mode in the 21st century.

All of the circuitry after the op-amp summer is identical to the R1 receiver described in August '92 *QST*. Fig 17.82 shows component values for a 3-kHz elliptical low-pass filter. Audio hiss may be objectionable during headphone listening. If you're bothered by hiss, add the RC networks described in the August '92 *QST* article to U6.

### Receiver Construction

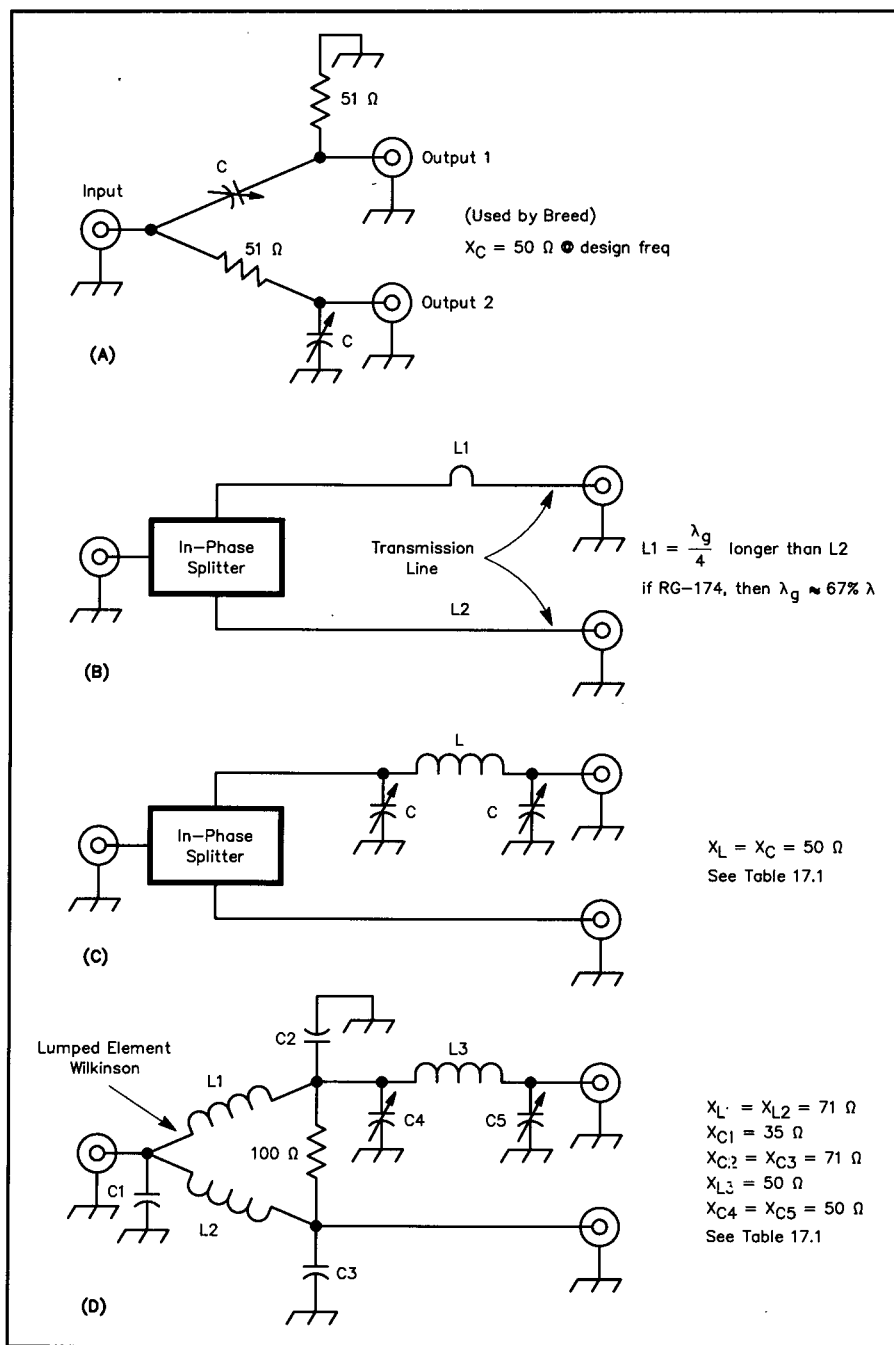

The first prototype used cut-up pieces of R1 boards interconnected over an unetched PC board ground plane. The RF grounding techniques were good and less care was used with the audio grounds. It worked fine. The single-board layout took much more care with the audio grounds, and still didn't have any problems. The only instability resulted from audio feedback via magnetic coupling between a speaker lead (either one!) and the inductors in the diplexer stages. This is easy to cure by simply moving the speaker wires a few inches away from the inductors, but it can be a real puzzle if you don't expect it.

A band-pass filter on the RF input is good practice, although a simple low-pass filter to suppress signals near the odd harmonics of the LO will suffice. On 40' m you may need a narrow band-pass filter to attenuate broadcast stations. Above 10 MHz, a preamp will be needed in quiet locations. A preamp also helps isolate the LO from the antenna. The R2 may be used on any frequency from 1 to 500 MHz with the SBL-1 mixers shown in the schematic. Other mixers can be substituted for higher or lower frequencies.

If you do all the trig' identities, follow the phase shifts through the schematic, and carefully connect everything, Murphy guarantees that you will end up with the wrong sideband. It is much easier to simply hook it up and then switch the LO connection if it's wrong. If you can convince Murphy that you really don't care, you have a 50% chance of getting it right the first time!

### Local Oscillator

The R2 board with SBL-1 mixers needs two +7 dBm (nominal) LO signals, 90° out of phase. All of the LO phase-shift techniques shown in Fig 17.85 have been

**Fig 17.85—Four possibilities for a 90° LO phase-shift network.** The simple RC network shown at A is fine for many MF/HF applications and has been used by the author on 40, 20 and 2 m. The actual value of the capacitors depends on terminating impedances. Start with 450 pF on 7 MHz, 225 pF on 14 MHz and 22 pF on 144 MHz. See text. The circuit at B uses transmission lines and is practical at VHF and UHF. Examples: If L1 and L2 are made from RG-174, L1 is 69.1 inches longer than L2 at 28.5 MHz; 13.7 inches longer at 144.2 MHz and 8.86 inches longer at 222.1 MHz. The circuits at C and D will work better for more serious applications (see text). Component values for a variety of frequencies are shown in Table 17.1.

tried, and there are many other untried schemes as well. Since there may be a few degrees of phase error in the splitters and mixers, it is necessary to tweak the LO phase-shift network for best opposite-sideband suppression. Some phase-shift networks are easier to tweak than others—

it is easier to adjust a trimmer capacitor than cut 1/8-inch pieces off RG-174 phasing lines!

The simple LO phase-shift network in Fig 17.85A has been used on 40, 20 and 2 m by tacking in different capacitors and adjusting them for best opposite-sideband

suppression. It works fine, but has two peculiarities:

- When adjusted for a 90° phase difference with loads connected to outputs 1 and 2, the output levels will be different.
- The phase at each output depends on the load impedance.

The LO-port impedance and conversion loss of the SBL-1 mixers are functions of drive level, so there is a complicated interaction between the adjustments of the network in Fig 17.85A and the AMPLITUDE BALANCE potentiometer (R30). In practice, just tweak them both and forget the theory, but strange things can happen with the network in Fig 17.85A in the system.

Anything that changes the LO drive level at the input or the impedances connected to the outputs of the network will require readjustment of both phase-shift network capacitors and the AMPLITUDE BALANCE control. One operator noted greatly reduced opposite-sideband suppression when he increased the supply voltage from 12 to 14!

The network in Fig 17.85A is easy to build and works well within the limitations described above. For more serious applications (especially if sideband selection or operation from a variety of supply voltages is anticipated), use one of the LO phase-shift networks shown in Fig 17.85C, Fig 17.85D and Table 17.1.

It is difficult to recommend an LO for a receiver board that may be used anywhere from VLF to microwaves! For HF use, this *Handbook*, *QRP Classics* and *Solid State Design* contain many suitable examples. For VLF and LF, old signal generators work fine, and they have incredible bandwidth. At VHF and up, the literature is a bit sparse, but an HF VFO followed by a simple transverter works well. At higher frequencies, a VXO and multiplier chain may be used.

### Tuning

There are two trimmer potentiometers on the R2 board and a single LO phase-

shift adjustment off the board. It's not quite "no tune," but it's easier than even a simple superhet! R57 sets the quiescent current of the audio-output stage. It can be set for a total R2 board current of about 100 mA—it's not critical.

The AMPLITUDE BALANCE pot (R30) and the LO phase-shift adjustment can be set by ear: tune in a strong carrier on the wrong sideband and then alternately tweak the two controls for a null.

One way to tune for best opposite-sideband suppression is by setting a signal generator on the audio image ("wrong side of zero beat") and then alternately adjusting the phase shift and amplitude balance (R30) while watching the output on an audio-frequency level meter. Optimize the circuit at a frequency near the middle of the audio range, and then tune around to make sure the opposite-sideband suppression is good from 300 to 3000 Hz. Adjust a step attenuator for the same signal level on the desired and undesired sideband and record the respective attenuator settings. The difference in attenuator settings is the opposite-sideband suppression. Once the phase shift and amplitude balance are adjusted, lock them in place with nail polish. After a year and thousands of miles on the road, the first prototype shows no signs of needing alignment.

### R2 Performance and Impressions

The R2 prototype with a 3-kHz elliptical filter was assembled and tested on the bench. There were no surprises—it was an R1 board with slightly better dynamic range, slightly better noise figure, and 41 dB of opposite-sideband suppression. The real shock came when a 40-m antenna and VFO were connected. CW signals simply disappeared when they passed through zero beat. Murphy had it connected for USB, and there was no sound of any LSB up in the phone band. It sounded too good—was something wrong with the picture? Comparisons with a couple of older commercially made radios confirmed the R2's performance. The bottom line is that the R2 sounds better than I

expected, because it has better selectivity than the radios I'm used to.

A 40-m R2 was demonstrated at the QRP Hospitality Suite in Dayton in 1992. Several experienced HF CW operators were amazed when we could not find any CW signals that were strong enough to detect on the wrong sideband.

### Comparison with a Superhet

Receiver fans may point out that the schematic in Fig 17.82 is as complicated as a superhet. If the image-reject D-C receiver has so many parts, why not just "do it right" and build a superhet?

First, this is a high-performance D-C design, with no attempt to reduce the parts count. It could be greatly simplified with only a small reduction in performance. Even in simplified form, it could still outperform most of the simple superhets I've encountered—especially those based on the ubiquitous NE602. The NE602 is not a bad part, but its limited dynamic range should confine its use to low-cost, low-current-drain, minimum-parts-count applications.

D-C receivers have a number of significant advantages over superhets. Because there is only one LO, there are no internally generated birdies. There are no image frequencies to filter out, and no spurious receiver tuning ranges at strange combinations of LO harmonics and the intermediate frequency. A low-pass front-end filter to reject signals near odd multiples of the LO frequency will ensure a spurious-free receiver.

Since D-C receivers do all of their signal processing at audio, the input frequency is unrestricted. An R1 board with an SRA-3 mixer and an old signal generator for an LO works well below 25 kHz. At the other end of the spectrum, I have an R1 board with a printed rat-race mixer working at 5760 MHz.

A D-C receiver can be combined with a VFO-controlled CW transmitter to build a transceiver that is simpler than a superhet transceiver. The only spurs are harmonics, which are reduced by the transmitter low-pass filter.

D-C receivers also have some disadvantages. The need for isolation between the antenna and LO makes D-C a poor choice for hand-held radios with integral whip antennas. At HF, a full-size outdoor antenna works best.

The D-C, image-reject approach is a poor choice for a band-switched radio. It is easy to obtain good performance over a single amateur band, but the RF phase-shift network and amplitude balance must be tweaked when changing bands.

Table 17.1

### LO Phase-Shift Network Component Values

For the network in Fig 17.85C			For the network in Fig 17.85D					
Frequency (MHz)	C (pF)	L (μH)	Frequency (MHz)	L1, L2 (μH)	C1 (pF)	C2, C3 (pF)	C4, C5 (pF)	L3 (μH)
3.525	903	2.26	3.525	3.21	1290	645	903	2.26
7.05	452	1.13	7.05	1.62	645	323	452	1.13
14.05	227	0.566	14.05	0.809	325	162	227	0.566
21.05	151	0.378	21.05	0.541	216	108	151	0.378
28.5	112	0.279	28.5	0.399	160	80	112	0.279
50.1	63.5	0.159	50.1	0.227	91	45	63.5	0.159
144.2	22.1	0.0552	144.2	0.0789	31.6	15.8	22.1	0.0552
222.1	14.3	0.0358	222.1	0.0512	20.5	10.2	14.3	0.0358

Finally, 41 dB is about the practical limit for opposite-sideband suppression in an easily reproduced analog design. While this is as good as some HF and most VHF SSB rigs, the fact remains that the basic superhet design is *capable* of better performance.

## R2 Applications

The modular 40-m QRP CW transceiver shown in Fig 17.79 features full break-in keying, 1 W output, a slow tuning rate, switched SSB and CW bandwidths, 93 dB two-tone, third-order IMD dynamic range, low-distortion audio, and true single-signal reception. The transmitter, VFO and break-in circuitry were borrowed from "The Ugly Weekender" and the "Optimized QRP Transceiver" in *The 1992 ARRL Handbook*.<sup>7</sup> The receiver is an R2 board with the RC LO phase-shift network from Fig 17.85A. It is a joy to operate.

The R2 board is small enough to build a high-performance portable HF CW transceiver in a smaller package than the popu-

lar commercial versions. For portable use, the receiver's audio power transistors can be removed to reduce the current drain, as discussed in the R1 article.

In *Microwave Update '92* the author showed another interesting R2 application: a no-tune microwave transceiver, using a Down East Microwave no-tune 1296-MHz transverter with an R2 board

<sup>7</sup>R. Lewallen, "An Optimized QRP Transceiver," *QST*, Aug 1980, pp 14-19; also see Feedback, *QST*, Nov 1980, p 53. "The Optimized QRP Transceiver" also appears on pages 30-40 to 30-43 of *The 1994 ARRL Handbook*, and in the second printing of *QRP Classics* (ARRL Order #3169). R. Hayward and W. Hayward, "The Ugly Weekender," *QST*, Aug 1981, pp 18-21. The Ugly Weekender also appears on pages 30-33 to 30-36 of *The 1993 ARRL Handbook*. Etched, plated and drilled PC boards for the VFO/buffer are available from FAR Circuits (see the Address List in the **References** chapter). Use the board's AUX OUT output for the correct drive level for the SBL-1 mixer.

and premixed VFO as a tunable 2-m IF. The transmit IF uses an SSB/CW exciter board that appears in the April 1993 *QST*. The use of image-reject techniques makes it possible to build single-conversion microwave radios with any desired IF.

## Conclusions

The image-reject, D-C receiver is a viable approach to SSB and CW reception for many applications. When combined with high-performance, D-C receiver techniques, it can provide basic receiver performance that surpasses many superhets. Image-reject techniques are in wide commercial use, and both Drake and Kenwood have recently introduced high-performance products that combine image-reject and superhet techniques. In the future, high-performance receivers will be built by combining a high dynamic range I and Q channel front end with a digital signal processor. Future Old Timers will sit around reminiscing about multiple-conversion superhets!

## A 1750-M TRANSCEIVER: THE CW-893

Here's a transceiver (Fig 17.86) from David Curry, WD4PLI, for people who want to explore the depths of the 1750-m band (160 to 190 kHz). They're the *Lowfers*, radio experimenters—many of them hams—who enjoy this band and manage to carry on useful communications despite low-power restrictions and high noise levels. *No license is required to operate on 1750 m.* Anyone can use the band. All you need is the proper equipment.

The WWII-surplus RBL receiver was the inspiration for this simple Lowfer CW transceiver—the CW-893. You can build the CW-893 in a couple of evenings and you'll soon be on the air—on 1750 m! (This transceiver first appeared in April 1994 *QST*.)

## Description

The receive portion of the CW-893 uses a *direct conversion* approach. The front end preselector uses a tunable two-pole Chebyshev band-pass filter to remove unwanted signals. Noise is always a problem

at these frequencies, so two noise limiters are included that provide very effective limiting of man-made and natural noise.

Audio filtering is included, with variable frequency and bandwidth controls for precise filtering of the desired signal. Ample audio output drives headphones and most speakers. The CW-893 is capable of providing over 100 dB of receive gain with virtually no power supply hum.

The transceiver generates 1 W of input power with its Class-E MOSFET amplifier. FCC Rules limit Lowfer power to 1 W, which is why CW is the mode of choice for this radio. Semi-break-in operation is provided with an adjustable time delay. The frequency is VFO controlled. Range extends from about 1 to 200+ miles, depending on band conditions and antenna quality.

## Construction Notes

Several parts are soldered directly to the component side of the circuit board. This provides the ground connection for many components. Be sure to solder these leads

to *both sides* of the PC board.

Solder the ICs first. Notice that some pins must be soldered on the component side. Next solder L1, L2 and T1. Install S1 after you mount the potentiometer. Mount the switch on the solder side of the circuit board.

The auxiliary low-pass filter described in Fig 17.87 offers a substantial reduction

Fig 17.86—A view of the author's CW-893 transceiver.

**Fig 17.87—An auxiliary low-pass filter for the CW-893 to assure that it meets FCC spectral purity requirements. The filter may be omitted if you check spectral purity on suitable equipment (see the **Test** chapter). L3 and L4 are 43 t, #20 enameled wire on T-94-3 cores. C1 and C2 are 0.01  $\mu$ F polystyrene capacitors (Mouser 23PS310).**

in harmonic output. To make absolutely certain that your transceiver conforms to FCC Part 15 Rules, build and install the filter in the enclosure.

Transformer T2 must be wound by hand on a T-68-3 toroid core. The kit manual provides detailed instructions. In addition, see the **Analog and Circuit Construction** chapters for more information on winding toroid transformers. The T2 primary is 93 t of #30 enameled wire. The secondary is made of 49 t of #25 enameled wire. Wind the turns evenly and firmly. Cut the leads to about one inch. Remove the enamel insulation from the lead ends with sandpaper.

The CW-893 is available as a kit complete with a circuit board, parts and instructions. The builder need supply only a suitable enclosure and various knobs. You can purchase the kit or PC board directly from David Curry (see Address List in **References**) for \$95, shipping included (California residents please add sales tax). David can provide information sheets on the CW-893 in return for an SASE with three units of First-Class postage.

### Checkout and Alignment

Refer to **Fig 17.88** (see pages 17.82 and 17.83) locate the following points:

- A:** 50- $\Omega$  transmit/receive antenna jack.
- B:** CW key jack.
- C:** Speaker/headphone output.
- COMM:** Common terminal for auxiliary relay.
- D:** Frequency monitor port.
- E:** Audio output for external amplifier, or AB1 deluxe audio board (available as a kit from the author).
- GND:** Ground.
- JP1:** Receive input select. Short JP1A and JP1B to use an antenna at port **A** for receive. (Receive-only antennas connect to JP1B.)
- N/C:** Normally closed terminal for auxiliary relay control.

**N/O:** Normally open terminal for auxiliary relay control.

**V<sub>cc</sub>:** 12 to 18 V dc.

Connect a 12-V power source to the V<sub>cc</sub> points and ground. A frequency counter or receiver covering 150 to 250 kHz is required for the following steps.

Connect a frequency counter to point **D**. Switch the transceiver on. Adjust tuning capacitor C10 to its maximum clockwise position. Turn the slug in T1 until the frequency reads 189 kHz on the counter.

If you don't have a frequency counter, use a long-wave receiver, general coverage receiver or ham transceiver that can accurately tune to 189 kHz. Attach a small piece of wire to the antenna jack. Tune your monitor receiver to 189 kHz. Listen for a tone while turning the slug of T1. Keep turning the slug until a zero beat is heard.

Next, align the preselector. Inductors L1 and L2 must be tuned to the same frequency. If you have a signal generator, adjust it for a low level (approximately 100  $\mu$ V) at the antenna jack. Turn the PRESELECTOR and the FILTER FREQUENCY controls to their 12 o'clock positions. Rotate the SERIES LIMITER and FILTER BANDWIDTH controls fully counter-clockwise. Tune the FREQUENCY control until you can hear the generator's signal. Adjust the slugs on L1 and L2 for maximum volume in your speaker or headphones, decreasing signal generator output as the generator tone becomes louder.

If you don't have access to a signal generator, connect a long piece of wire to the antenna jack and listen for any signals you can find (even an interference signal will do!). Once you find a usable signal, turn the PRESELECTOR capacitor to the same general setting as the FREQUENCY capacitor. Now adjust the slugs in L1 and L2 for maximum signal strength.

### Operating Tips

The audio gain stage has a built-in limiting function. This can be used to increase the gain of a signal that's bur-

ied in man-made noise, effectively cutting off the peaks of the noise while leaving the signal unaffected. The SERIES LIMITER clips any remaining distortion from the shunt limiter and lowers the volume to a comfortable level. The audio FILTER FREQUENCY and BANDWIDTH controls are adjusted for the amount of filtering desired.

While there is plenty of audio power available to drive a speaker, use headphones whenever possible. D-C receivers derive much of their gain in the audio amplifier stages, which may begin to oscillate (howl) at high output levels. Headphones are better for weak signals and require less audio gain.

D-C receivers are also prone to *microphonics*—amplification of mechanical vibrations. Use care to avoid audio feedback if you install a speaker near the chassis or circuit board.

An important feature of the CW-893 receiver section is the input PRE-SELECTOR control. The preselector filter is very narrow. If, for example, the signal you want to hear is on 180 kHz, tune the FREQUENCY control to either 179 or 181 kHz. The signal will be heard as a 1-kHz tone. Choose the upper or lower frequency based on which provides the clearest reception.

Transmitting with the CW-893 is as easy as plugging in a CW key, selecting a clear frequency and using a *resonant* vertical transmitting antenna. Consider a sign that uses the last two or three letters of your Amateur Radio call sign. (It's considered poor practice to use your full call sign.)

When transmitting, adjust the TR delay potentiometer (R30) for the desired keying delay. In addition, the power amplifier drive control (R36) should be set for desired input power. You could install a 1-mA meter in the enclosure to monitor the power amplifier current. Meters can be expensive, however, so a VOM or VTVM can be used instead. Connect this to the meter – and + points on the circuit board. The voltage indicated corresponds to the input current to the power amplifier. One watt of input power is 83 mA at 12 V, or 83 mV on a VOM or VTVM connected to the – and + points.

You can also use the CW-893 to send a beacon signal. Beacons are helpful to other Lowfers who want to know if they can hear you. It also helps with antenna experimentation and propagation tests. To use the transceiver as a beacon, simply connect a beacon ID generator (a memory keyer set to the "repeat" mode, for example) to the key input (point "B").

## Antennas

The type and location of your 1750-m antenna are of paramount importance. FCC Rules restrict the length of the *transmitting* antenna system (antenna *plus* feed line) to 15 m (49 ft, 2 1/2 inches). Just about any type of antenna design will do for casual, short-range experiments (less than one mile).

For greater distances, use a *resonant* vertical antenna. Because the permitted antenna length (15 m) is much less than  $\lambda/4$  (437 m), inductive and/or capacitive loading is generally used to resonate the antenna.<sup>1</sup>

## Information Sources

The CW-893 kit manual includes a detailed discussion of antennas with several suggested designs. *The Low and Medium Frequency Radio Scrapbook* is available by mail directly from Ken Cornell (see Address List in **References**) for \$17.50 (shipping included). There's a partial list of 1750-m CW beacon stations in WB8IMY's article, "Lowfing on 1750 Meters" in the October 1993, *QST*, page 67.

Lowfer newsletters are also available. If you join the Longwave Club of America, you'll receive the *Lowdown* (see Address List in **References**).

<sup>1</sup>Etching patterns, a part-placement diagram and a discussion of vertical antennas are available from the Technical Department Secretary (see Address List in **References**) for an SASE. Request the '96 *Handbook* 1750-m Transceiver Template.

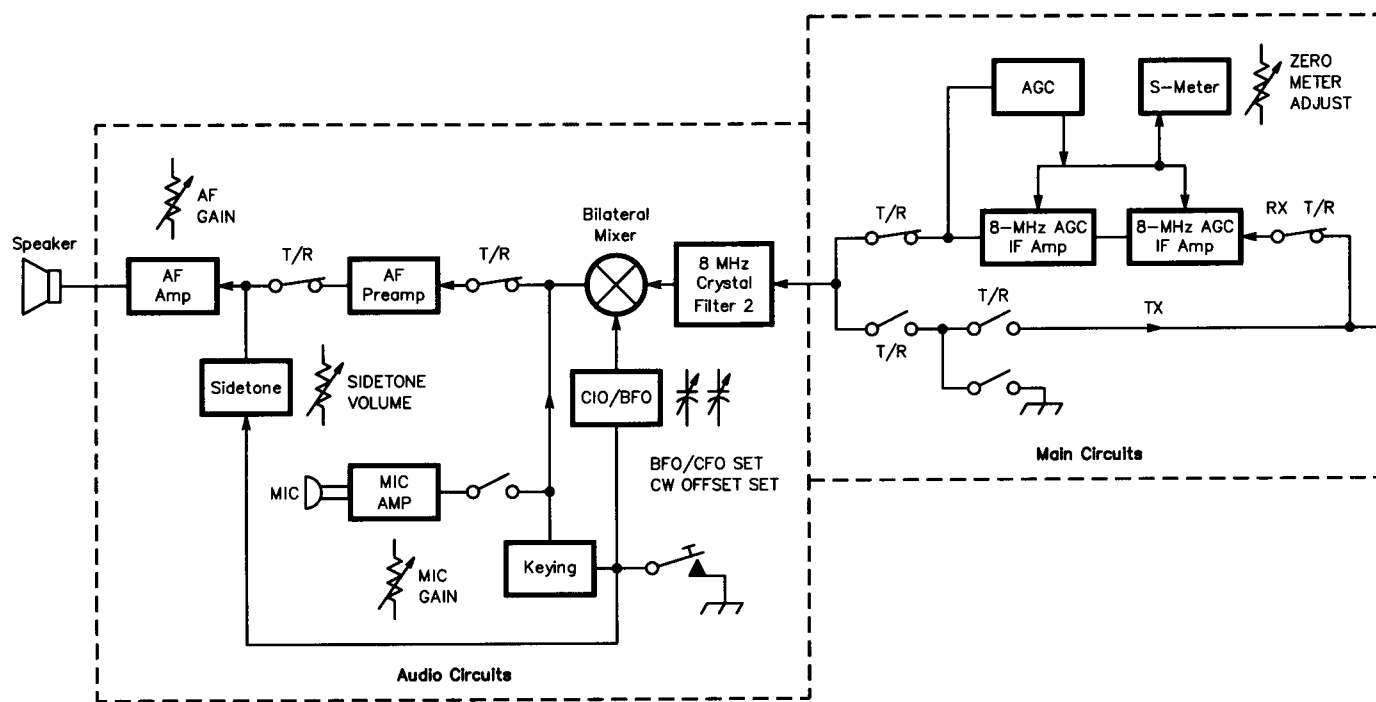

Fig 17.89—Block diagram of the transceiver.

## A 30/40 W SSB/CW 20-M TRANSCEIVER

This project is a unique *Handbook* offering. Unlike many projects, this one was not created to be duplicated by the home constructor. This project is for the confident and experienced builder who is looking for a challenge. The transceiver was created in the ARRL Lab by Zack Lau, KH6CP/1, to meet an unusual set of design goals.

Some old-timers may remember Project Goodwill. The project purchased and distributed QRP 20-m CW transceiver kits to prospective hams in many foreign countries with small ham populations. Those transceivers ran out a few years ago, and ARRL began development of a new transceiver.

The goal was to supply an inexpensive, reliable, ready-built transceiver that provided moderate (not QRP) RF output in both the CW and SSB modes. Fig 17.89 shows the transceiver block diagram. This transceiver was intended for inexpensive commercial manufacture. One of the important design goals was to eliminate as much tuning as possible, much like the microwave no-tune transverters. Of course, this conflicted with the next goal, which was to make the design as cheap as possible without sacrificing too much performance. Another goal was to accommodate a wide-tolerance PC-board process (single-sided with thick

traces—50-mils minimum). Finally, the board was to use controls and connectors that are board-mounted.

In an attempt to simultaneously reduce the amount of tuning and keep costs down, a decision was made to use bilateral filters, mixers, and amplifiers where possible. It could be argued that the SBL-1s are too costly for an inexpensive transceiver project, but they offer several advantages. Being inherently bilateral, one needs only two mixers instead of four, reducing the number of parts needed. See the schematic in Fig 17.90 (see pages 17.86 and 17.87). Also, they have pretty

Fig 17.90—(see next two pages) Schematic diagram of the 20 m SSB/CW transceiver.

C1-5, C41-45—100-pF silver mica.  
C7, C8, C65, C66—70-pF maximum ceramic or film trimmer capacitors.  
C83—24-pF air trimmer (Johnson 189-509 used).  
C84—50-pF tuning capacitor.  
D6, D7, D8, D9, D10, D20, D21—1N4007 rectifier diodes used as PIN diodes.  
D26, 27—1N4001 rectifier diodes thermally coupled to the nearest MRF477.  
D28, D29—1N34 germanium diodes.

K1—Omron G2U-112-US SPDT relay or equiv.  
L1, L2—17 t #22 enameled wire on a T-50-6 core.  
L3—35 t #28 enameled wire on a T-50-6 core. Tap 8 turns up from ground end.  
L4—13 t #28 enameled wire on a T-37-6 core.  
L5, L7—12 t #22 enameled wire on a T-44-2 core.

L6—15 t #22 enameled wire on T-68-6 toroid core.  
Q1, Q2, Q3, Q14, Q16, Q19, Q20—2N3904 NPN BJT.  
Q4, Q5, Q11, Q12, Q15, Q18—2N3906 PNP BJT.  
Q6, Q7, Q8, Q9, Q10, Q25—2N5486 N-channel JFET.  
Q13—VN10KM VMOS FET, or equiv.  
Q17—TIP 30 PNP BJT.  
Q21—2N2222A metal cased NPN BJT.  
Q22, Q24—2N5109 NPN BJT with heat sinks.  
Q23—MRF476 NPN BJT with heat sinks.  
Q26—40673 dual-gate MOSFET, or equiv.  
Q27, Q28—MRF477 NPN BJT with appropriate heat sinks.  
RFC1—1 mH toroidal RF choke.  
FT-37-72 toroid filled with one layer of #28 enameled wire.  
RFC2—8 t #18 enameled wire on an FT-50-43 core.  
T1, T2, T6, T7—12 t #28 enameled wire primary feeds crystal filter. 5 t #28 enameled wire secondary on an FT-37-43 core.  
T3—20 t #28 enameled wire on an FT-37-43 core. Tap 7 t from collector end. Secondary is 4 t of #28 enameled wire over the primary.  
T4, T5—18 t #28 enameled wire center-tapped primary on an FT-37-43 toroid. Secondary, 2 t #28 enameled wire. (One way of reducing the IF gain is to use only one half of the primary.)  
T8, T9, T10, T13—5 t bifilar wound #28 enameled on an FT-37-43 toroid.  
T11—5 t #24 enameled wire primary on an FT-37-43. Secondary, 3 t #22 enameled wire (to MRF 476).  
T12—3 t #23 enameled wire primary on an FT-37-43 toroid. 5 t #22 enameled wire secondary (output).  
T14—18 t #28 enameled wire primary. 5 t #28 secondary on an FT-37-43 core.  
T15—Input is 3 t #24 enameled wire on a BLN-202-73 balun core. Output to transistors is 1 t center-tapped #24 enameled wire.  
T16—8 t #20 bifilar wound on an FT-50-43 ferrite toroid.  
T17—Output transformer.  $\frac{3}{16}$ -inch brass tubing and unetched circuit-board stock (double-sided) primary through 4 FB-63-43 ferrite beads. 4 t #20 enameled wire secondary through tubing.  
T18, T19—31 t #24 enameled wire on a T-50-3 toroid. 1 t #24 enameled wire secondary.  
U1, U9—SBL-1 double-balanced mixer.  
U2—NE5534 quad op amp.  
U3—LM380 audio amplifier.  
U4, U5—MC1350 IF amplifier.  
U6—LM358 dual op amp.  
U7, U10—78L05 regulator.  
U8—LM393 dual comparator.  
U11—LM317T adjustable regulator.  
Y1, Y2, Y3, Y4, Y6, Y7, Y8, Y9—Matched 8-MHz microprocessor crystals (HC-18/U case). 250-Hz matching should be adequate.  
Y5—8-MHz microprocessor crystal.

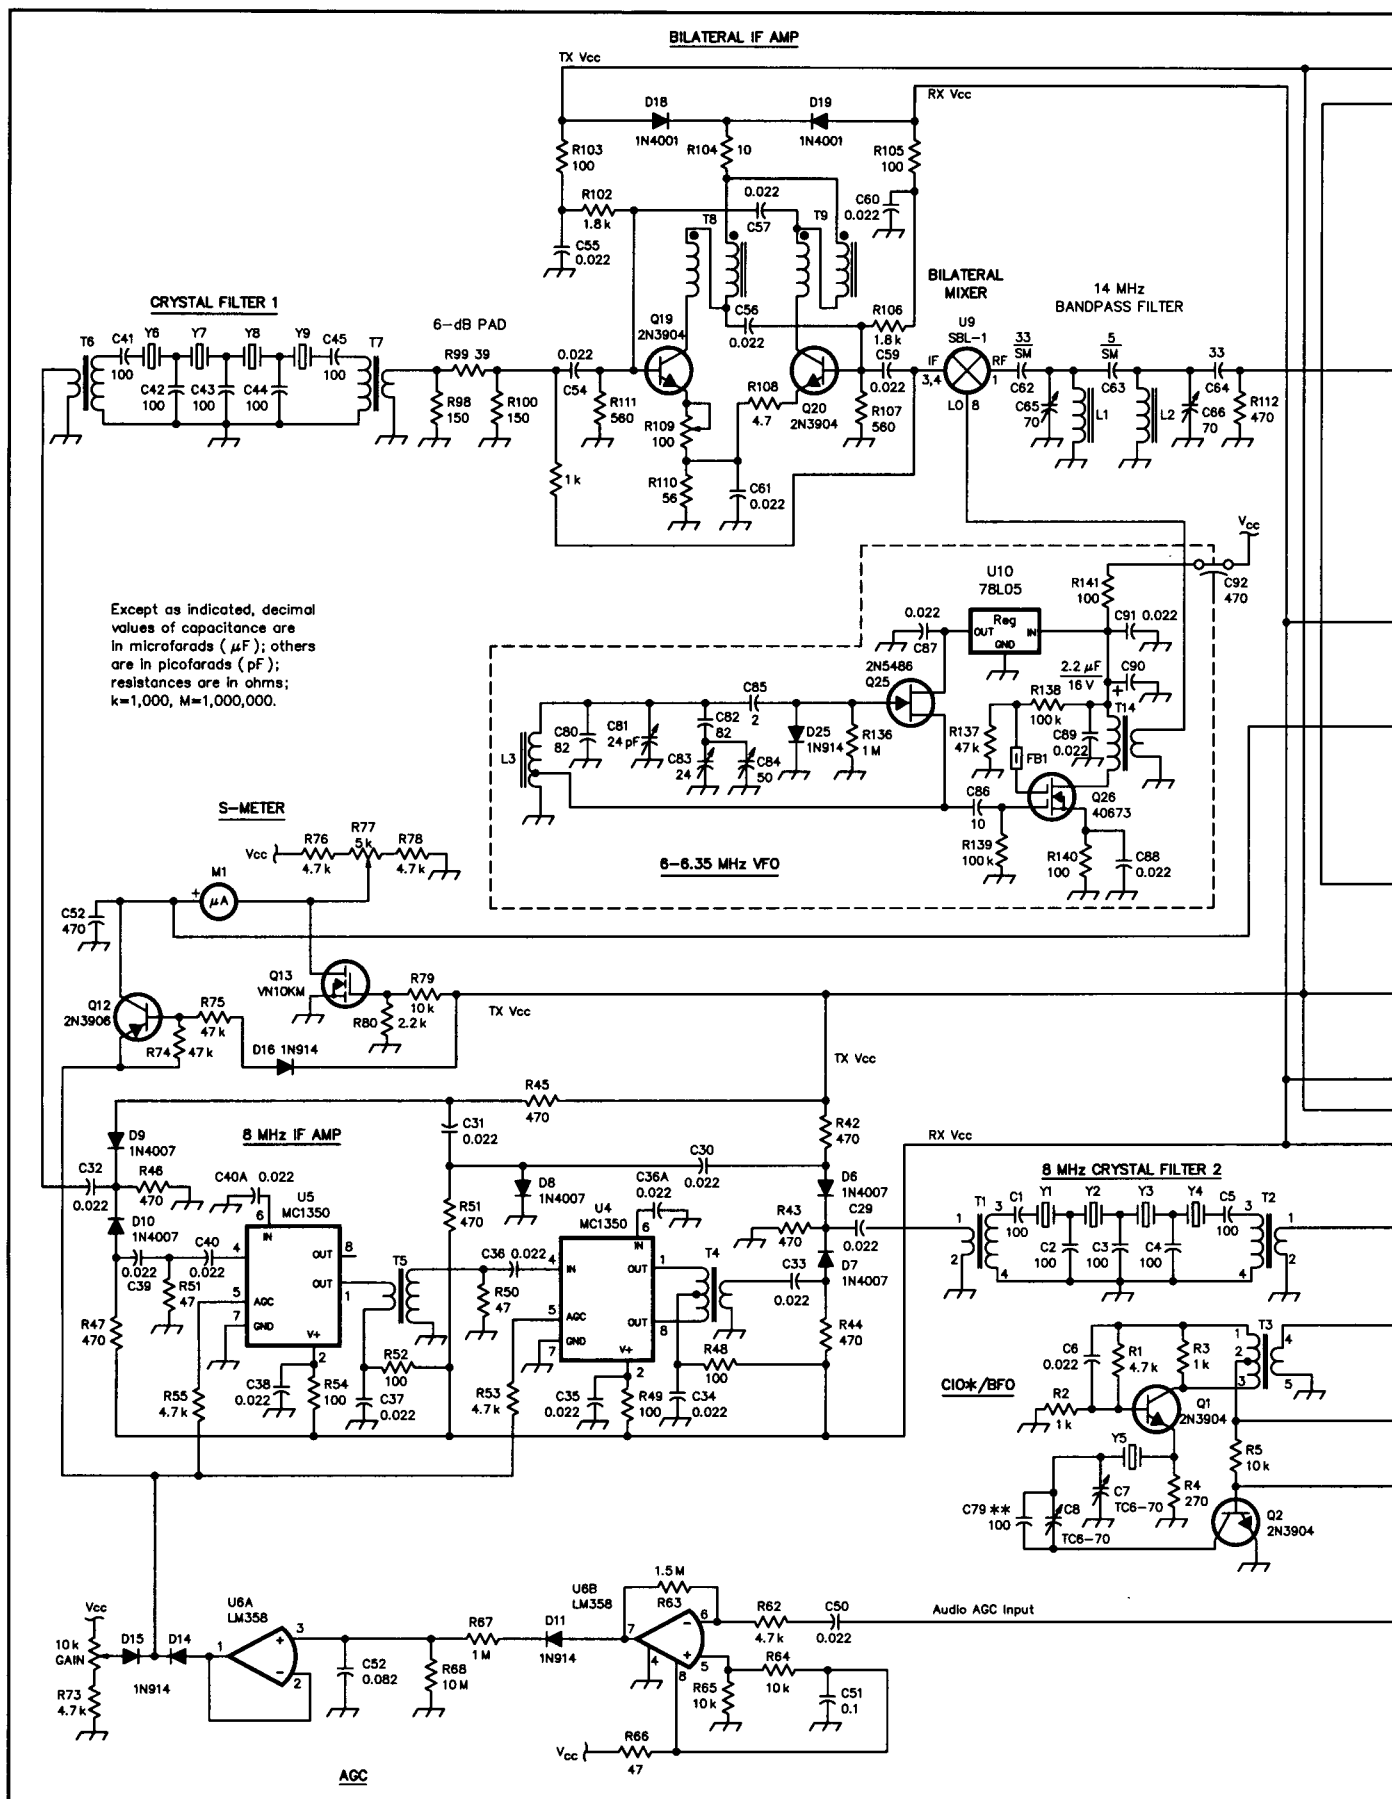

Fig 90—See previous page for details.

good carrier suppression, which eliminates a trimmer that would require adjustment, a very important consideration for this project. Finally, they are low impedance devices, which makes broadband matching much easier. As a bonus, they offer good dynamic range performance, sometimes outperforming NE602-based designs by 15 to 20 dB.

The no-tune requirement caused real problems in the power amplifier. The push-pull amplifier uses a pair of MRF477s that could probably be replaced by a single narrow-band MRF477 amplifier. A narrow-band amplifier would require adjustment, but one would get a significant savings. Additionally, a narrow-band amplifier would give more gain, allowing the driver stage to be run with a bit more feedback, increasing stability. The final amplifier shown is only conditionally stable, it will oscillate with severe mismatches. Fortunately, these transistors are pretty rugged, though you may wish to add some sort of SWR foldback circuitry for added insurance. To keep the costs down, such circuitry wasn't developed. A more complex bias circuit that independently biased the transistors might be better, but the simple circuit shown seems to work adequately with matched pairs of RF transistors.

The biasing circuit shows an interesting change in technology—it's probably more cost effective to use an integrated circuit and a variable resistor than to use the old alternative—a hand-selected 2-W resistor. Of course, if you just happen to have a junk box full of 2-W resistors, you're in good shape.

An 8-MHz IF was chosen, which allows

the use of cheap microprocessor crystals and a 6-MHz VFO. Matching transformers are used because the mixer and amplifiers present close to 50- $\Omega$  terminations. Two separate four-pole filters are used to get a total of eight poles of filtering.

The cost cutting is most apparent in the simple AGC circuit. Initially, a hang-AGC circuit was used with good results, but it was removed to trim the cost as much as possible. An inferior audio-derived AGC circuit was used instead. One advantage of the audio-derived circuit is that it's less susceptible to BFO leakage, something that can easily be a problem when putting almost all the circuitry for an SSB transceiver on a single, single-sided PC board.

The audio amplifier is an old standby LM380 with an appropriate RC stabilization network on the output. While this IC does not have as much gain, or output, as newer chips, like the Signetics TDA 1015, it does seem easier to use. That's an important consideration when filling a big board with circuits that are bound to interact if you give them a chance. 2N5486 JFETs are used for audio switching. While it's certainly possible to reduce the parts count by using quad switching chips instead of transistors, ICs are more difficult to lay out properly in a complicated circuit. The sidetone is a triangle wave.

The VFO uses a JFET and a MOSFET buffer amplifier. Unfortunately MOSFETs are apparently being phased out, but you can still get them from a variety of surplus sources.

Zack built an "ugly" prototype on several unetched PC boards, and that circuit went through many changes as he worked with

the manufacturer. What you see here is the circuit as it was when development stopped. It is presented in the *Handbook* because there has been a consistent demand for an SSB transceiver with more than a few watts of output. Consider this a work in progress. If you build it, drop the *Handbook* Editor a note telling your experience and ideas. With a little more development, this could be a useful and widely popular project.

### Construction

If the circuits are all working properly, alignment should be pretty easy. While there are two interactive adjustments for the band-pass filter, the BFO/carrier insertion oscillator and the VFO alignment, they aren't terribly difficult. Other adjustments are the S-meter zero, the sidetone volume, transmit gain, MRF477 bias setting, and mic-gain adjustment.

The bias setting for the finals is a trade-off, as one does get more gain and better IMD performance with a higher bias current, but the amount of heat generated is higher. A setting that results in a total current of 1 A during transmit seems to work well.

The mic gain should be adjusted for 30 W on voice peaks for good linearity, while 40 W is available on CW. One of the prototypes has a noise floor of -129 dBm.

### 1996 Updates

Lance, WS2B, tells us that Motorola recently discontinued the MRF476 (Q23). NTE Cross Reference software gives the NTE236 as an alternative device.

Dan's Small Parts may have the 40673 and the VN10KM.

## THE NORCAL SIERRA: AN 80-15 M CW TRANSCEIVER

Most home-built QRP transceivers cover a single band, for good reason: complexity of the circuit and physical layout can increase dramatically when two or more bands are covered. This holds for most approaches to multiband design, including the use of multipole switches, transverters and various forms of electronic switching.<sup>1</sup>

If the designer is willing to give up instant band switching, then plug-in band modules can be used. Band modules are especially appropriate for a transceiver that will be used for extended portable operation, for example: back-packing. The reduced circuit complexity improves reliability, and the extra time it takes to change bands usually isn't a problem. Also, the operator need take only the modules needed for a particular outing.

The Sierra transceiver shown in Fig 17.91 uses this technique, providing coverage of all bands from 80 through 15 m with good performance and relative simplicity.<sup>2</sup> The name Sierra was inspired by the mountain range of the same name—a common hiking destination for West Coast QRPers. The transceiver was designed and built by Wayne Burdick, N6KR, and field tested by members of NorCal, the Northern California QRP Club.<sup>3</sup>

### Features

One of the most important features of the Sierra for the portable QRP operator is its low current drain. Because it has no relays, switching diodes or other active band-switching circuitry, the Sierra draws only 30 mA on receive.<sup>4</sup> Another asset for field operation is the Sierra's low-frequency VFO and premixing scheme, which provides 150 kHz of coverage and good frequency stability on all bands.

The receiver is a single-conversion superhet with audio-derived AGC and RIT. It has excellent sensitivity and selectivity, and will comfortably drive a

<sup>1</sup>One of N6KR's previous designs, the Safari-4, is a good example of how complex a band-switched rig can get. See "The Safari-4...." Oct through Dec 1990 QEX.

<sup>2</sup>Band modules for 160, 12 and 10 m have also been built. Construction details for these bands are provided in the Sierra information packet available from the ARRL. Write to the ARRL Technical Department Secretary and request the '96 Handbook Sierra template package.

<sup>3</sup>For information about NorCal, write to Jim Cates, WA6GER, who is in the References Address List. Please include an SASE.

<sup>4</sup>Most multiband rigs draw from 150 to 500 mA on receive, necessitating the use of a larger battery. A discussion of battery life considerations can be found in "A Solar-Powered Field Day," May 1995 QST.

Fig 17.91—The Sierra transceiver. One band module is plugged into the center of the main PC board; the remaining boards are shown to the left of the rig. Quick-release latches on the top cover of the enclosure make it easy to change bands.

speaker. Transmit features include full break-in keying, shaped keying and power output averaging 2 W, with direct monitoring of the transmitted signal in lieu of sidetone. Optional circuitry allows monitoring of relative power output and received signal strength.

Physically, the Sierra is quite compact—the enclosure is 2.7×6.2×5.3 inches (HWD)—yet there is a large amount of unused space both inside and on the front and rear panels. This results from the use of PC board-mounted controls and connectors. The top cover is secured by quick-release plastic latches, which provide easy access to the inside of the enclosure. Band changes take only a few seconds.

### Circuit Description

Fig 17.92 is a block diagram of the

Sierra. The diagram shows specific signal frequencies for operation on 40 m. Table 17.4 provides a summary of crystal oscillator and premix frequencies for all bands. The schematic is shown in Fig 17.93. See Table 17.5 for band-module component values.

On all bands, the VFO range is 2.935 MHz to 3.085 MHz. The VFO tunes "backwards": At the low end of each band, the VFO frequency is 3.085 MHz.

U7 is the premixer and crystal oscillator, while Q8 buffers the premix signal prior to injection into the receive mixer (U2) and transmit mixer (U8).

A low-pass filter, three band-pass filters and a premix crystal make up each band module. To make the schematic easier to follow, this circuitry is integrated into Fig 17.93, rather than drawn sepa-

**Table 17.4**  
**Crystal Oscillator and Premix (PMO)**  
**Frequencies in MHz**

The premixer (U7) subtracts the VFO (2.935 to 3.085 MHz) from the crystal oscillator to obtain the PMO range shown. The receive mixer (U2) subtracts the RF input from the PMO signal, yielding 4.915 MHz. The transmit mixer (U8) subtracts 4.915 MHz from the PMO signal to produce an output in the RF range.

RF Range	Crystal Oscillator	PMO Range
3.500-3.650	11.500	8.415-8.565
7.000-7.150	15.000	11.915-12.065
10.000-10.150	18.000	14.915-15.065
14.000-14.150	22.000	18.915-19.065
18.000-18.150	26.000	22.915-23.065
21.000-21.150	29.000	25.915-26.065

rately. J5 is the band module connector (see the note on the schematic).

The receive mixer is an NE602, which draws only 2.5 mA and requires only about 0.6 V (P-P) of oscillator injection at pin 6.

An L network is used to match the receive mixer to the first crystal filter (X1-X4). This filter has a bandwidth of less than 400 Hz. The single-crystal second filter (X5) removes some of the noise generated by the IF amplifier (U7), a technique W7ZOI described.<sup>5</sup> This second filter also introduces enough loss to prevent the IF amplifier from overdriving the product detector (U4).

The output of the AF amplifier (U3) is dc-coupled to the AGC detector. U3's output floats at  $V_{cc}/2$ , about 4 V, which happens to be the appropriate no-signal AGC voltage for the IF amplifier when it is operated at 8 V. C26, R5, R6, C76 and R7 provide AGC loop filtering. Like all audio-derived AGC schemes, this circuit suffers from pops or clicks at times.

Transmit signal monitoring is achieved by means of a separate 4.915 MHz oscillator for the transmitter; the difference between this oscillator and the BFO determines the AF pitch. Keying is exponen-

tially shaped, with the rise time set by the turn-on delay of transmit mixer U8 and the fall time determined by C51, in the emitter of driver Q6.

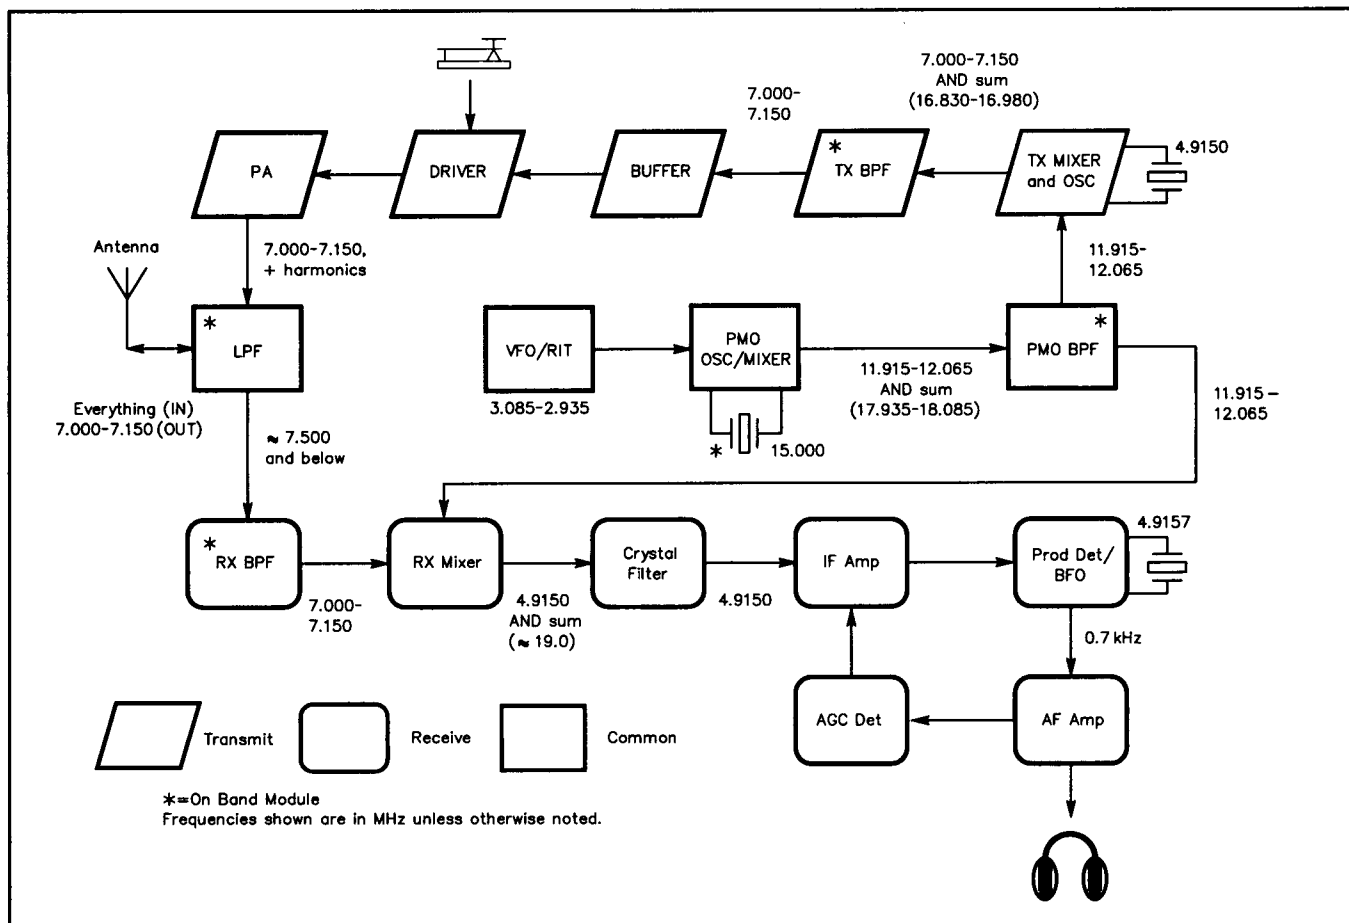

## CONSTRUCTION

The Sierra's physical layout and packaging make it relatively easy to build and align, although this isn't a project for the first-time builder. The boards and custom enclosure described here are included as part of an available kit.<sup>6</sup> Alternative construction methods are discussed below.

With the exception of the components on the band module, all of the circuitry for the Sierra is mounted on a single 5×6 inch PC board. This board contains not only the components, but all of the controls and

<sup>6</sup>Full and partial kits are available. The full kit comes with all components, controls, connectors, and a detailed assembly manual. Complete band modules kits are available for 80, 40, 30, 20, 17 and 15 m. For information, write to Wilderness Radio (see Address List in **References**).

<sup>5</sup>*Solid-State Design*, p 87.

**Fig 17.92—Block diagram of the Sierra transceiver. Three different-shaped symbols are used to show transmit, receive and common blocks. Those blocks with an asterisk (\*) are part of the band module. Signal frequencies shown are for 40 m; see Table 17.4 for a list of crystal oscillator and premix frequencies for all bands.**

**Table 17.5**  
**Band Module Components**

All crystals are fundamental, 15-pF load capacitance, 0.005% frequency tolerance, in HC-49 holders. Fixed capacitors over 5 pF are 5% tolerance. All coils are wound with enameled wire.

Part	Band					
	80 m	40 m	30 m	20 m	17 m	15 m

connectors as well. The board is double-sided with plated-through holes, which permits flexible arrangement of the circuitry while eliminating nearly all hand-wiring. The only two jumpers on the board, W1 and W2, are short coaxial cables between the RF GAIN control and the receiver input filters.

A dual-row edge connector (J5) provides the interface between the main board and the band module. The 50 pins of J5 are used in pairs, so there are actually only 25 circuits (over half of which are ground connections).

The band module boards are 1.25x4 inches (HW). They, too, are double-sided, maximizing the amount of ground plane. Because the band modules might be inserted and removed hundreds of times over the life of the rig, the etched fingers that mate with J5 are gold-plated. Each etched finger on the front is connected to the corresponding finger on the back by a plated through hole, which greatly improves reliability over that of a single finger contact.

Each band module requires eight toroids: two for the low-pass filter, and two each for the receive, transmit and premix band-pass filters. The builder can secure the toroids to the band module with silicone adhesive or Q-dope. Right-angle-mount trimmer capacitors allow alignment from above the module. Each band module has a top cover made of PC board material. The cover protects the components during insertion, removal and storage.

The VFO capacitor is a 5-40 pF unit with a built-in 8:1 vernier drive. The operating frequency is read from a custom dial fabricated from 0.060-inch Lexan. The dial mounts on a hub that comes with the capacitor.

The Sierra's custom 0.060-inch aluminum enclosure offers several benefits in both construction and operation. Its top and bottom covers are identical U-shaped pieces. The bottom is secured to the main board by two 0.375-inch standoffs, while the top is secured to the bottom by two long-life, quick-release plastic latches. As a result, the builder can easily remove both covers to make "live" adjustments or signal measurements without removing any controls, connectors or wires. The front and rear panels attach directly to the controls and connectors on the main board. This keeps the panels rigid and properly oriented.

As can be seen in the photograph, the interior of the rig is uncluttered. NorCal QRP Club members have taken advantage of this, building in keyers, frequency counters and other accessories—and even storing up to four band modules in the top cover. One popular addition is an S/RF meter, the circuit shown in Fig 17.94.

The construction techniques described above represent only one way to build the Sierra; other physical layouts may better suit your needs. For example: If no built-ins are needed, the rig could be built in a smaller enclosure. You could replace the VFO capacitor with a small 10-turn pot and a varactor diode. If necessary, elimi-

nate RIT and metering.

If a different physical layout is required, determine the orientation and mounts for the band module connector first, then arrange the various circuit blocks around it. Use short leads and good ground-plane techniques to avoid instability, especially on the band modules. Point-to-point or "dead-bug" construction are possible, but in some cases shields and additional decoupling may be required. Use a reliable connector if band modules will be repeatedly inserted and removed.

### Alignment

The minimum recommended equipment for aligning the rig is a DMM with homemade RF probe and a ham-band transceiver. Better still is a general-coverage receiver or frequency counter.<sup>7</sup> Start with a 40- or 20-m module; these are usually the easiest to align.

First, set the VFO to the desired band edge by adjusting C52. If exactly 150 kHz of range is desired, squeeze or spread the windings of L7 and readjust C52 iteratively until this range is obtained. RIT operation can also be checked at this time. Reduce the value of R19 if more RIT range is desired.

Prepare each band module for alignment by setting all of its trim caps to midrange. (The final settings will be close to midpoint in most cases.)

<sup>7</sup>The alignment procedure given here is necessarily brief. More complete instructions are provided with the ARRL template package and the kit.

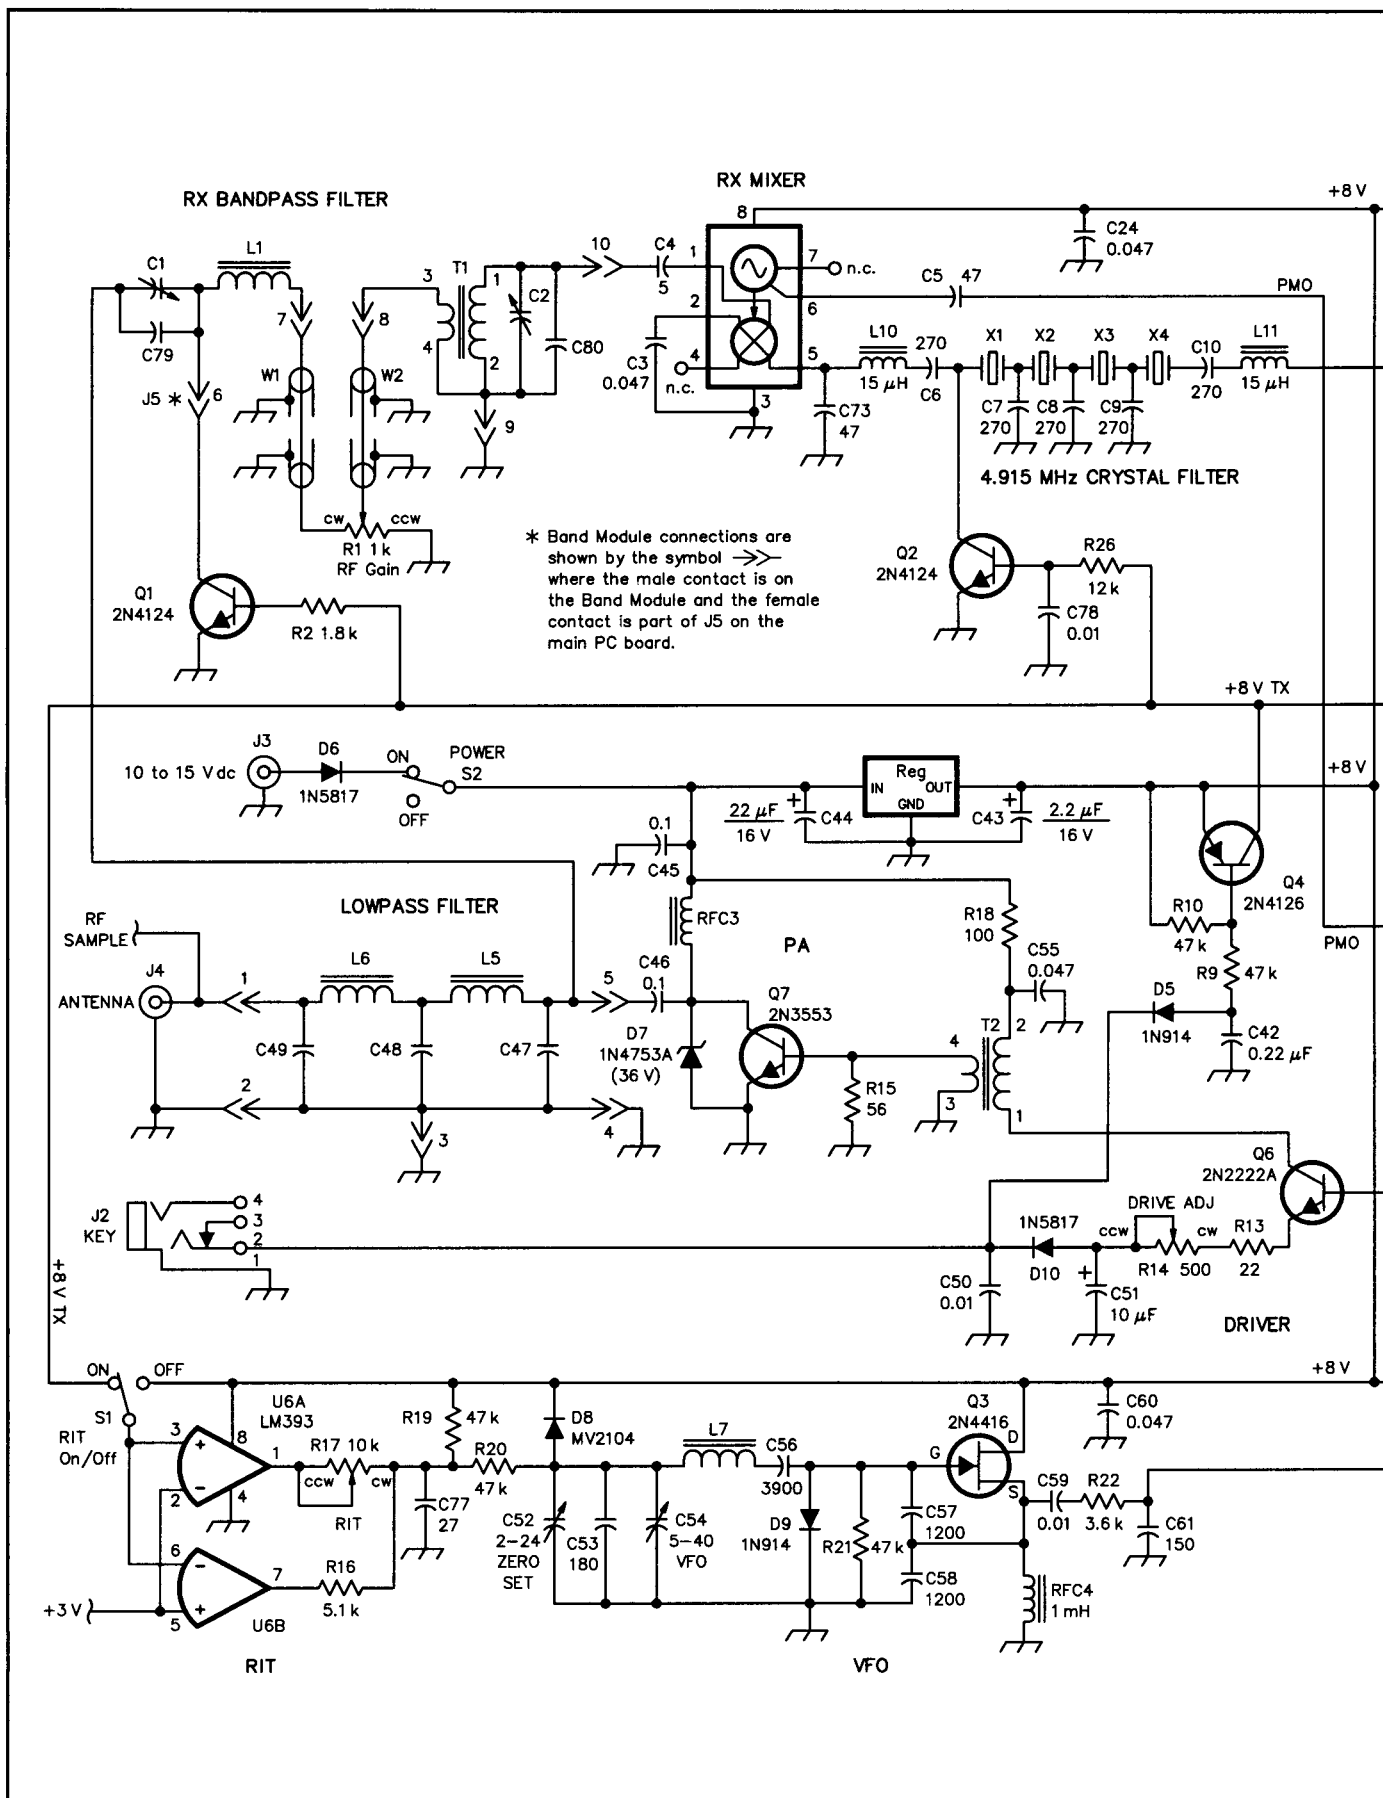

Fig 93—(See page 94 for details.)

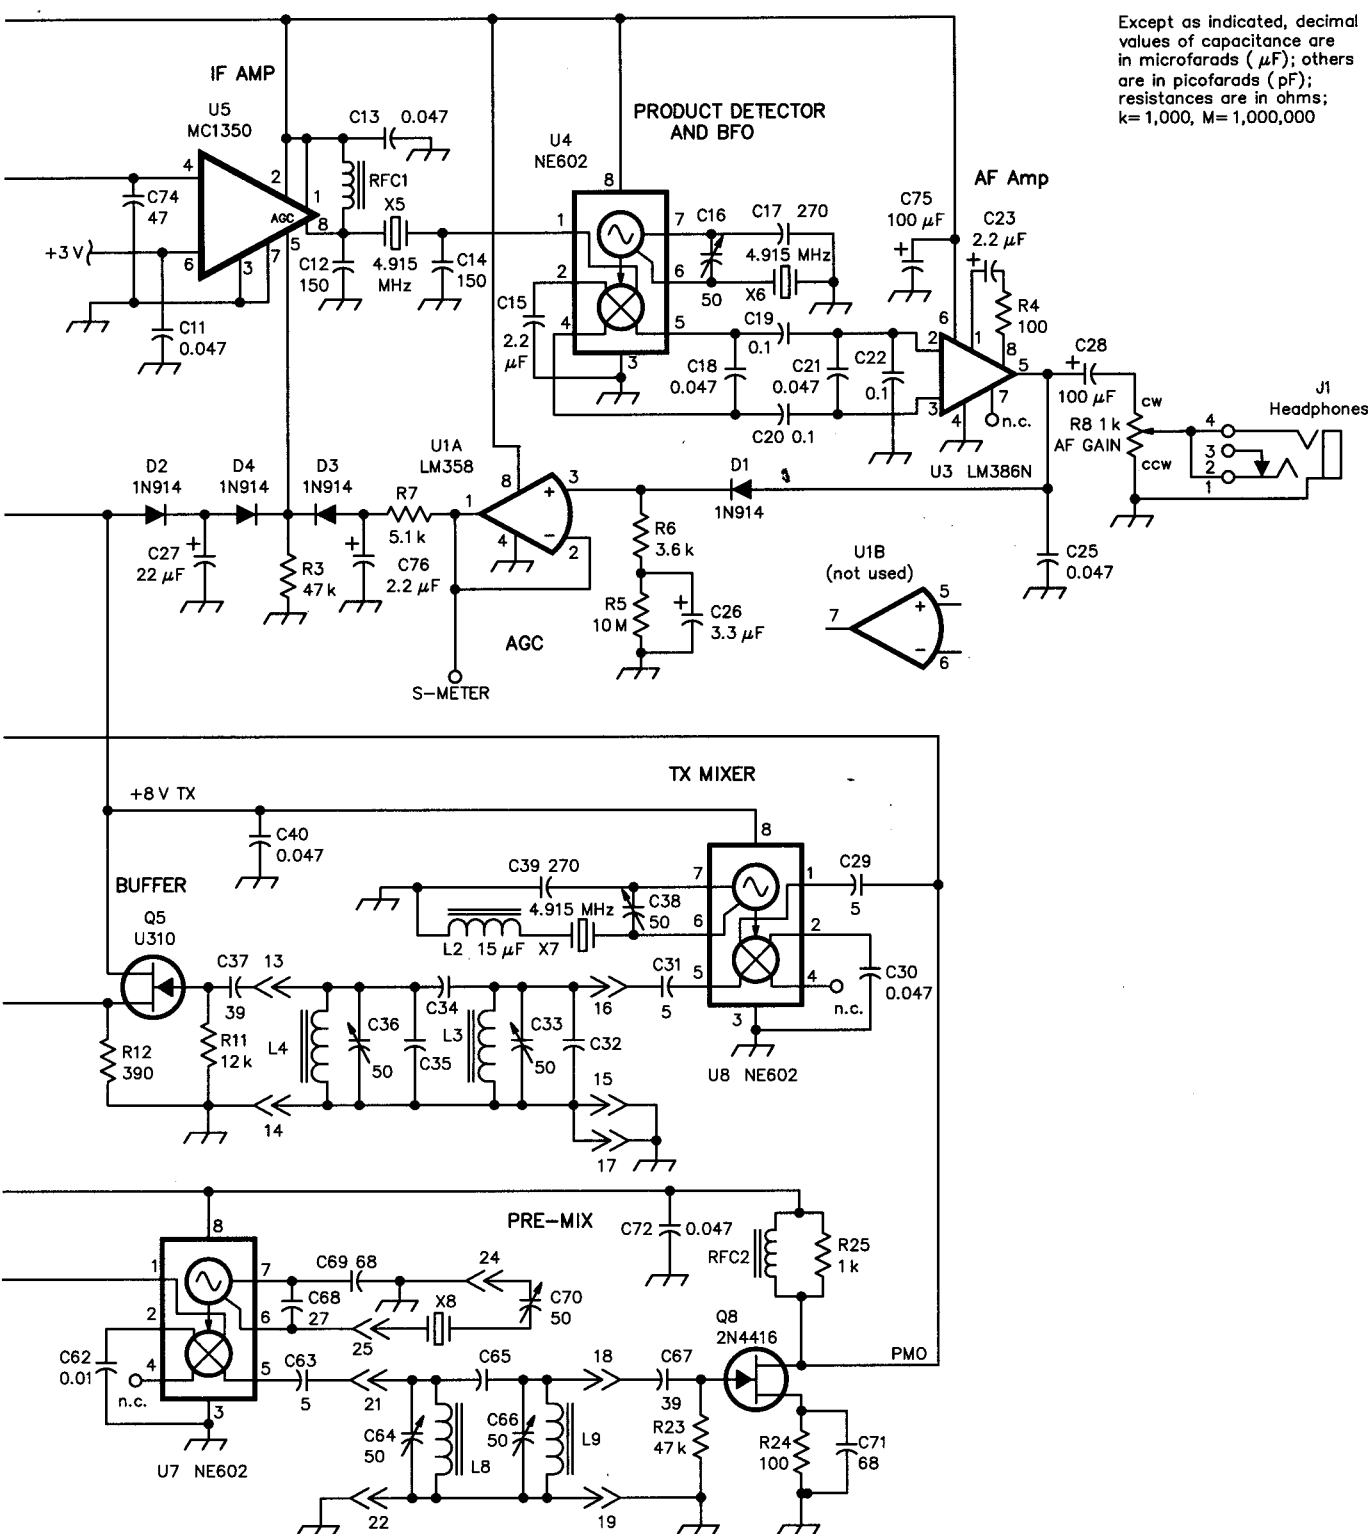

Fig 17.93—(see previous two pages) Schematic of the Sierra transceiver. Parts that change for each band are shown in Table 17.5.

C1, C2, C33, C36, C64, C66, C70—9-50 pF right-angle-mount ceramic trimmer (same for all band modules, Mouser 24AA084)

C16, C38—Ceramic trimmer, 8-50 pF (Mouser 24AA024).

C52—Air variable, 2-24 pF (Mouser 530-189-0509-5).

C53—Disc, 180 pF, 5%, NP0.

C54—5-40 pF air variable with 8:1 vernier drive.

C56—Polystyrene, 3900 pF, 5%.

C57, C58—Polystyrene, 1200 pF, 5%.

D6, D10—1N5817, 1N5819 or similar.

D7—36 V, 1 W Zener diode (Mouser 333-1N4753A).

D8—MV2104 varactor diode, or equivalent.

J1, J2—PC-mount 3.5-mm stereo jack with switch (Mouser 161-3500).

J3—2.1-mm dc power jack (Mouser 16PJ031).

J4—PC-mount BNC jack (Mouser 177-3138).

J5—50 PIN, dual-row edgeboard connector with 0.156-inch spacing (Digi-Key S5253-ND).

L10, L11—18  $\mu$ H; 18 t #28 enameled wire on an FT-37-61 toroid.

L2—Miniature RFC, 15  $\mu$ H (Mouser, 43LS185).

L7—19  $\mu$ H; 58 t #28 enameled wire on a T-68-7 toroid.

Q5—U310, J310, 2N4416 or other high-transconductance device.

R1, R8—PC-mount 1-k $\Omega$  pot (Mouser 31CW301).

R14, R101—500  $\Omega$  trimmer (Mouser 323-4295P-500).

R17—PC-mount 10-k $\Omega$  pot (Mouser 31CW401).

RFC1—3.5  $\mu$ H; 8 t #26 enameled wire on an FT-37-61 toroid.

RFC2—7  $\mu$ H; 4 t #26 enameled wire on an FT-37-43 toroid.

RFC3—34  $\mu$ H; 9 t #26 enameled wire on an FT-37-43 toroid.

RFC4—Miniature RFC, 1 mH (Mouser 43LS103).

S1, S2—SPDT, PC mount, right angle toggle switch with threaded bushing. C&K 7101SDAV2QE is used in the kit; Digi-Key CKN1059-ND will work but does not have a threaded bushing.

T2—Primary: 12 t #26 enameled wire; secondary: 3 t on an FT-37-43 toroid.

U1—LM358N dual op-amp IC.

U2, U4, U7, U8—NE602AN mixer-oscillator IC.

U3—LM386N-1 audio amplifier IC.

U5—MC1350P IF amplifier IC.

U6—LM393N dual comparator IC.

U9—8 V regulator, TO-92 package (Digi-Key AN78L08-ND).

W1, W2—RG-174 coaxial jumper, about 3 inches long (see text).

X1-X7—4.915 MHz, HC-49 (Digi-Key CTX050). X1 through X5 should be matched (their series-resonant frequencies within 50 Hz).

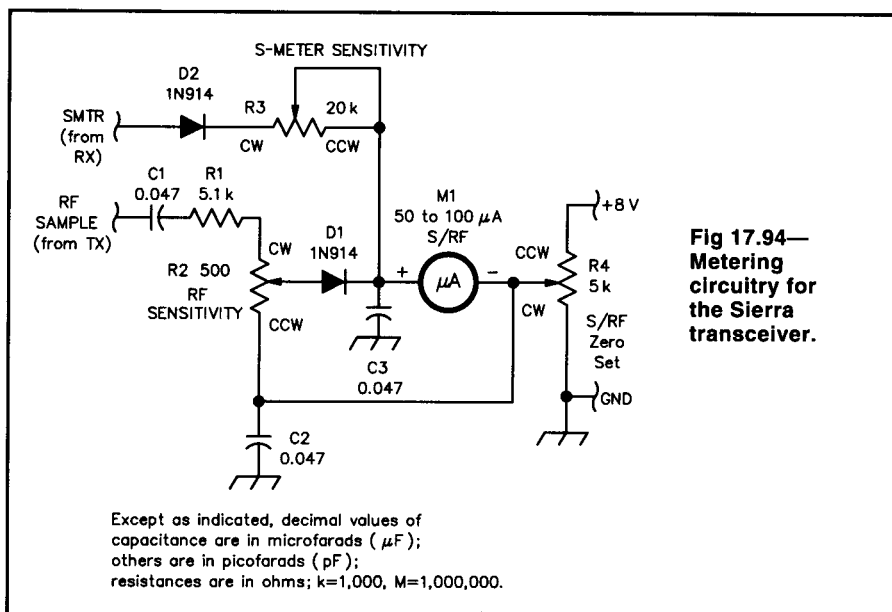

Fig 17.94—Metering circuitry for the Sierra transceiver.

Receiver alignment is straightforward. Set BFO trimmer C16 to midrange, RF GAIN (R1) to maximum and AF GAIN (R8) so that noise can be heard on the phones or speaker. On the band module, peak the premix trimmers (C64 and C66) for maximum signal level measured at Q8's drain. Set the fine frequency adjustment (C70) by lightly coupling a frequency counter to U7, pin 7. Next, connect an antenna to J4 and adjust the receiver filter trimmers (C1 and C2) for maximum signal. The AGC circuitry normally requires no adjustment, but the no-signal gain of the IF amplifier can be increased by decreasing the value of R3.

Before beginning transmitter alignment, set the drive-level control, R14, to minimum. Key the rig while monitoring the transmitted signal on a separate receiver and peak the transmit band-pass filter using C33 and C36. Then, with a dummy load or well-matched antenna connected to J4, set R14 to about 90% of maximum and check the output power level. It may be necessary to stagger-tune C33 and C36 on the lower bands in order to obtain constant output power across the desired tuning range. On 80 m the -3 dB transmit bandwidth will probably be less than 150 kHz.

Typically, output on 80, 40 and 20 m is 2.0-2.5 W, and on the higher bands 1.0-2.0 W. Some builders have obtained higher outputs on all bands by modifying the band-pass filters. However, filter modification may compromise spectral purity of the output, so the results should be checked with a spectrum analyzer. Also, note that the Sierra was designed to

be a 2-W rig: additional RF shielding and decoupling may be required if the rig is operated at higher power levels.

## PERFORMANCE

The Sierra design uses a carefully selected set of compromises to keep complexity low and battery life long. An example is the use of NE602 mixers, which affects both receive and transmit performance. On receive, the RF gain will occasionally need reduction when strong signals overload the receive mixer. On transmit, ARRL Lab tests show that the rig complies with FCC regulations for its power and frequency ranges.

Aside from the weak receive mixer, receiver performance is very good. There are no spurious signals (birdies) audible on any band. ARRL Lab tests show that the Sierra's receiver has a typical MDS of about -139 dBm, blocking dynamic range of up to 112 dB and two-tone dynamic range of up to 90 dB. AGC range is about 70 dB.

The Sierra's transmitter offers smooth break-in keying, along with direct transmit signal monitoring. There are two benefits to direct monitoring:

- the clean sinusoidal tone is easier on the ears than most sidetone oscillators and
- the pitch of the monitor tone is the correct receive-signal pitch to listen for when calling other stations.

The TR mute delay capacitor, C27, can be reduced to as low as 4.7  $\mu$ F to provide faster break-in keying if needed.

The prototype Sierra survived its christening at Field Day, 1994, where members of the Zuni Loop Expeditionary Force

used it on 80, 40, 20 and 15 m. There, Sierra compared favorably to the Heath HW-9 and several older Ten-Tec rigs, having as good or better sensitivity and selectivity—and in most cases better-sounding sidetone and break-in keying. While the other rigs had higher output power, they couldn't touch the Sierra's small size, light weight and low power consumption. The Sierra has consistently received high marks from stations worked too, with reports of excellent keying and stability.

## CONCLUSION

At the time this article was written, over 100 Sierras had been built. Many have been used extensively in the field, where the rig's unique features are an asset. For some builders, the Sierra has become the primary home station rig.

The success of the Sierra is due, in large part, to the energy and enthusiasm of the members of NorCal, who helped test and refine early prototypes, procured parts for the field-test units and suggested future modifications.<sup>8</sup> This project should serve

as a model for other clubs who see a need for an entirely new kind of equipment, perhaps something that is not available commercially.

<sup>8</sup>The author would like to acknowledge the contributions of several NorCal members: Doug Hendricks, K16DS; Jim Cates, WA6GER; Bob Dyer, KD6VIO; Dave Meacham, W6EMD; Eric Swartz, WA6HHQ; Bob Warmke, W6CYX; Stan Cooper, K4DRD; Vic Black, AB6SO; and Bob Korte, KD6KYT.

## AN HF 50-W LINEAR AMPLIFIER

If your QRP transmitter operates with 1 to 2 W output, and you have occasionally wished for moderate power increase, this project is for you! With a flick of the switch, you can increase your signal nearly 3 S-units going from 1 to 50 W.

This amplifier project features a complete 50-W unit that covers all ham bands from 160 to 10 m in a compact easy-to-build package. Designed with readily obtainable parts coupled with detailed schematics, parts list, and mechanical drawings make this an attractive project for the moderately experienced builder. This project was designed and built by Rod Blocksom, KØDAS.

The amplifier features internal control circuits to protect it from high antenna SWR and over-drive conditions. The amplifier is designed for excellent linearity and harmonic suppression through the use of negative feedback and a band-switched bank of low-pass filters. A built-in directional-coupler circuit provides metering of the forward and reflected power. And lastly, the amplifier operates from 12 V dc for convenient operation at home, mobile or portable.

### Circuit Design Details

#### RF Amplifier Circuit

Fig 17.95 (see pages 17.96 and 17.97) is the schematic for the entire amplifier. A basic wideband push-pull RF circuit forms the heart of the amplifier. Motorola MRF477 bipolar transistors were chosen for their high gain and availability in the low-cost TO-220 plastic package. Care was taken to achieve a symmetrical base and collector feed layout on the PC board with this package. The emitters are electri-

cally connected to the mounting tabs which helps reduce the emitter-to-emitter ground impedance in the push-pull circuit. High-gain transistors are necessary to achieve 50 W with only one stage of amplification. Overall amplifier gain must be 15 to 17 dB.

The RC networks in the base feed to each transistor stabilize the wide variation of the MRF477 base input impedance from 1.8 to 30 MHz. Negative feedback using a low-impedance winding from the collector decoupling transformer also helps stabilize the input impedance and flatten the inherent gain variations of the MRF477 over the HF band.

Wideband RF transformers with a

1:9 impedance ratio couple RF into and out of the push-pull amplifier stage. This wideband transformer is relatively easy to build and provides adequate performance at the 50-W power level. The transformer leakage inductance is compensated with shunt capacitors soldered directly on the low-impedance balanced winding of each transformer.

#### Low-Pass Filter Circuit

The nine ham bands between 1.8 and 30 MHz are filtered for harmonics at the output of the amplifier by six low-pass filters (see Table 17.6). All harmonics must be at least 40 dB less than the fun-

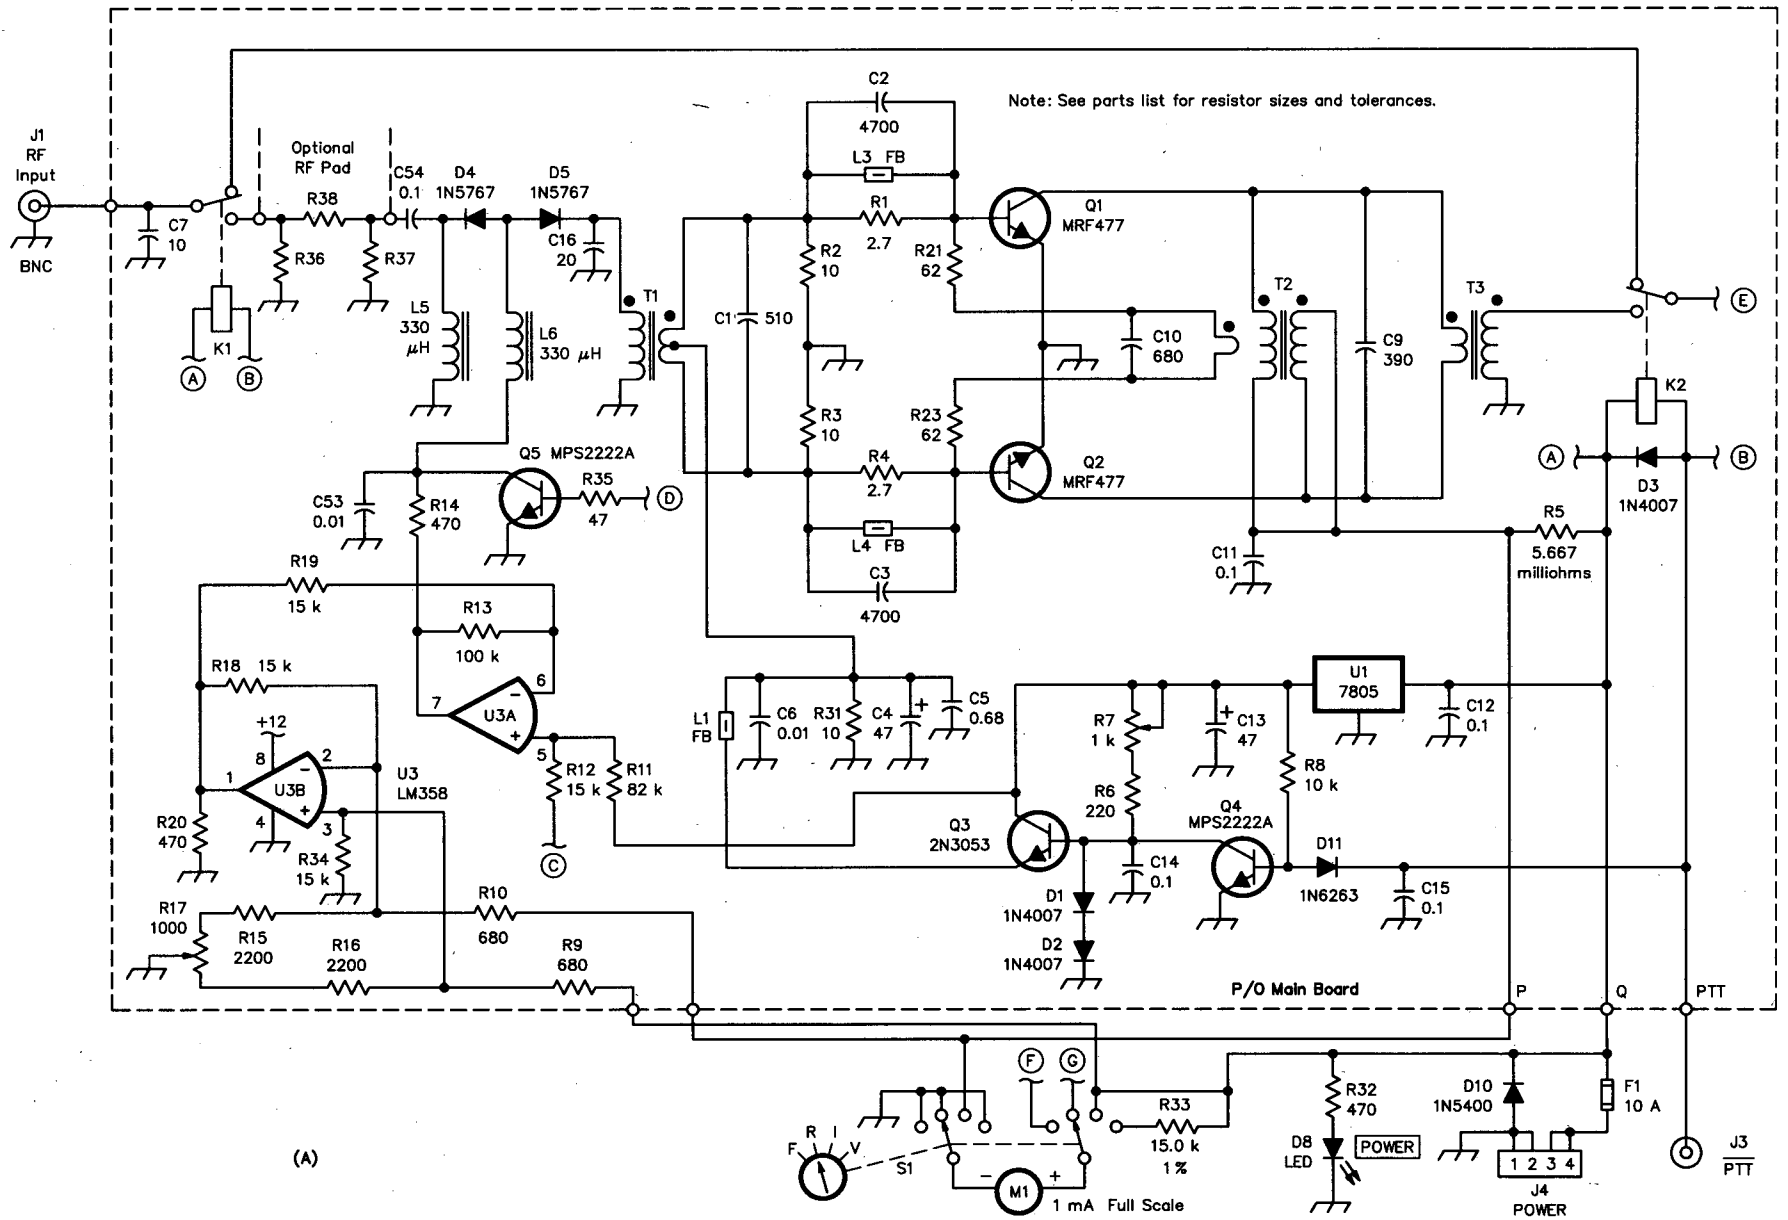

**Table 17.6**

damental to comply with FCC requirements. The filters must meet several additional design requirements besides harmonic reduction. A compact layout was needed to keep the overall amplifier reasonably small. Standard-value capacitors were used along with toroidal inductors. The use of toroids eliminates stray magnetic coupling between filter sections without elaborate shielding. Only two different cores and one wire gauge are used in the filters.

The six filters are mounted on two PC boards located on either side of the rotary band switch. This arrangement minimizes stray inductance associated with switching leads to the desired low-pass filter. The result is a filter assembly with very low passband insertion loss, low SWR in the passband and adequate stop-band harmonic attenuation. Elliptic function filters fulfill these requirements nicely. They also offer advantages in trouble shooting with simple ham shack test equipment.

All nine HF ham bands, except for the

30-m band, can be adequately filtered using only six, two-section elliptic filters. The 30-m band is separated from the 40 and 20-m bands far enough that a two-section elliptic filter will not provide adequate harmonic suppression. The solution requires either seven two-section filters or a three-section filter (with a steeper roll off) for the 30 and 20-m bands. The latter was chosen because it is more cost effective.

The main amplifier board contains T/R relays that bypass the amplifier during receive. The relays are controlled by an external PTT line to allow transceiver operation. By simply disconnecting the PTT line or the 12 V dc power, the amplifier is automatically bypassed to allow QRP transceiver operation. The low-pass filters are placed between the antenna and the T/R relays for two reasons: the filters provide some measure of receiver protection from strong out-of-band signals, and placing the T/R relays on a PC board connected with microstrip transmission line eliminates

expensive coaxial relays and associated cable interconnects.

### Directional Coupler Circuit

Accurate measurement of forward and reflected power is required for a good control circuit to protect the RF devices from accidental destruction. A broadband directional coupler requiring no alignment or tweaking is incorporated in the amplifier design. The circuit is simple and low cost but the key to its performance is symmetry and careful adherence to the physical layout. RF voltage detector circuits on both forward and reflected power ports of the directional coupler provide the signals for the protection circuits and for the front-panel meter.

### Protection Circuit

A PIN diode attenuator in series with the RF input controls the amount of drive applied to the MRF477s. The PIN diodes are normally biased "on" offering very little attenuation to the RF

**Fig 17.96—Worst-case spectral plots for the 50-W amplifier. A shows 50-W power output on 24.9 MHz. All harmonics and spurious emissions are at least 52 dB below the peak fundamental output. This amplifier meets current FCC spectral-purity requirements. B shows two-tone IMD for 50-W output at 21.2 MHz. The third-order products are approximately 34 dB below PEP output.**

drive signal. However, if excessive reflected power or excessive collector current without proper output power is present, the PIN diodes are proportionally biased off reducing the RF drive to a safe level. The operator is made aware of these conditions by the front-panel meter and can take steps to correct the situation.

### Construction

For etching patterns, filter information, construction tips and check-out procedure, write, phone or e-mail the Technical Department Secretary at ARRL HQ and request the '95 *Handbook* 50-W PA template package. The etching pattern and filter details are cru-

cial to successful construction of this amplifier.

### Conclusion

The 50-W HF amplifier just described is a low-cost, reproducible design that will give the builder years of reliable operation. Its performance is equal to, or better than, available commercial units (see Fig 17.96). If a higher power level is desired, the advanced amateur should have no trouble modifying this design for a 100 or 150-W version. The low-pass filter assembly and directional coupler were tested at 150 W with no signs of degraded performance. A finned heat sink will definitely be required at these higher power levels.

AN EXPERIMENTAL 1/2-W CW TRANSMITTER

Using the transmitter shown in Fig 17.97—a 74HC240 octal inverting buffer IC operating as a crystal oscillator and power amplifier—Lew Smith, N7KSB, has worked all continents and over 30 countries using just a roof-mounted ground-plane antenna. It is a simple, inexpensive means of having fun on 10, 15 or 20 m.

It's important to operate the circuit at a supply voltage from 7.8 to 8 V as a compromise between maximum power output and device safety.

The logic chips have built-in input and output buffers. The extra gain provided by the extra stage makes it harder to get rid of key clicks. The 1/2-W rig's key-click filter therefore uses an unusually large (33-ms) time constant.

The output stages in 74HCxxx devices are designed to have equal value pull-up and pull-down transistors. This minimizes even-order harmonics, simplifying the 1/2-W rig's output filtering.

The 74HC240 can directly drive a power MOSFET amplifier, as exemplified by the 74HC240-IRF510 transmitter described in "An Easy-to-Build 15-W Transmitter" (*Hambrew* magazine, Spring 1994).

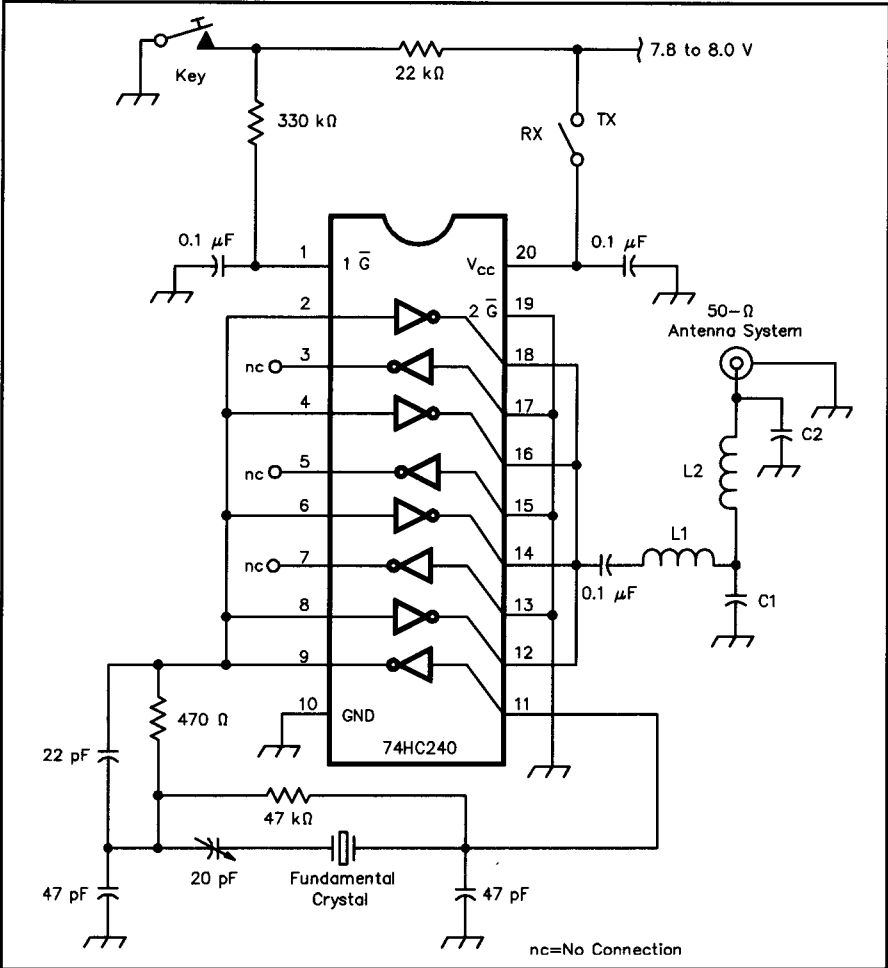

Fig 17.97—N7KSB's experimental 1/2-W CW transmitter uses a 74HC240 high-speed CMOS octal buffer: One section serves as a crystal oscillator; four sections amplify the signal; three sections are unused. (See Table 17.7 for output filter values.) Because the IC dissipates 1/2 W on 20 m and 0.9 W on 10 m, it needs a heat sink. (Epoxy the IC to the ground plane, dead-bug style.) L1 is sensitive to lead length, so plug-in filters (Lew uses phono plugs and jacks) may require removal of one or two turns to compensate for the extra lead length. (ARRL Lab tests indicate that this transmitter meets current FCC spectral-purity specifications for equipment in its power-output class and frequency range. The test version produced 0.51 W at 14 and 21 MHz, and 0.47 W at 28 MHz, with a 7.83-V supply.)

Table 17.7 Output Filter Component Values for the 74HC240 Transmitter			
Band (m)	10	15	20
C1 (pF)	330	470	680
C2 (pF)	100	150	220
L1 (turns, length)	3 t, 5/8"	4 t, 5/8"	5.5 t, 5/8"
L2	7 t, 5/8"	10 t, 1"	12 t, 1"

C1 and C2 are mica or ceramic; L1 and L2 are #14 wire with air cores (3/8" diam form).

# Digital Signal Processing

Digital signal processing (DSP) is one of the great technological innovations of recent times in electronics. This description of DSP for hams was written by Jon Bloom, KE3Z. The basic idea behind DSP is to represent a signal waveform by a sequence of numbers, then process those numbers digitally—usually with a computer—to effect changes to the signal or to extract information from the signal. Similarly, signals can be created by calculating a sequence of numbers that represent the desired waveform.

The advantages of processing signals

digitally are: the “circuit” never needs tuning, as the computer program doesn’t age or change with temperature variations; flexibility, since the way in which the signal is processed is controlled by software, allowing easy changes to the processing; and some unique capabilities the software approach to signal processing makes available, such as processing that adapts itself to the nature of the incoming signal.

DSP has become of great interest to amateurs in the past few years because the devices needed to do it—fast, dedicated DSP chips—have become easily available

and inexpensive. Projects that make use of DSP are showing up more and more often in the amateur magazines and books, and tools that allow the average amateur to work with DSP have become readily obtainable.

In this chapter, we will look at the mechanisms by which DSP is performed, starting with the way waveforms can be turned into sequences of numbers and then, after processing, back into waveforms. We will also look at some of the ways signals can be generated and how they are processed to filter, demodulate and analyze them.

## DSP Fundamentals

Any introduction to DSP necessarily begins by covering some fundamental concepts. Among these are the effects of digitizing a waveform to create a sequence of computer words and the effect this operation has on the design of a DSP hardware system.

### SAMPLING

The process of generating a sequence of numbers from an analog, or continuous, waveform is known as *sampling*. In sampling a signal, we measure the amplitude, or voltage, of the signal periodically, at a regular interval. This results in a sequence of numbers that state the amplitude of the signal at discrete times. For that reason, DSP is often called *discrete-time* signal processing.

The result of this sampling process might be as shown in Fig 18.1. The sequence of numbers tells us the amplitude of the signal at the sampling instant, but

we do not know the values of the waveform between the sampling points. You might suspect that we could miss important information about the signal by neglecting the values between the sampling points and, in fact, that can happen if the samples aren’t taken close enough together in time. But what is “close enough”? If we sample the sine wave shown in Fig 18.1 one million times per cycle, we are going to end up with a pretty close approximation of the sine wave! But if we sample it once a week, we won’t have much useful information. Somewhere between these two extremes lies the minimum sampling rate we can use and still represent the sine wave.

To discover the minimum acceptable sampling rate, it is useful to look at the sampling process itself. What we put into the sampling circuit is a continuous waveform; what we get out is a set of discrete sample values. One way to look at this

Fig 18.1—Sampling a sine wave. The upper graph shows the input waveform, while the lower graph shows the result of sampling the signal at discrete times.

Fig 18.2—Sampling is a multiplication, or mixing, process.

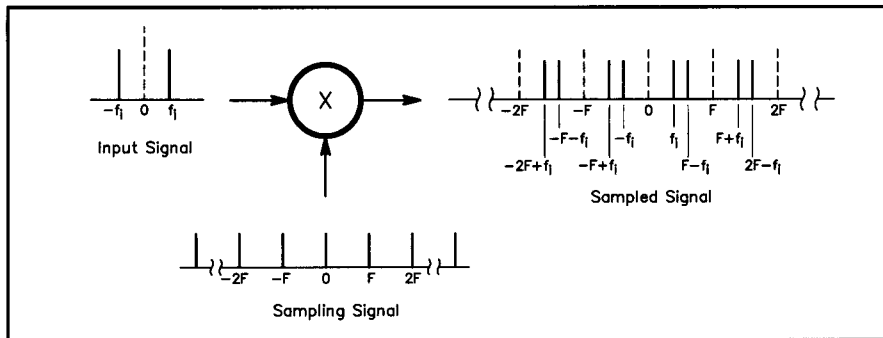

Fig 18.3—The sampled spectrum can be found by mixing the spectrum of the input signal with that of the sample pulses.

process is as a multiplication of two signals, as shown in Fig 18.2. One of the signals is the input waveform, while the other is a series of pulses, each with an amplitude of 1 and separated in time by the sampling interval,  $T$ . By multiplying these two signals together, we get zero at all times between the sampling pulses and a sample equal to the amplitude of the input waveform at the sampling times.

Now that we can treat sampling as multiplication, we are on more familiar ground. We are used to multiplying signals, since that is precisely what happens in an ideal double-balanced mixer (see the **Mixers** chapter). So we can analyze the result of the multiplication by looking at the frequencies of the two signals, shown in Fig 18.3. The input signal is a sine wave in this case, which has a single positive frequency component,  $f_i$ , and a negative component,  $-f_i$ . But what of the sampling pulses? It turns out that the frequency spectrum of the sampling pulses comprises a component at 0 Hz, one at the sampling frequency,  $F = 1/T$ , and components at all of the positive and negative harmonics of the sampling frequency:  $-4F, -3F, -2F, -F, 2F, 3F, 4F$  and so on. Multiplying—mixing—this signal with the input sine wave thus gives us sum and difference frequencies around each of the components of the sampling signal. That is, we have signal components around the sampling frequency, for example, at  $F-f_i$

and  $F+f_i$ . And we have components at  $2F\pm f_i$ , at  $3F\pm f_i$ , and so on. We also have components around 0 Hz, at  $f_i$  and  $-f_i$ , as well as around the negative-frequency components of the sampling signal, at  $-F\pm f_i$ ,  $-2F\pm f_i$  and so on.

Now, if our input signal was at a frequency of  $F-f_i$ , instead of  $f_i$ , the input would mix with the 0-Hz component of the sampling signal to give us outputs at  $F-f_i$  and  $-F+f_i$ , with the component at  $F$  to give  $f_i$  and  $2F-f_i$ , with the component at  $-F$  to give  $-f_i$  and  $-2F+f_i$ , and so on. The result would be indistinguishable from sampling a signal at  $f_i$ ! Such an input signal is called an alias, since it “looks like” a frequency that it is, in fact, not. Any signal at a frequency above  $F/2$  is indistinguishable from a signal below  $F/2$ . That is, a signal at  $F/2 + f_i$  is an alias of a signal at  $F/2 - f_i$ ; you can’t tell them apart. This fact leads to one of the most fundamental laws of DSP, *the sampling theorem*, which states that you must sample a signal at a sampling rate greater than twice the highest frequency component of the input signal to avoid aliasing.

### Normalized Frequencies

The sample values we get from a waveform depend on both the waveform and the sampling rate. If we were to sample a 1-kHz sine wave signal at a 10-kHz rate, we would get the same set of sample val-

ues as if we had sampled a 2-kHz signal at a 20-kHz rate. To the computer that processes the numbers, both cases are exactly the same. For that reason, we often find it convenient to *normalize* frequencies in our design and analysis of DSP systems. A normalized frequency is the actual frequency divided by the sampling frequency. Since we should restrict our input signals to actual frequencies of 0 to  $F/2$ , this results in normalized frequencies of 0 to 0.5, since  $(F/2)/F=0.5$ .

### QUANTIZATION

Usually, we perform sampling with an analog-to-digital (A/D) converter. Every so often—at the sampling rate—the processing computer asks the A/D converter for the amplitude of the waveform. Since the A/D converter must give its result as a binary number, it can only respond with one of a limited number of amplitude values. For example, an 8-bit A/D converter can give one of 256 values. When the signal the A/D is measuring falls between two of the values it can represent, the A/D reports the nearest value that it can. This means that, most often, the value reported by the A/D is not exactly the amplitude of the input signal; there is a small error, called the *quantization error*. How large the error is depends on how close the amplitude of the input signal is to one of the binary values the converter can report.

The amplitude relayed by the A/D converter to the computer can, therefore, be thought of as the sum of two signals: the actual input signal and an error “signal.” The peak amplitude of the error signal is equal to one-half the amplitude of the least-significant bit (LSB) of the A/D converter, as the difference between the input signal and a reportable binary value cannot exceed this amount. (Of course, this assumes a perfect A/D converter; deficiencies in the A/D can increase this error value.) If the input signal is varying, the error signal will vary as well, as the difference between the actual amplitude and the reported amplitude changes with each sample. Normally, with a signal composed of numerous frequencies, changing all the time, all possible error values of  $\pm 1/2$  LSB are about equally likely. The result in this case is that the error signal looks random; it is noise—quantization noise. From this, we can calculate an effective A/D signal-to-noise (S/N) ratio, which is the ratio of the desired full-scale signal to the noise term. The result, taking into account the random nature of the error signal, is:

$$S/N = 6.02N + 1.76 \text{ dB} \quad (1)$$

where  $N$  is the number of bits of the con-

verter. For example, an 8-bit A/D converter would give an S/N ratio of:

$$6.02(8) + 1.76 = 49.9 \text{ dB.}$$

The amplitude of this noise is distributed across the frequency range of the sampling system. That is, the 49.9 dB S/N ratio of the example converter includes noise from dc to  $F/2$ . If digital filtering is used in the processing to reduce the bandwidth, the amount of noise is reduced proportionally. This can be used to advantage, as we will see. But it is important to remember that we *assumed* the error signal was random. If there is a harmonic relationship between the sampling rate and the input signal, the error signal will *not* be random, and the error may show up at discrete frequencies, rather than as random noise.

## DSP SYSTEM HARDWARE

The sampling theorem suggests that we had better not allow any signals at frequencies above one-half the sampling rate to get into our A/D converter. If we do, we won't be able to tell whether the signal we're processing is above or below  $F/2$ . To eliminate this risk, we usually place a low-pass filter, called an *antialiasing filter* ahead of the A/D. The job of this filter is to attenuate any signal at a frequency above  $F/2$  to the point where its amplitude is negligible. Fig 18.4 shows the block diagram of a DSP system with an antialiasing filter included.

After we've processed the signal in the computer, we may want to output the processed signal as a waveform. We do this by feeding the samples into a digital-to-analog (D/A) converter. This results in a "staircase" waveform, where the output amplitude is held constant during the sample period. This staircase waveform has a spectrum similar to that of the sampled signal of Fig 18.3, but having the sample amplitudes "connected" by the D/A modifies the spectrum somewhat. Instead of having equal-amplitude components around all harmonics of the sampling frequency, the amplitudes of the components lessen as the frequency is increased. Specifically, the amplitude of any frequency component is:

$$A_o = A_s \frac{\sin \pi f/F}{\pi f/F} \quad (2)$$

where:  $A_o$  is the amplitude of frequency  $f$

**Fig 18.4—Block diagram of a DSP system. The low-pass filter in the input subsystem is the *antialiasing filter*, while the output low-pass filter is the *reconstruction filter*.**

at the output of the D/A converter,  $A_s$  is its amplitude at the input of the D/A converter, and  $F$  is the sampling frequency. This applies not only to the signals around the sampling frequency and its harmonics, but also to the signals from 0 Hz to  $F/2$ . At  $F/2$ , the result is:

$$A_o = A_s (0.637)$$

which represents a -3.9-dB amplitude error, with less error at lower frequencies, down to no error at 0 Hz. If such an amplitude error is unacceptable in a particular application, you can either choose a faster sampling rate, so that the highest signal frequency falls well below  $F/2$  (called *oversampling*), or correct the amplitude error with filtering. Some D/A converters designed for DSP work include internal error correction for this effect.

Most likely, we will want to remove the signal components above  $F/2$  from the output of the D/A converter. We do this by following the D/A converter with a low-pass filter, to remove these components of the signal, as shown in Fig 18.4. Such an output filter is called a *reconstruction filter*.

For both the antialiasing and reconstruction filters, which are analog filters, the necessary filter complexity is determined by how close to  $F/2$  the highest desired signal frequency will be. For example, requiring the filter to pass a signal just below  $F/2$  while rejecting its alias just above  $F/2$  will require a filter with a very steep roll-off. Such filters are both complex and difficult to construct reliably. Also, they typically exhibit a large degree of phase distortion. For that reason, we usually oversample by two to three times. This allows us to relax the requirements for the antialiasing and reconstruction filters, making them simple and benign.

## A/D and D/A Converters for DSP

Getting the right kind of A/D converter

is important for DSP. A basic A/D converter simply digitizes the voltage that appears at its input. Depending on the type of circuit used in the converter, this digitization may take a relatively short period of time or a long time. How long it takes to perform the conversion affects the highest sampling rate the A/D converter can support. If the converter isn't finished performing its calculations for a given sample, it can't begin calculating the next one. So, one of the key parameters to consider in choosing an A/D converter is its maximum sampling rate.

But there's another issue to consider as well. What happens if the input voltage changes while the A/D converter is doing its processing? The answer is that the A/D will probably report some value between the initial voltage, at the start of the conversion, and the final voltage. This will seriously affect the accuracy of our sample values. Remember, we assumed that each sample value was a snapshot of the input voltage at one instant of time.

The solution to this problem is to add a sample-and-hold (S/H) amplifier ahead of the A/D converter. This circuit is clocked, or strobed, at the same time the A/D converter is commanded to begin its conversion. The S/H amplifier "freezes" its output level, holding a steady voltage on the input of the A/D converter regardless of any succeeding changes in the voltage coming into the S/H amplifier. Often, an S/H amplifier and an A/D converter are packaged into a single integrated circuit part. Such devices are known as *sampling A/D converters*.

While D/A converters don't have to worry about their inputs changing between samples, they do have to be able to quickly change their output voltages from sample to sample. Be sure to use a D/A converter rated for the output sampling rate you intend to use.

## Processing Signal Sequences

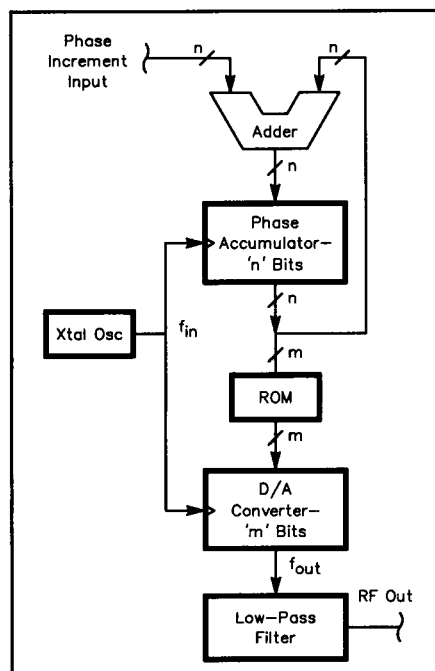

While we have to expend a certain amount of effort to turn waveforms into sampled sequences and back into waveforms again, the heart of DSP lies in the processing of those signals. Processing of signals is performed largely by three fundamental operations of DSP: addition, multiplication and delay. Adding two

**Fig 18.5—Flow diagram symbols. At A, the symbol for adding two sample values. B is the symbol for multiplying a sample value by a constant, K. Delaying the sample value by one sample period is shown at C.**

**Fig 18.6—An example flow diagram.**

**Fig 18.7—Direct digital synthesis (DDS) can be performed using digital hardware, without a DSP chip.**

numbers together or multiplying two numbers together are common computer operations, and we won't dwell on them too much. Delay, on the other hand, takes some explaining.

Delaying a signal, in DSP, means processing previous samples of the signal. For example, you might take the current input sample and add its value to that of the previous input sample, or to the sample before that. It's difficult to explain without tiresome mathematics exactly how and why delays enter into our processing so importantly. We can draw an analogy, however, to analog R-L-C circuits, in which the delays (phase shifts) of the inductors and capacitors work together to create frequency-selective circuits. Processing discrete-time signals on the basis of a series of samples performs much the same function as the phase shifts of reactive analog components. Just as the inductor or capacitor stores energy, which is combined with later parts of the applied signal, stored sample values are combined in DSP with later sample values to create similar effects.

We will represent DSP algorithms in two ways: by flow diagrams and by equations. Flow diagrams are made up of the elements of **Fig 18.5**. These provide a convenient way to diagram a DSP algorithm. One item of note is the delay block, labeled  $z^{-1}$ . For any given sample time, the output of this block is what was at the input of the block at the previous sample time. Thus the block provides a one-sample delay. It is important to recognize that the signals “step” through the flow diagram. That is, at each sample time, the input sample appears and, at the same time, all of the delay blocks shift their previous inputs to their outputs. Any addition or multiplication takes place (we assume) instantaneously, producing the output. The output then remains stable until the next sample arrives. While real calculations do, of course, require time to complete, the algorithms don’t take that into account—and don’t need to. Everything happens on the basis of the incoming sequence of sample values.

**Fig 18.6** shows an example flow diagram. In this simple case, the previous input sample is multiplied by 2 and added to the current input sample. That sum is then added to the previous *output* sample, which is multiplied by  $-3$ , to form the current output sample. We have added notation to this diagram to show how the various signals in the diagram are represented mathematically. The key to reading this notation is to understand a term of the form

$x(n)$ . This can be read as “ $x$  as a function of  $n$ .” The variable  $n$  is the *sample index*, an integer value, and sample number  $n$  is, in this case, the current input sample.  $x(n)$  is simply the amplitude value of the current sample, sample number  $n$ . The output of the delay block in the lower left is the previous input sample value. (Recall that the delay block shifts its input to its output each time a new sample arrives.) Thus it is the value of  $x$  when  $n$  was one less than its present value, or  $x(n-1)$ . Similarly,  $y(n)$  is the current output value, and  $y(n-1)$  is the output value at the previous sample time. Putting these signal notations together with the multipliers, or *coefficients*, shown on the diagram lets us construct an equation that describes this algorithm:

$$y(n) = x(n) + 2x(n-1) - 3y(n-1) \quad (3)$$

This equation exactly describes the algorithm diagrammed in Fig 18.6, giving the output sample value for any value of  $n$ , based on the current and previous input values and the previous output value. We can use the diagram and the equation interchangeably. Such an equation is called a *difference equation*.

## GENERATING SINE WAVES

Up until now, we have been talking about processing a sequence of numbers that came from a sampled waveform. But we also can let the computer calculate a sequence of numbers to generate a signal. One of the easiest—and most useful—signals we can generate in this manner is a sine wave.

One commonly used technique for generating a sine wave is the *phase accumulator* method. We generate our samples at a constant rate—the sampling frequency. For any frequency we wish to generate, we can easily calculate the change in phase of a signal at that frequency between two successive samples. For example, say we are generating samples at a 10-kHz rate—every 0.1 ms. If we want to generate a 1-kHz signal, with a period of 1 ms, we note that the signal changes  $36^\circ$  in 0.1 ms. Therefore, the phase angle of the signal at each sample proceeds:

 $0^\circ, 36^\circ, 72^\circ, 108^\circ, 144^\circ, 180^\circ, \dots$ 

All we need do is find the sine (or cosine, if we prefer) of the current phase angle; that will be the value of our output sample:

 $\sin(0^\circ), \sin(36^\circ), \sin(72^\circ), \sin(108^\circ), \dots$ 

Once the phase passes  $360^\circ$ , it rolls over; it always has a value between 0 and  $360^\circ$ . Finding the sine or cosine can be

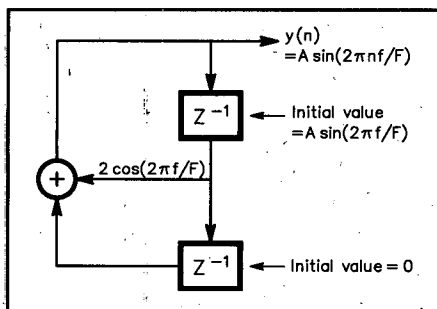

Fig 18.8—A DSP sine-wave oscillator algorithm.

Fig 18.9—These two sine-wave signals have different frequency contents, even though the sine wave in each has the same period.

done in the computer in one of several ways, although most often it is done with a look-up table, as that is the quickest way.

This kind of generator can be implemented directly in digital hardware, as shown in Fig 18.7, and is an example of *direct digital synthesis* (DDS).

Another generator is shown in Fig 18.8. This flow diagram shows a DSP sine-wave oscillator. Like any oscillator, it has no signal input, just an output. By choosing proper coefficients and placing the correct starting values in the delay elements, we can generate a particular frequency. While this algorithm works well, it suffers from two defects compared to the phase accumulator technique. First, it is difficult to change the frequency while the system is running. You have to change not only the coefficients, but the contents of the storage elements as well. This leads to a phase discontinuity in the output when the

change is made, which often is undesirable. The second problem has to do with *finite-length* binary words. Since the coefficient is a number stored in a computer, it must be represented as a set of binary bits. You can't use just any value you want; you have to use values that can be represented by the available number of bits. In this oscillator, the frequency change caused by a one-LSB difference in coefficients is different at low frequencies than at higher frequencies. That's not true of the phase accumulator. So this oscillator is most suitable for applications where a fixed, unchanging frequency is called for.

## TIME AND FREQUENCY

Often we are interested in the frequency content of a signal. Using DSP, we have tools that allow us to calculate the frequency content—with some restrictions. The restrictions arise because the frequency content of a signal is not always easy to define. We've all learned that a sine wave consists of a signal at a single frequency, where the frequency is the reciprocal of the period of the sine wave. Actually, that's a simplification.

Consider the signals of Fig 18.9. The sine wave at A has a frequency of  $1/t$ , where  $t$  is the period of the sine wave. But what about the signal at B? There is a sine wave there, but only one cycle, preceded and followed by a steady zero-volt signal. Since the signal at B is not the same as the signal at A, they *cannot* have the same frequency content! (If they did, they'd be the same signal.) The signal at B is similar to a signal from a CW transmitter keyed on and off, although typically the transmitter would send more than one cycle of the signal at a time. When we abruptly turn a CW transmitter on and off, we get key clicks: signals at frequencies near the frequency of the sine wave. So the turning on and off of the signal changes the frequency content.

What this example demonstrates is that when you analyze the frequency content of an aperiodic signal (one that does not repeat endlessly) over a short period of time, you may get a different result than if you had used a longer period of time. In fact, to be absolutely precise about the frequency content of a real signal, you would have to analyze it over *all* time! That's a bit impractical, of course. Fortunately, if you look at the signal over a relatively long period of time, the difference between what you get as a result and what you would get if you looked at the signal for all of time is pretty small. What's "a relatively long period of time"? That depends on the nature of the signal. In the example of the on-off keyed CW transmitter, you would want to include

many of the on-off transitions. The more you include, the more closely your result will come to "reality."

## FOURIER TRANSFORMS

Since we can't look at a signal for all of time, we have to come up with a way of getting close enough. The way we do this is by using a Fourier transform. The Fourier (pronounced **foor-ee-ay**) transform is a mathematical technique for determining the content of a signal. Applied to a signal over a particular period of time, it determines the frequency content of that signal by assuming that the signal being analyzed repeats itself indefinitely.

Of course, when we analyze a real-world signal, such as a couple of seconds of speech, we know that those few seconds of signal do not, in fact, repeat endlessly. So at best, the Fourier transform can give us only an approximation of the frequency content. But if we look at a large enough period of the signal, that approximation will be pretty good. We also have a mathematical trick up our sleeve that will help us control the error, as we'll see.

### The Discrete Fourier Transform (DFT)

In DSP, we make use of a variant of the Fourier transform called the *discrete Fourier transform* (DFT). This is an algorithm that calculates the Fourier transform of a sampled signal. Mathematically, the DFT of a signal is computed thus:

$$X(k) = \sum_{n=0}^{N-1} x(n)e^{-j2\pi nk/N} \quad (4)$$

That  $e^{-j2\pi nk/N}$  part may look pretty daunting, but there is a simplification, called Euler's rule, that we can use to state the DFT in more familiar terms:

$$X(k) = \sum_{n=0}^{N-1} x(n) [\cos(2\pi nk/N) - j \sin(2\pi nk/N)] \quad (5)$$

In this equation,  $N$  is the number of samples we're processing,  $n$  is the sample index, starting at 0, and  $x(n)$  is the value of sample number  $n$ . For any value of  $k$ , the frequency index, we get  $X(k)$ , which is the content of the signal at the frequency  $kF/N$ , with  $F$  being the sampling frequency. We can do this for values of  $k$  from 0 to  $N-1$ . For example, say we were sampling at 10 kHz and we took 50 samples. Each value of  $k$  would represent a frequency of:

$$\frac{k}{N} F = k \frac{10000}{50} = k \cdot 200 \quad (6)$$

so, for  $k=1$ ,  $X(k)=X(1)$  is the content of the signal at 200 Hz. For  $k=2$ ,  $X(k)=X(2)$

**Fig 18.10**—The 50-point DFT of a signal with 1000-Hz and 1300-Hz components, sampled at a 20 kHz rate, shows the effect of spectral leakage. The 1000-Hz signal falls exactly on the fifth frequency bin ( $k = 5$ ) and doesn't leak at all. The 1300-Hz signal falls between bins 6 and 7, causing it to spread over a number of bins.

is the content of the signal at 400 Hz, and so on. The dc value of the signal is at 0 Hz, so it is given when  $k=0$  and  $X(k)=X(0)$ .

To calculate  $X(k)$  for a particular value of  $k$ , we plug  $k$  into equation 5, then compute the sum for all of the input sample values. There is a niggling detail left: the value we calculate has both real and imaginary components: it's a complex number. The imaginary component arises because of the  $j$  in equation 5. What this means is that the signal has both an amplitude and a phase. We can calculate the amplitude and phase from the complex value of  $X(k)$  like so:

$$X(k) = a + jb$$

$$|X(k)| = \sqrt{a^2 + b^2} \quad (7)$$

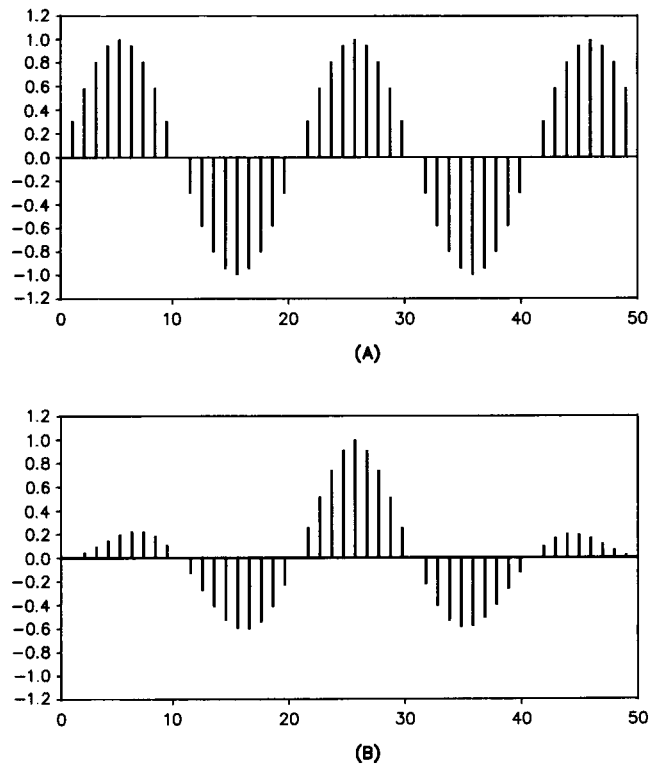

$$\theta(k) = \tan^{-1} \frac{b}{a}$$

Here, the values of  $a$  and  $b$  are what we calculated with cosines and sines in equation 5.  $|X(k)|$  is the amplitude, and  $\theta(k)$  is the phase angle.

Note from equation 6 that if we use values of  $k$  greater than  $N/2$ , the corresponding frequency for  $X(k)$  is greater than  $F/2$ . Since the sampling theorem says frequencies above  $F/2$  are aliases, what are these values? It turns out that in the DFT, half of the actual amplitude of a frequency component appears at the expected value of  $k$ , and half appears at the alias frequency. If the input samples,  $x(n)$ , are all real numbers, the value of  $X(k)$  at the alias frequency is the complex conjugate of the value at the actual frequency, meaning the complex number has the same real part and an imaginary part that is equal in value but opposite in sign. Mathematically, we write this as:

$$X(N - k) = X^*(k) \quad (8)$$

What this means in practice is that once

**Fig 18.11**—Windowing minimizes the effects of discontinuity at the ends of the sample set for the DFT. Here, the samples at A have a window function applied, resulting in the samples at B.

we have calculated the value of  $X(k)$ , we know the value of  $X(N-k)$ : just reverse the sign of the imaginary part. But even easier, just calculate values of  $X(k)$  for  $k$  from 0 to  $(N-1)/2$  and then double the calculated amplitude to account for the alias-frequency part. The result is the spectrum of the sampled signal.

There are times, though, when the samples we are processing with the DFT are not real numbers. In that case, the values in the bins where  $k > N/2$  will not be complex conjugates of the bins  $k < N/2$ ; there will be no simple relationship between a frequency bin and its alias.

### Spectral Leakage

In equation 5 we are limited to integer values of  $k$ . That means we can calculate, in our example, values of  $X(k)$  at 1200 Hz ( $k = 6$ ) and 1400 Hz ( $k = 7$ ), but not at 1300 Hz. But what if there is a frequency component of 1300 Hz in the signal we are analyzing? Simply, part of that signal shows up in the 1200-Hz “bin,” part shows up in the 1400-Hz bin, and smaller parts show up in other nearby bins. This is the error we discussed earlier. It occurs because in our example, a 1300-Hz signal doesn't occur an integer number of times in our 50 samples. That is, if a 1300-Hz

sine wave began at the first of the samples, the last of the samples would not occur just as a cycle of the sine wave was completing. Since the DFT assumes the same 50 samples occur over and over, we get a discontinuity at the end of the set of samples. This abrupt discontinuity causes unexpected frequency components, just as does fast on-off keying of a CW transmitter.

This phenomenon is known as *spectral leakage*, since a signal component at a frequency between bins appears to “leak” into adjacent bins. **Fig 18.10** shows an example DFT with input signals of 1000 and 1300 Hz each at the same amplitude. The 1000-Hz signal falls directly on a bin and therefore produces a single line. But for the 1300-Hz signal, it is clear that not only has the signal leaked into nearby bins, but the actual amplitude of the signal isn't obvious, since the signal is divided up among several bins.

We can improve the situation somewhat by taking more samples. Equation 6 shows that increasing  $N$  moves the bins closer together. Analyzing a signal that falls between two bins will still cause leakage into nearby bins, but since the bins are closer together the spread in frequency will be less. But this doesn't solve the problem of the amplitude variation.

To minimize that problem, we use a technique known as windowing. (This is the mathematical trick we mentioned earlier.) We multiply each sample of the set we're analyzing by a value determined by the position of that sample in the set. Fig 18.11 shows a set of samples before and after windowing. The samples near the beginning and end of the sample set have been reduced in amplitude. The effect of this is to reduce the amount of discontinuity that occurs at the end of the sample set and the beginning of the (assumed) identical following set of samples. Reducing this discontinuity reduces the spectral leakage problem.

You don't get something for nothing, however. Obviously, we have distorted the signal we're analyzing. The effect of this shows up in the resulting spectrum, shown in Fig 18.12. Now each frequency component is leaked across several frequency bins, even if it normally would fall right on a bin. But the leakage is more consistent; you don't get zero leakage at some frequencies and lots of leakage at others. Rather, you get about the same amount at all frequencies. This means that the relative amplitudes of signal components, viewed across several bins of frequency, are nearly the same no matter what the actual frequency of the component. We have traded some resolution for consistent results.

You can't multiply the samples by just any old values to create the windowed set of samples. But a number of window types have been mathematically defined that give the consistent results we are looking for. Among these are the Hamming, Hanning, Blackman and Kaiser windows. Which to use depends in part of how much resolution you are willing to trade for consistency. The more consistent you want the amplitude to be, the less resolution you will get.

### The Inverse DFT (IDFT)

Since we now have a way to determine the frequency content of a set of samples,

it would be handy to also have a way to relate the frequency content back to the original set of samples. This is done with the *inverse DFT* (IDFT):

$$x(n) = \frac{1}{N} \sum_{k=0}^{N-1} X(k) e^{j2\pi nk/N} \quad (9)$$

Except for the fact that now the inputs are the frequency bins,  $X(k)$ , and the result is a sample value,  $x(n)$ , this looks very much like equation 4. A  $1/N$  factor has appeared, and the sign of the exponent has changed. Simplifying via Euler's rule gives us:

$$x(n) = \frac{1}{N} \sum_{k=0}^{N-1} X(k) [\cos(2\pi nk/N) + j \sin(2\pi nk/N)] \quad (10)$$

which looks much like equation 5. So alike are these equations that often the same software routine is used to implement both the DFT and the inverse DFT.

### THE FAST FOURIER TRANSFORM (FFT)

Calculating the entire spectrum of a sampled signal, for all values of  $k$  from 0 to  $N-1$ , requires a lot of calculation. For each value of  $k$ , each of the input samples must be processed by taking a sine and cosine, multiplying by the sample value, and adding that to the resulting sum. In our example, where  $N$  was 50, we have to do this  $N(N-1)/2 = 50(50-1)/2 = 1225$  times! Even on a fast computer, that's a lot of calculation. And the number of calculations increases by the square of  $N$ .

There is help on the way. If we choose a convenient number of samples to analyze, some of the  $\sin(2\pi nk/N)$  and  $\cos(2\pi nk/N)$  values are the same because the sine and cosine functions are periodic. This allows us to factor out the common sine and cosine values from the DFT sum and combine those repeated multiply-and-add operations into one operation. If we're really clever about selecting the right num-

ber of samples, we can do this at a number of places, dramatically reducing the number of calculations we have to do. The result is a fast Fourier transform (FFT) algorithm.

The details of FFT algorithms are beyond the scope of this book, but the result is not: the FFT produces exactly the same results as the DFT, only faster—thus its name. Because it is just a fast DFT, the FFT has the same properties as the DFT, including spectral leakage, so windowing is often used with the FFT as well.

There have been a number of FFT algorithms developed over the years. By far, the most commonly used FFT algorithms are those developed by Blackman and Tukey. These are the *radix-2* algorithms. The convenient number of samples used by these algorithms is a power of two. You can use a radix-2 algorithm on 4 samples, 8 samples, 16 samples, or any number  $2^m$  samples, where  $m$  is an integer 2 or greater. The speed improvement of using a radix-2 FFT increases as the number of samples increases, as shown in Table 18.1.

### THE Z-TRANSFORM

We used equation 3 to mathematically describe the algorithm of Fig 18.6. This equation is useful, but it's hard to manipulate algebraically because it has no common variables:  $x(n)$  is a different value from  $x(n-1)$ . Manipulating the equations that represent DSP systems with algebra is useful because, if we can do it, we can find different ways of implementing the same system, and some algorithms we find will be easier to implement than others. To get the difference equation into a form we can manipulate, we will use the *z-transform*. The mathematics that underlie the *z-transform* are outside the scope of this book. We will concentrate on the mechanics of using *z-transforms*.

Earlier, we labeled our delay block in the flow diagram with  $z^{-1}$ . This is because  $z^{-1}$  represents a one-sample delay in a

Fig 18.12—The DFT of a 1000-Hz signal, sampled at 20 kHz and windowed. Note that, even though 1000 Hz falls directly on a frequency bin, the signal is spread over several adjacent bins.

Table 18.1

#### Speed Improvement of the Radix-2 FFT

Number of points (N)	Number of complex multiplications in DFT = $N^2$	Number of complex multiplications in radix-2 FFT = $(N/2)\log_2 N$	Improvement factor
4	16	4	4.0
8	64	12	5.3
16	256	32	8.0
32	1024	80	12.8
64	4096	192	21.3
128	16384	448	36.6
256	65536	1024	64.0
512	262144	2304	113.8
1024	1048576	5120	204.8

z-transform expression. To convert the difference-equation term  $x(n-1)$  to its z-transform, we take the z-transform of  $x(n)$ , which is  $X(z)$ , and multiply it by the one-sample delay,  $z^{-1}$ . The result is  $X(z)z^{-1}$ . If the term is  $x(n-2)$ , we multiply  $X(z)$  by two delays:  $X(z)z^{-1}z^{-1} = X(z)z^{-2}$ . If we perform this operation on all of the terms of equation 3, we get:

$$Y(z) = X(z) + 2X(z)z^{-1} - 3Y(z)z^{-1} \quad (11)$$

Now we can factor out the  $X(z)$  and  $Y(z)$  terms and solve the equation for  $Y(z)/X(z)$ , which we denote as  $H(z)$ :

$$H(z) = \frac{Y(z)}{X(z)} = \frac{1 + 2z^{-1}}{1 + 3z^{-1}} \quad (12)$$

This equation is known as the *transfer function* of the system. It can be expressed in a slightly different, but equivalent, form:

$$H(z) = \frac{1 + 2z^{-1}}{1 + 3z^{-1}} \times \frac{z}{z} = \frac{z + 2}{z + 3} \quad (13)$$

In working with DSP systems, you will often encounter transfer functions like the ones above. To implement the system described by the transfer function, you may have to convert the function back to a difference equation. You do this from a transfer function like that of equation 12 by cross multiplying the two sides, then bring the  $Y(z)$  term to one side and all other terms to the other side to get a result like equation 11. Finally, take the *inverse* z-transform of each term, turning, for example,  $X(z)z^{-1}$  into  $x(n-1)$ . From the resulting difference equation, you can either construct a flow diagram or just write your program directly.

## IMPULSE RESPONSE

One of the important measures of how a DSP algorithm acts is its *impulse response*. This is the output sequence of a system when the input is a sequence of values equal to 0, followed by a single value equal to 1, followed again by values of zero. This input sequence is called the *unit-impulse sequence*, denoted by  $\delta(n)$ :

$$\delta(n) = \{..., 0, 0, 0, 1, 0, 0, 0, ...\} \quad (14)$$

Normally,  $n$  is zero when the sequence value is 1. The preceding zero values in the sequence are at  $n = -1$ ,  $n = -2$  and so

on, while the following zero values are at  $n = 1$ ,  $n = 2$  and so on. The output of a system when this sequence is input—its impulse response—is denoted as  $h(n)$ . For the system of equation 3, the impulse response is:

$$\begin{aligned} h(n) &= 0 \text{ for } n < 0 \\ h(0) &= 1 + 2(0) - 3(0) = 1 \\ h(1) &= 0 + 2(1) - 3(1) = -1 \\ h(2) &= 0 + 2(0) - 3(-1) = 3 \\ h(4) &= 0 + 2(0) - 3(3) = -9 \\ h(5) &= 0 + 2(0) - 3(-9) = 27 \\ &\dots \end{aligned}$$

Here, we assume the output was 0 when we started. Note that the output continues to be nonzero indefinitely for  $n > 0$ , even though all future inputs are 0. This is an example of an *infinite* impulse response (IIR). If the output had returned to zero and stayed there, it would be a *finite* impulse response (FIR). The infinite nature of the impulse response of this example comes from the feedback of the output signal into the system. If no feedback exists in the system, the impulse response will be finite.

The usefulness of the impulse response is twofold. First, you can determine exactly how an algorithm will respond to a given input sequence by knowing the algorithm's impulse response. The logic is this: any particular input sample will cause an output that is equal to the impulse response times the input value. If the input value were 1, the output generated by that input would be exactly the impulse response. If the input value were 2, the output values would be doubled. But in a real signal, the input samples are not preceded and followed by an infinite number of zero values; they are preceded and followed by other input sample values. So the output of a system is the sum of the current input sample value times the impulse response, plus the value of the preceding input sample times the impulse response, with that output shifted by one sample time. And the earlier samples contribute shifted, weighted copies of the impulse response as well. The output sequence for a particular input sample,  $x(n)$ , is:

$$y(n) = x(n)h(0) + x(n-1)h(1) + x(n-2)h(2) + \dots$$

We can write this in compact form as follows:

$$y(n) = \sum_{k=-\infty}^{\infty} x(n-k)h(k) \quad (15)$$

Equation 16 is called the *convolution sum*, and the process of taking this sum is called *convolution*. The value of  $k$  must be an integer. While  $k$  runs from  $-\infty$  to  $+\infty$ , it is only necessary to compute the sum for values of  $k$  for which  $x(n-k)h(k)$  is not 0. In our example system of equation 3,  $h(k)$  is zero for all values of  $k$  less than 0. But, since our example impulse response is infinite, we would have to compute the sum for values of  $k$  up to the point where  $h(k)$  becomes zero, if that ever happens. (It doesn't, in this example.) Some mathematics can be used to show that equation 15 is equivalent to:

$$y(n) = \sum_{k=-\infty}^{\infty} x(k)h(n-k) \quad (16)$$

We can use these equations interchangeably.

The second useful characteristic of the impulse response is that the frequency response of the algorithm can be obtained by taking the DFT of the impulse response. This is a powerful tool for analyzing a DSP system. Of course, if the impulse response is infinite, you would theoretically need an infinitely long DFT—and an infinite amount of time to calculate it! But in practice, useful IIR systems have impulse responses that approach 0 as  $k$  gets large, although they never quite get there. So a very good approximation of the frequency response can be gotten by taking enough of the impulse response sequence that the remaining values are all very close to zero and performing the DFT on that truncated sequence. For an FIR system, on the other hand, an exact frequency response can be obtained by taking the DFT of its impulse response sequence.

The impulse response sequence of an FIR system may be too short for a useful DFT. If, for example, the sequence has only 20 nonzero terms, a 20-point DFT would result in only 10 frequency bins between 0 and  $F/2$ . In this case, we simply append zero values to the end of the impulse response sequence to create the desired number of samples, then take the DFT. This approach also allows us to create a sequence length that is usable with an FFT algorithm, speeding our analysis.

# Digital Filters

Filters make up one class of system that is of special interest in DSP. As we have seen, an algorithm that has a particular impulse response also has a particular frequency response, determined by the DFT of the impulse response. So, by creating a system with the proper impulse response we can achieve a particular frequency response—a filter. There are several reasons why DSP filtering might be preferable to using analog filters. The principal reasons are based on the precise, unchanging nature of digital systems. In general, more stringent filter requirements—steeper roll-off in the frequency response, or less distortion in the phase response—call for more complex filters. As a filter gets more complex—adding inductors and capacitors in the case of analog filters, or adding additional delay elements in the digital case—the sensitivity of the filter's response to small errors in the element values becomes more severe. Thus for analog filters, precise values of resistance, inductance and capacitance must be maintained if the filter is to operate as designed. Establishing those precise component values is difficult, and maintaining them during temperature variations and aging of the components is more so. DSP filters, on the other hand, are unchanging. The “component” values consist of numbers stored in a computer, which are not susceptible to temperature changes or aging. For that reason, highly complex filters that would not be viable in the analog realm are easily formed by DSP algorithms.

DSP filters can be broadly divided into two classes, depending on whether the impulse response of the filter is finite or infinite. Each class has its advantages and disadvantages; which to use will depend on the requirements of the filter and the system being used.

Designing a filter begins with specification of the desired filter response. The specification must describe the cut-off frequency (or frequencies) of the filter, the allowable amplitude variation in the pass band and the amount of attenuation in the stop band. Refer to the **Filters** chapter for background on filter response specification. In specifying DSP filters, we often use normalized frequencies, since the filter design depends on the ratio of the filter cut-off frequency to the sampling frequency, rather than the actual signal frequency.

Just as the sampled signal includes alias components around the harmonics of the sampling frequency, so too does the frequency response of a DSP filter. It is not possible to use a DSP filter to filter out

Fig 18.13—Structure of an FIR filter.  $N$  is the number of delay elements, or *taps*.

these alias components. (Unless the sampling rate is changed, as described below.) They exist because of the nature of a discrete-time signal, and a digital filter can't change that. So, a filter that passes a particular frequency also passes all aliases of that frequency.

## FIR FILTERS

The basic structure of an FIR filter is shown in Fig 18.13. This kind of filter is sometimes referred to as a *transversal* filter. The difference equation of this filter can be determined by inspecting the flow diagram:

$$y(n) = x(n)h(0) + x(n-1)h(1) + \dots + x(n-[N-1])h(N-1)$$

Or, writing it in more compact form:

$$y(n) = \sum_{k=0}^{N-1} x(n-k)h(k)$$

Note that this equation is the convolution sum, just like equation 15, except that since  $h(k)$  is a finite-length sequence,  $k$  runs from 0 to  $N-1$ . Thus the FIR filter directly implements convolution.

The impulse response of the filter of Fig 18.13 is easy to find by feeding the unit-impulse sequence (equation 14) into the filter. The single nonzero input sample first appears at the input, where it is multiplied by the coefficient  $h(0)$ . Since this sample was preceded by an infinite number of 0 values, all of the delay elements have 0 at their outputs. Only the multiplied input sample contributes to the output;  $h(0)$  is the result. When the next sample arrives, the 1 is shifted to the output of the first delay element, to be multiplied by  $h(1)$ . All other sample values being 0,  $h(1)$  is the resulting output. On succeeding samples, as 0 values arrive at the input, the 1 value is shifted successively to each delay-element output, to be multiplied by  $h(2)$ ,  $h(3)$ , and so on, up to  $h(N-1)$ . Thus the impulse response of the filter is simply equal to the coefficients  $h(0)$  to  $h(N-1)$ .

The trick, of course, is to find the particular impulse response that gives the desired frequency response for the filter. There are two questions: how many filter elements, or *taps*, are needed? And what

are the proper coefficient values to use to give the desired response? In general a longer filter—a higher value of  $N$ —can provide steeper roll-off in the frequency response. In practice, most FIR filter design approaches start by estimating the number of taps needed, then redesigning the filter if the number of taps selected is found to be too few or too many. Calculating the required coefficients, on the other hand, is more exact, but requires a lot of calculation.

Finding proper coefficient values is complicated by one other issue. We would like the impulse response to be symmetrical about its center. That is, we want  $h(0) = h(N-1)$ ,  $h(1) = h(N-2)$ ,  $h(2) = h(N-3)$  and so on. We want this because an FIR filter with a symmetrical impulse response has a constant delay at all frequencies. This constant delay, which can also be stated as a linear phase response, means that the filter will not introduce phase distortion to the signal. For many uses, especially in digital data communication, this is a crucial filter requirement. Not only is the delay of a symmetrical FIR filter constant, it is easily calculated:

$$d = \frac{N-1}{2}T \quad (17)$$

where  $d$  is the filter delay in seconds,  $N$  is the number of taps, and  $T$  is the sampling interval in seconds.

One feasible approach to designing an FIR filter relies on the facts that the DFT of the impulse response equals the frequency response and that the IDFT can transform a frequency-domain sequence to the time domain. Thus if we take the IDFT of the desired frequency response, we get the needed impulse response. That works, but it suffers from the same discontinuity problem as the DFT itself. In performing the DFT of a signal, this problem shows up as spectral leakage. In the case of finding an impulse response for our FIR filter, it shows up as a ripple in the frequency response. Only at the exact frequencies of the bins of the specified frequency response do we get the correct result; between those bins we get variations in the response. We can attack that problem in the same way we attacked spectral leakage—

with windowing. But in doing so, we modify the frequency response, just as we spread out the signal components over several bins in the DFT. That makes it more difficult to get the exact frequency response we want without trial and error.

A better design results from using a complicated design algorithm developed by Parks and McClellan. This approach results in an *equiripple* design, where all of the passband ripples are of the same amplitude, as are all of the stopband ripples.

Since finding the needed coefficients for a given filter design requires so much calculation, it is a good task for a computer. And DSP filter-design programs are easily available at low cost. For that reason,

we will not dwell on the design mathematics; use of a filter-design program to calculate the coefficients is by far the most desirable approach. The Bibliography at the end of this chapter lists some filter-design software tools.

### IIR FILTERS

While FIR filters have some exceptionally useful qualities, particularly linear phase response, they require a large number of taps—and a lot of computing power—to implement sharp filters. An IIR filter, on the other hand, can give an equivalent frequency response using fewer calculations. What it will not provide is linear phase response. In circumstances where the computational requirements are

of more concern than linear phase response, IIR filters may be desirable.

Unlike the FIR filter, the IIR filter includes feedback—that's what makes its impulse response infinite. Its difference equation shows this:

$$y(n) = A_0x(n) + A_1x(n-1) + \dots + A_jx(n-j) - B_1y(n-1) - B_2y(n-2) - \dots - B_ky(n-k) \quad (18)$$

IIR filters can be implemented using several different algorithms, or structures, as shown in Fig 18.14. The structure at A is most easily understood, as it can be drawn directly from inspection of the difference equation.

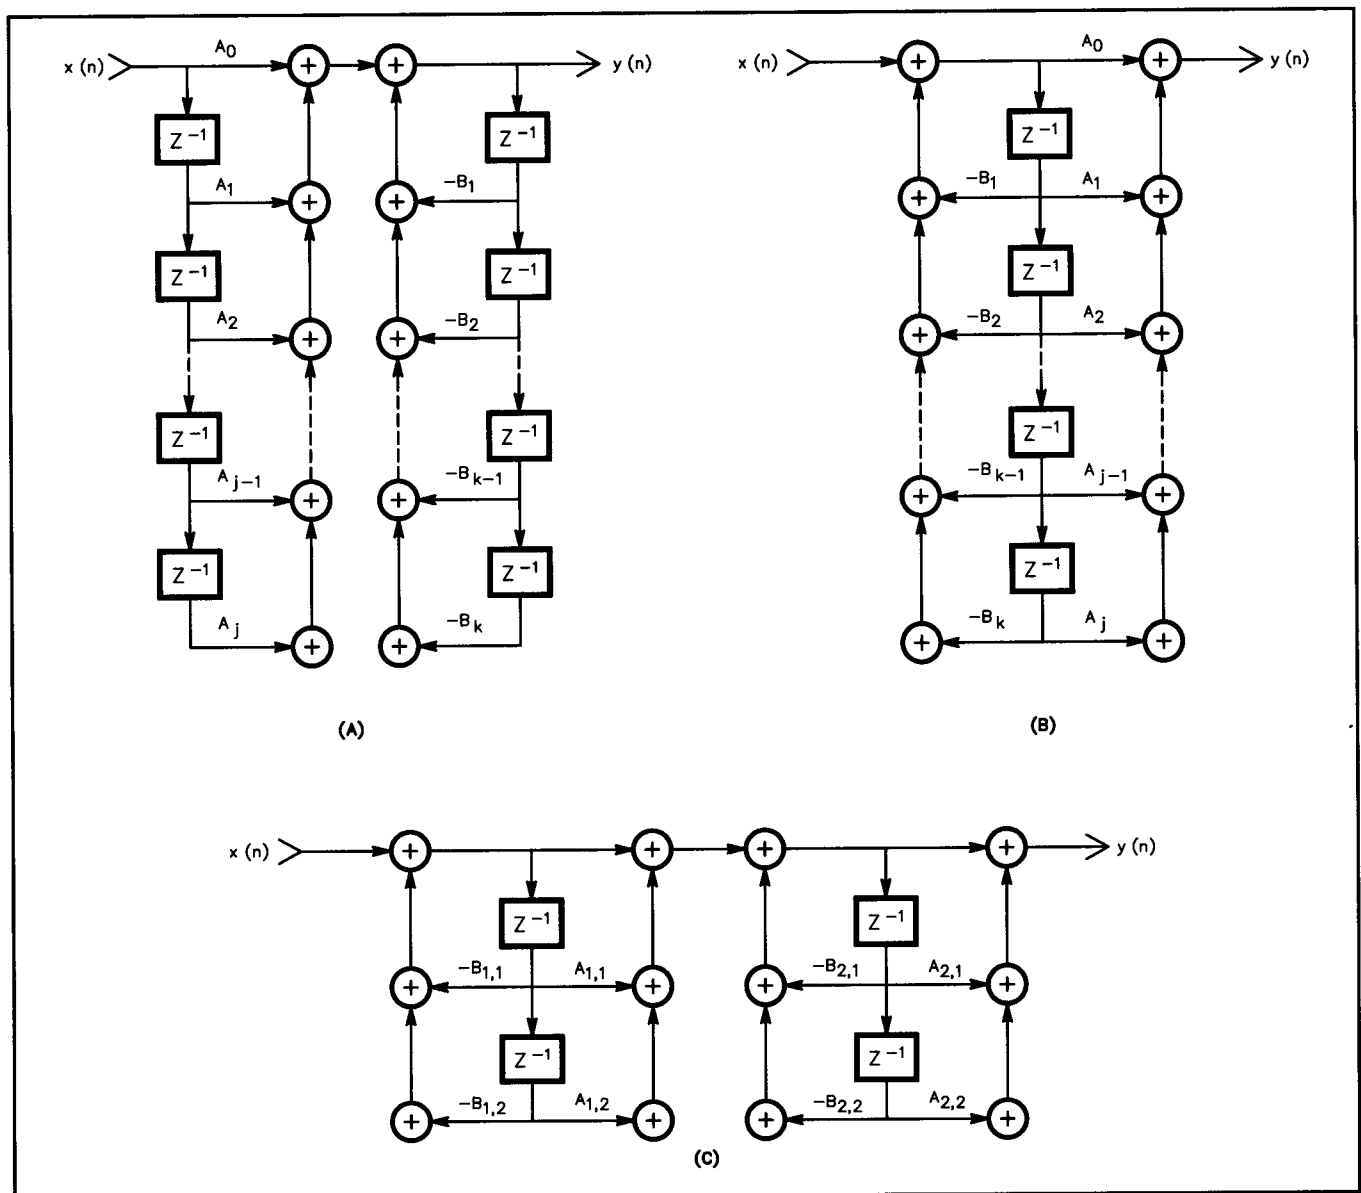

Fig 18.14—IIR filter structures. At A is the direct-form (I) structure; B is the direct-form (II) structure; and C is the cascade structure.

It may not be obvious, but the structure of Fig 18.14B acts just like the structure in A. It contains fewer delay elements, though, which reduces the amount of storage needed to keep the delayed sample values.

Often, a filter-design program used to design IIR filters will give its result in the form of a transfer function. As explained above, the transfer function can be translated to a difference equation, from which the filter can be drawn or implemented. There is a catch, though. As IIR filters get larger, with larger values of  $j$  and  $k$  in equation 18, finite-word-length effects become a problem. The coefficients used in the filter cannot be represented exactly in the computer; they can only be approximated by the number of bits used to represent numbers in the machine. While this isn't a big problem for FIR filters, the feedback inherent in IIR filters makes it

a concern. Small errors in the coefficients may, after being fed back through a number of delay stages to add to the output many times, produce undesirable effects. To combat this problem, the structure shown in Fig 18.14C may be used. Here, the large filter is broken up into a series of second-order (two delays) filters. Cascading these smaller filters results in the overall response desired. To calculate the coefficients of these smaller filters requires applying some algebra to the transfer function of the larger filter. The desired result is a transfer function of the form:

$$H(z) = \frac{A_{10} + A_{11}z^{-1} + A_{12}z^{-2}}{1 + B_{11}z^{-1} + B_{12}z^{-2}} \times \frac{A_{20} + A_{21}z^{-1} + A_{22}z^{-2}}{1 + B_{21}z^{-1} + B_{22}z^{-2}} \times \dots \quad (19)$$

Good filter-design programs will calculate the coefficients of the cascaded sections for you.

The most common design technique used for IIR filters is to design an equivalent analog filter, then transform it to a digital filter. Because of this, many IIR filter-design programs require you to specify the filter shape from among the types of analog filters: Butterworth, Chebyshev or elliptical. See the **Filters** chapter for a description of these filter types.

We assume when analyzing the operation of an IIR system that the delay elements initially store 0 values, until an input signal arrives. Because the impulse response is infinite, initial nonzero values may have long-lasting effects on the output signal. For this reason, any implementation of an IIR filter or system should start by zeroing the storage elements before processing begins.

## Nonlinear Processes

In analog electronics, we amplify signals, sum them and pass them through frequency-selective circuits. Each of these linear operations has its DSP equivalent, as we've seen. But analog electronics also includes *nonlinear* processing of signals. Examples of nonlinear processes are rectification, clipping, limiting and mixing. One thing that distinguishes nonlinear from linear processing is that in linear systems, the same frequencies that are input to the system appear at the output, possibly with changes in amplitude and/or phase, but without the appearance of frequency components different from those at the input.

As discussed in the **Mixers** chapter, nonlinear processes result in the multiplication of one signal by another (or several others), either explicitly, as in a mixer circuit, or implicitly, as in a nonlinear amplifier or a diode. The same multiplication process is used in DSP, but here we have to be very careful when performing nonlinear operations. A sampled signal comprises not only the frequency of the original signal, but also components around the sampling frequency and its harmonics, as shown in Fig 18.3. Performing a nonlinear operation on sampled signals, therefore, requires that we consider the resulting frequency components and how they will appear in the sampled spectrum.

We begin by taking a closer look at the spectrum of a sampled signal, shown in

**Fig 18.15.** Here, the input signal has one frequency component (it's a sine wave),  $f_1$ , which shows up in the sampled spectrum at  $f_1$ ,  $-f_1$ ,  $F \pm f_1$ ,  $-F \pm f_1$  and so on. Notice that the spectrum between  $-F/2$  and  $0$  is exactly like the spectrum from  $F/2$  to  $F$ . This is inherent in the sampling process and will always be the case. Because of this, we can concentrate on the spectrum from  $-F/2$  to  $F/2$ , knowing that all of the harmonic spectra are simply copies of this spectrum. When we generate new fre-

quency components, by nonlinear operations, that fall above  $F/2$ , we can treat them as though they "wrap around" to the negative side, between  $-F/2$  and  $0$ . Generated frequency components more negative than  $-F/2$  wrap around to the positive spectrum.

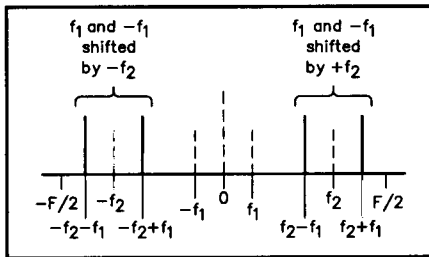

Now consider what happens when we multiply two sine-wave signals together. This is done by taking each sample of one signal and multiplying it by the corresponding sample of the other signal, as shown in Fig 18.16. In analog electronics,

**Fig 18.15**—The spectrum of a sampled signal can be analyzed by referring to only the part from  $-F/2$  to  $F/2$  ( $F$  is the sampling frequency), the unshaded part of this diagram. The spectrum around each harmonic of the sampling frequency is a copy of the unshaded spectrum.

**Fig 18.16**—Mixing two sine waves is the same as multiplying them. For real-number signals, this results in two signals, the sum and difference of the input signals.

**Fig 18.17**—The mixing process can be thought of as shifting one signal's frequency components up by the positive frequency of the other signal and down by the negative frequency of the other signal.

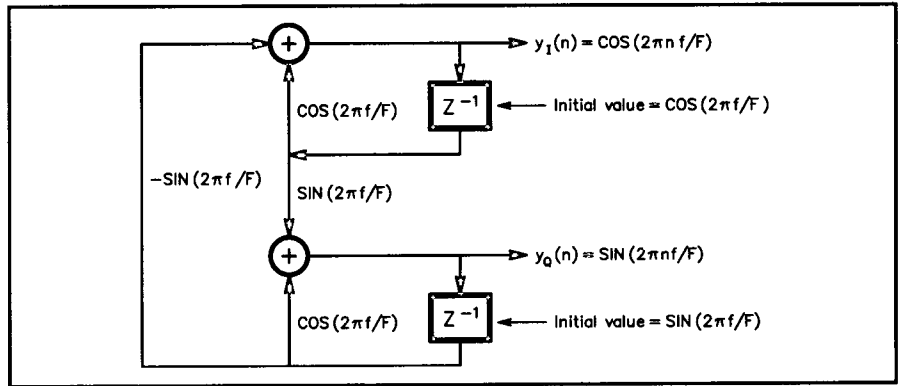

**Fig 18.18**—If the frequency shift caused by mixing causes a component to exceed the  $F/2$  boundary, the signal will wrap to the opposite end of the spectrum, as shown here.

we learned through trigonometry that multiplying two sine waves produces sum and difference frequencies. That's true here, too, but we'll look at it in a different, equally valid, way, shown in **Fig 18.17**. We will consider that the positive frequency component of one signal,  $f_2$ , shifts the other signal,  $f_1$ —both its positive and negative frequency components—up in frequency by the frequency value of  $f_2$ . Similarly, the negative frequency component of  $f_2$  shifts the components of  $f_1$  down by the same amount. The result is four frequency components, two positive and two negative, as shown in **Fig 18.17(b)**. We could have chosen  $f_2$  as our shifted signal and  $f_1$  as the amount to shift by and gotten the same resulting spectrum.

**Fig 18.18** shows the result if this process ends up shifting a signal beyond the  $F/2$  limit, wrapping it around to the other side of the spectrum. Note that, in this case, the wrapped components appear at frequencies different from where they would be if we had done the mixing with analog electronics. This is because of aliasing, which occurs when a frequency component exceeds  $F/2$ .

An example shows why analyzing the effect of a nonlinear operation in this way is important. We can simulate a half-wave rectifier by replacing all of the negative-amplitude samples of a signal with zeroes.

**Fig 18.19**—A quadrature sine-wave oscillator provides two sine waves, with a  $90^\circ$  phase difference between them.

We might be tempted to do that to, for example, demodulate an AM signal. But a look at the spectral result will show this to be a poor technique. Mathematically, half-wave rectification of a sine wave is like multiplying the input signal by a square wave that has the same frequency as the input signal and amplitude values of +1 and 0. Spectrally, the square wave comprises a dc component and frequency components at the fundamental and all of the odd harmonics of the fundamental. So, the result of rectification is to create frequency-shifted copies of the input signal around 0 Hz and around the odd harmonics of the square wave. Some of these harmonics will show up at frequencies above  $F/2$ , no matter what  $F$  we choose, and these components will alias into the spectrum below  $F/2$ . The result will be nothing like what we get with a physical half-wave rectifier, and most likely nothing like what we wanted. The lesson is that we have to be very careful that our nonlinear operations do not generate unwanted frequency components that show up as aliases. That doesn't mean we can't *do* nonlinear operations, just that we need to exercise caution.

## COMPLEX AND ANALYTIC SIGNALS

As we've seen, multiplying two signals shifts the positive and negative components of one of the signals in two directions, generating two sets of frequency components. In analog electronics, we deal with this reality by using filters to eliminate the unwanted second component, leaving only the desirable one. We can do that in DSP, too, but there is another way that is often better.

In all of our preceding discussion, each positive frequency component was mirrored by a corresponding negative frequency component. This is a characteristic of any signal that is composed of

amplitude values that are only real numbers. But if we can create a signal that is composed of *complex* amplitude values, this need not be the case. In fact, a complex signal can have only positive-frequency components or only negative-frequency components. Such a signal is called an *analytic* signal.

Consider the usefulness of such signals. If we multiply together two single-frequency

signals that have only positive-frequency components, the resulting spectrum is simply a frequency component at the sum of the frequencies of the two signals; there are no negative frequencies present to get shifted into the positive frequency range. This gives us a pure frequency

shift, rather than the sum-and-difference result of multiplying two real-value signals.

A sampled, single-frequency analytic signal has the form:

$$x(n) = A \cos(2\pi n f / F) + j A \sin(2\pi n f / F) \quad (20)$$

where  $A$  is the peak amplitude of the sine wave,  $f$  is the frequency of the signal and  $F$  is the sampling frequency. This signal has only positive frequencies. A signal of the form:

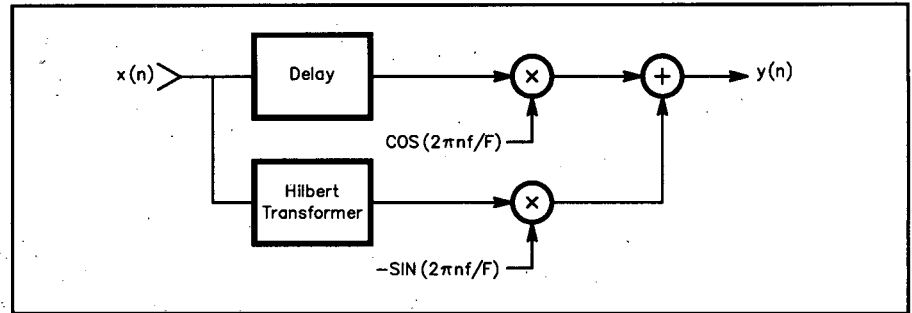

$$x(n) = A \cos(2\pi n f / F) - j A \sin(2\pi n f / F) \quad (21)$$

has only negative frequencies. An analytic signal that comprises multiple positive-frequency components is made up of a sum of components of the form of equation 20. That means that the imaginary part of the signal is equal to the real part, but shifted  $90^\circ$  at all frequencies.

In a computer, such as a DSP system, we handle complex numbers by operating on the real and imaginary parts separately. We call the real part of the analytic signal the *I* (in-phase) component and the imaginary

**Fig 18.20—Generating an analytic signal from a sampled input signal requires passing the input through a Hilbert transformer filter to generate the Q (quadrature) channel. The I (in-phase) channel is created by passing the signal through a delay equal to the fixed delay of the Q channel.**

**Fig 18.21—Frequency shifting a signal to produce a real-number result doesn't require calculation of the imaginary part of the output, but the imaginary part of the analytic signal does play a part in finding the real part of the output.**

part the Q (quadrature) component. Complex arithmetic dictates that, when we add two complex values, we add the real parts together then we add the imaginary parts together; we still keep the real result separate from the imaginary result. Complex multiplication is a bit more involved. We can multiply two complex numbers like so:

$$(a + jb)(c + jd) = (ac - bd) + j(ad + bc) \quad (22)$$

It is easy to generate a single-frequency analytic signal like that of equation 20. Referring to the section on Generating Sine Waves, we can use the phase-accumulator method to generate the I component of the signal, then subtract  $90^\circ$  from the current phase angle and compute the output value for that angle to get the Q component.

There also is an oscillator structure, shown in Fig 18.19, we can use to generate the I and Q components for a single-frequency complex signal.

## HILBERT TRANSFORMERS

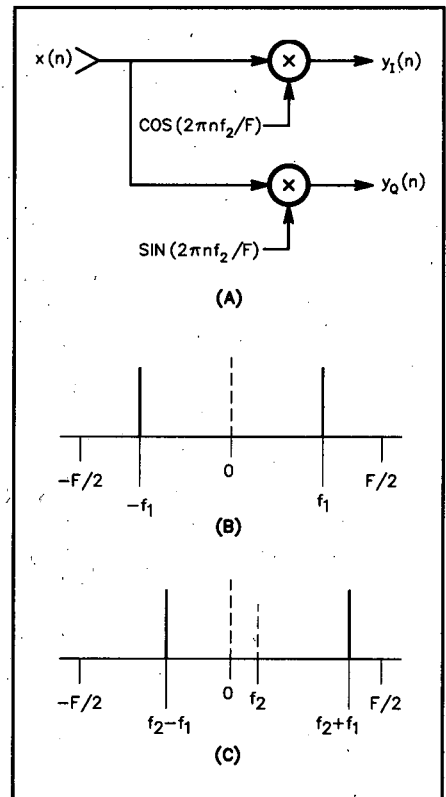

But what if we want to create an analytic signal from a sampled, real signal? We need to shift all of the frequency components of the sampled signal by  $90^\circ$ . Fortunately, in DSP we have a straightforward way to do that: the *Hilbert transformer*. Recall that in the FIR Filters section we noted that an FIR filter with a symmetrical impulse response exhibits a constant delay of  $(N-1)/2$  sample periods. It turns out that an FIR filter with an *antisymmetrical* impulse response—that is,  $h(0) = -h(N-1)$ ,  $h(1) = -h(N-2)$ , and so on—produces a delay of  $(N-1)/2$  and a shift of  $90^\circ$  at all frequencies. This is exactly the kind of filter we need to create the Q component of our analytic signal!

A system using a Hilbert transformer to create an analytic signal is shown in Fig 18.20. Since the Hilbert transformer

includes not only a  $90^\circ$  phase shift, but also a fixed delay of  $(N-1)/2$  sample periods, we need an  $(N-1)/2$  delay in the I channel so that the difference between the two channels becomes solely the  $90^\circ$  phase shift. We also need to have the amplitudes of the two channels the same, so the I channel should have the same frequency response as the Hilbert transformer in the Q channel. A Hilbert transformer filter can be designed by most FIR filter-design programs.

When you use analytic signals to perform frequency shifting, you may at some point end up with a signal you want to output to the D/A converter. The D/A, of course, handles only real numbers. Feeding just the real part of the analytic signal into the D/A produces an output waveform that has both positive and negative components, but that's what we expect of a real signal. So, once the processing of the analytic signal is complete, we simply discard the Q-channel signal and use the I-channel values for our output. This may allow us to skip computing the output Q-channel values altogether, as shown in Fig 18.21. Note, though, that we do need the Q channel to compute the real part of the frequency-shifted signal, because the multiplied real values include terms from the imaginary part, as shown in equation 22.

A complex signal can also have positive and negative frequencies that are not mirror images of one another. One way of generating such a signal is shown in Fig 18.22. Here, a real input signal is formed into a complex signal and frequency shifted, both at the same time. (This is an example of a *half-complex mixer*. It takes in a real signal and produces a complex signal.) With a complex signal such as this, we cannot simply output the real part and expect only the positive frequencies to generate mirror

**Fig 18.22—Generating a frequency-shifted complex signal from a real signal can be accomplished by multiplying the real signal by a single-frequency analytic signal, as shown at A. Note that the resulting spectrum, shown at B, has both positive and negative frequency components, but they are not mirror images of one another.**

images; the negative frequencies will have mirror images in the positive part of the spectrum, too. Still, such complex signals can be useful at intermediate steps in the processing, before a real signal is output.

# Demodulating Signals

One important application of DSP to Amateur Radio is in the demodulation of signals. Although DSP hardware isn't quite yet up to the task of processing directly at amateur operating frequencies, it can demodulate signals at audio and low-IF. An application of audio-frequency demodulation is in the field of modems for digital communication. These devices modulate an audio signal to send digital data and demodulate the received signal to recover the digital data. We also are seeing DSP used more and more as the principal demodulation means in communication receivers, where the DSP operates at a low IF that is mixed from the operating frequency by analog electronics.

There are many algorithms you can use to demodulate each type of modulated signal. We present here a sample of some of the more commonly used techniques. We begin by generating quadrature signals at *baseband* (centered on 0 Hz). From these, we will detect the modulating waveform. The incoming signal consists of a carrier frequency that is modulated in some way. To generate our quadrature baseband signals, we multiply the incoming signal by two signals that are each at the carrier frequency but 90° different in phase. This scheme, shown in Fig 18.23, is similar to the half-complex mixer described above. It shifts the signal so

that it is centered at 0 Hz in both the I and Q channels. A low-pass filter removes the unwanted negative-frequency components, along with, possibly, filtering out signals that lie outside the bandwidth of the desired signal. The I and Q channel sequences can then be used to demodulate the signal.

## AM DEMODULATION

One's first inclination is to demodulate an AM signal by rectification of the signal. But, as explained in the Nonlinear Processes section, that's a technique fraught with peril. A better way is to use the I and Q channels developed in Fig 18.23. These two signals together describe (mathematically) the incoming signal as a rotating vector, with the I channel holding the x-axis (real) component of the vector and the Q channel holding the y-axis (imaginary) part. (See Fig 18.24.) All we need to do is to find the length of the vector for each sample of the signal; the vector length is the amplitude of the signal, which is what we want to detect.

Finding the length of the vector can be done using the Pythagorean theorem:

$$|y(n)| = \sqrt{[I(n)]^2 + [Q(n)]^2} \quad (23)$$

For each sample, then, we calculate equation 23, using the current I- and Q-channel sample values. We can filter  $y(n)$  to remove the dc component and feed the

result to our output D/A converter to produce the detected audio.

Since DSP chips, and computers in general, don't usually provide a square-root function, the program to implement AM detection will have to calculate the square root. This is most speedily done using a look-up table, although a square-root algorithm can be used if desired.

## FM DEMODULATION

FM detection is a bit trickier than AM detection. The method described here begins by detecting not the frequency, but the phase of the incoming signal. Since the I and Q channels describe the incoming signal as a vector, we can find the phase of the signal by finding the angle of the vector described by the I and Q signals. This is done using trigonometry:

$$y_p(n) = \tan^{-1} \left[ \frac{Q(n)}{I(n)} \right] \quad (24)$$

Once again, we will most likely use a look-up table to find the arc tangent.

This scheme performs phase detection of the signal, not frequency detection. We can convert the output to a demodulated FM signal by passing the result of equation 24 through a *differentiator* filter. FIR filter design programs can usually generate a design for a differentiator filter. The resulting system is shown in Fig 18.25.

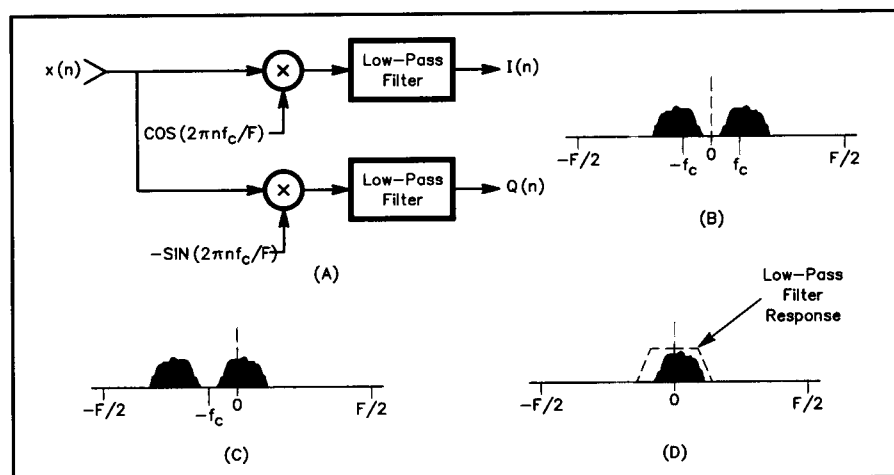

Fig 18.23—Demodulation begins by generating baseband I and Q channels. The technique is shown at A, where an analytic signal at the carrier frequency,  $-f_c$ , multiplies the input signal, whose spectrum is shown at B. The result of this multiplication is the spectrum at C. This signal is low-pass filtered to remove the unwanted alias spectrum and, possibly, unwanted signals near the desired passband. After filtering, the spectrum at D results.

Fig 18.24—The I and Q channels together describe the signal as a rotating vector. From the I and Q sample values we can compute the instantaneous amplitude or phase of the signal.

## SSB DEMODULATION

The technique we will use for SSB demodulation has long been known in analog electronics. Called the *phasing method*, it is shown in Fig 18.26. The Q-channel signal is passed through a Hilbert transformer FIR filter to further shift it by  $90^\circ$ . The I channel is delayed by an amount equal to the fixed delay of the Q-channel filter,  $(N-1)/2$  samples. If an odd number of taps is used in the Q-channel filter, the needed delay of the I channel will be an integral number of samples. The delayed I channel and the transformed Q channel are then summed.

We originally generated our I and Q channels by mixing the incoming signal with a signal at the carrier frequency. That places the lower sidebands below 0 Hz and the upper sidebands above 0 Hz. Summing the two channels causes the positive frequencies in the signal to sum to zero, while the negative frequencies add. Since the result of the summation is a real signal, these resulting frequencies are mirrored in the positive part of the spectrum. What we have done is eliminate the part of the signal above 0 Hz—the upper sideband part—while preserving the part of the signal below 0 Hz—the lower sideband part. If instead of adding the two channels we subtract them, we preserve the upper sideband part and eliminate the lower sideband part.

Fig 18.25—FM demodulation is performed by phase detecting the signal via the arc tangent function, then passing the result through a differentiator.

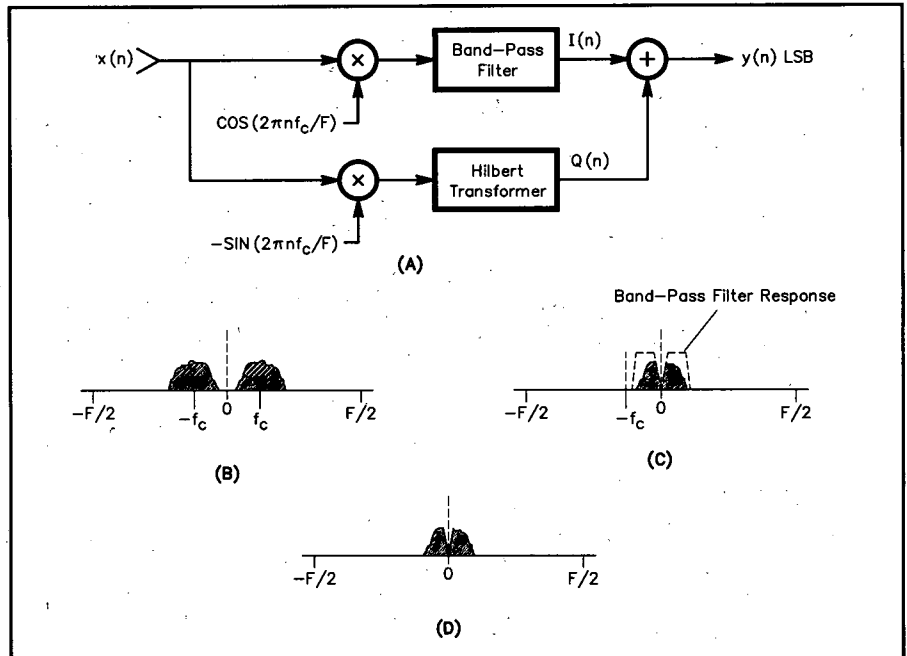

Fig 18.26—The phasing method of SSB demodulation, as implemented in DSP. The system is shown at A. The input signal (B) is mixed with an analytic signal at the carrier frequency,  $-f_c$ , then the Q channel is phase-shifted via a Hilbert transform, while the I channel is band-pass filtered with a delay equal to that of the Q-channel filter, producing the spectrum at C. Summing the two channels gives the spectrum at D, which represents the lower sideband of the original signal.

## Decimation and Interpolation

It is often useful to change the effective sampling rate of an existing sampled signal. For example, say you have a system sampling at a 21-kHz rate and you want to filter a 600-Hz signal with a 100-Hz-wide band-pass filter. You could design a filter to do that directly, but it would likely be a very complex filter requiring a lot of processor power to implement. The filter would be easier if the sampling rate were lower, say 7 kHz, since the normalized filter width would be wider. (A 100-Hz-wide filter for a 21-kHz signal would have a normalized width of  $100/21000=0.0048$ , while if the sampling rate were 7000 Hz the normalized width would be  $100/7000=0.014$ .) You may not be able to change the *actual* sampling rate—perhaps the available antialiasing filter won't allow sampling at a lower

rate—but you can change the *effective* sampling rate by processing.

### DECIMATION

The reduction of the sampling rate by processing is known as *decimation*. The procedure is simple: just throw away the unwanted samples. For example, to reduce the effective sampling rate from 21-kHz to 7 kHz, throw away 2 out of 3 of the incoming samples. This procedure allows you to divide the sampling rate by any integer value.

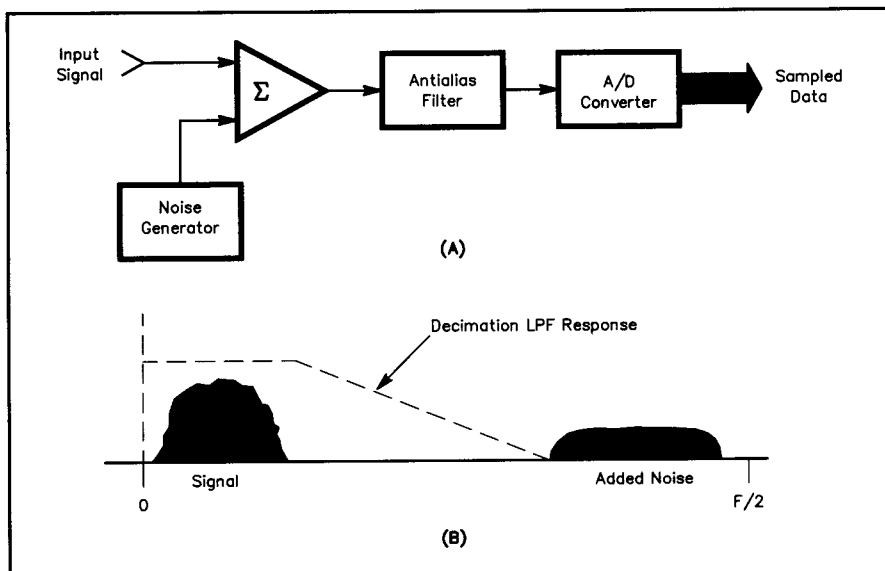

Of course, throwing away samples changes the signal being processed. Fig 18.27 shows the effect of decimating a signal by a factor of 3 by keeping only every third sample.  $F_1$  is the original sampling rate, and  $F_2$  is the new sampling rate,  $1/3$  the original. The resulting signal is indis-

tinguishable from a signal that was sampled at  $1/3$  the original sampling rate. This means that it contains alias components around the harmonics of  $F_2$ . More importantly, it means that any signals present in the original sampled signal at frequencies above  $F_2/2$  may alias into the range 0 to  $F_2/2$ , just as they would have if the signal had actually been sampled at  $F_2$ . To eliminate this possibility, it is necessary to digitally filter out any such signals *before* performing the decimation. This can be done with a low-pass filter, at the original sampling rate, that cuts off at  $F_2/2$ . This filter is called a *decimation filter*.

It may seem like this is no improvement to our example system; now we have to have two filters: a decimation filter and our 600-Hz band-pass filter. But the combined processing of these two filters is less

**Fig 18.27**—The signal at A is sampled at an  $F_1$  rate. At B, the signal has been decimated by a factor of 3 by throwing away two out of three samples. The result is that alias components have been formed around harmonics of the new sampling rate,  $F_2$ . Note that in the original spectrum, signal components existed at frequencies above  $F_2/2$ . These components alias into the range 0 to  $F_2/2$  after decimation.

**Fig 18.29**—Dithering is accomplished by adding noise to an oversampled signal. The noise should fall outside the passband of the digital decimation filter.

than the processing we would need for the single filter at the original sampling rate. **Fig 18.28** shows why this is so. The decimation filter needs only to attenuate those signals that would alias into the 100-Hz passband of the final 600-Hz filter. Signals that alias into the frequency range above that filter and below  $F_2/2$  will be removed by the band-pass filter. That means that the decimation filter need not have a particularly sharp cutoff, so it doesn't have to be a complex filter, costly

in terms of processing requirements.

## INTERPOLATION

Just as we sometimes want to decimate a signal to reduce its effective sampling rate, we also sometimes want to *interpolate* a signal to increase its rate. Referring to our example of decimation, we may want to output the filtered 600-Hz signal, sampled at 7 kHz, through a system that has a reconstruction filter that cuts off well above 3500 Hz (half the sampling fre-

**Fig 18.28**—In this example, the decimation low-pass filter has to pass the frequencies that will exist after the final filter, shown as a shaded area, while eliminating frequencies that might alias into the final filter.

quency). We can do this by increasing the effective sampling rate to one that accommodates our reconstruction filter.

Just as decimation was performed by removing samples, interpolation is performed by inserting them. If we want to raise our 7-kHz sampling rate by a factor of 3, to 21 kHz, we need to have three times as many samples. We can do that by adding two new samples between each of the existing samples. Usually, we add samples whose value is zero. While this increases the number of samples, it does not change the content of the signal. Specifically, the alias components that lie on either side of the old 7-kHz sampling frequency and its harmonics are still present. To make use of the new signal, we need to digitally filter out all of these components except those around 600 Hz. So, we need a low-pass filter, operating at the sampling frequency of 21 kHz, to eliminate these unwanted signals so they won't appear in the output.

In this example, we know that, because of our 100-Hz-wide filter, all of the signal appears in narrow bands centered on 600 Hz,  $7000-600=6400$  Hz,  $7000+600=7600$  Hz, and so on. The highest frequency we need to pass through our interpolation low-pass filter is 650 Hz. The lowest frequency we need to reject is 6350 Hz. We can design our low-pass filter accordingly. With this much difference between our passband and stopband frequencies, we'll find that the needed interpolation filter is simple and won't take much processing.

## OVERSAMPLING

One place where decimation and interpolation are often used is to implement oversampling—sampling at a rate much higher than the sampling theorem demands. One reason to use oversampling was shown above: to relax the require-

ments of the antialiasing and reconstruction low-pass filters. Another advantage of oversampling is in noise reduction. As explained above, if the quantization noise that arises from quantizing the input signal is random in nature, it will be distributed evenly throughout the spectrum. If we make use of oversampling, the noise of interest will be distributed evenly from 0 Hz up to one half the sampling frequency. When we pass the digitized signal through our decimation low-pass filter, much of this noise will be filtered out. This in-

creases the effective signal-to-noise ratio, since the signal is unchanged but the total noise is reduced. This approach can allow use of a low-resolution, but fast, A/D converter to act as if it had more resolution—more bits.

We stress again that this technique assumes randomness on the part of the quantization noise. That may not always be the case. In situations where that can't be assumed by the characteristics of the input signal, *dithering* is sometimes used. Dithering is the introduction of noise into the

input signal, before digitization. Usually, the amplitude of this noise is equal to several quantization levels—several times the A/D LSB value. Adding noise may seem to defeat the purpose of oversampling, but the trick is to add noise that is limited in frequency to a range that will fall outside the passband of the decimation filter. That way, the noise doesn't contribute to the final signal-to-noise ratio but does force the quantization noise to become random. Such a scheme is shown in Fig 18.29.

## DSP Hardware and Development Tools

DSP relies on operations—addition, multiplication and shifting—that are common computer operations. But the large number of such operations needed by any useful DSP algorithm, and the small amount of time available to do them—the interval between two incoming samples—means that general-purpose processors find it difficult to process signals even at audio frequencies. For that reason, most real-time DSP is performed by specialized processors.

### DSP CHIPS

Processors for DSP differ from general-purpose processors in important ways. The most important differences exist to optimize the repeated multiply-add-shift operation of DSP algorithms. One of these optimizations is the use of the *Harvard architecture*. This scheme of computer organization has separate program memory and data memory. The program instructions and constant values are stored in one memory, while the data to be processed is stored in another. This allows the processor to fetch a value from program memory and one from data memory at the same time, in a single memory cycle. Consider the effect of this on the FIR filter algorithm. To implement each tap of the filter, the program must multiply a constant value (the filter coefficient) by a data value (the stored sample value). The processor can fetch both values from memory simultaneously, saving one memory cycle. When large filters are being implemented, the savings can quickly mount. And typically, the processor can perform the needed multiplication, subsequent addition of the product to an accumulator, and shifting of the data value in the storage array in a single machine cycle. Contrast this with the many cycles needed to per-

form the same operations in a general-purpose computer and you can see why specialized processors are so much more capable of processing sampled signals. DSP chips also often include other optimizations, such as *pipelining* of instructions and specialized addressing modes to support FFT operations.

### Fixed Point vs Floating Point

One of the things that makes general-purpose computers so useful is their ability to perform *floating-point* calculations. Floating-point representation of numbers treats the stored value as a fraction (the *mantissa*) of magnitude less than 1 and an exponent (usually base 2). This approach allows the computer to handle a great range of numbers, from the very small to the very large. Some modern DSP chips support floating-point calculations, too. But this is not as great an advantage for signal processing as it is for general-purpose computing because the range of values needed in DSP is fairly small. For this reason, *fixed-point* processors are common for DSP.

A fixed-point processor treats a stored value as just the mantissa part—there is no

exponent. This does not mean that only fractional numbers can be handled. The radix point—the separation between the integer and fractional parts of a number—can be between any two bits of the stored number. Indeed, the selection of a radix point is somewhat arbitrary. But having a fixed radix point does complicate things somewhat for the programmer. When multiplying two numbers, let's say they are 16-bit values, the resulting number has twice as many bits—32, in this case. And where the radix point falls in those 32 bits depends on where it was in the original numbers. If the 16 bits were composed of three bits of integer value, followed by 13 bits of fractional value, the 32-bit product would have 6 bits of integer value and 26 bits of fraction. That means that to store the upper part of the product as a 16-bit value, the product has to be shifted left three bits. Because of this, fixed-point DSP chips often include special shift hardware that allows shifting of the data during load and store instructions. The programmer must ensure that the proper shift values are part of the instruction. It is also imperative that the product not overflow the three least-significant bits of integer

**Table 18.2**  
**Some Common DSP Chips**

Manufacturer	DSP chip	Word size (bits)
<b>Fixed-point</b>		
Analog Devices	ADSP-2100 family	16
Motorola	DSP56000 family	32
Texas Instruments	TMS320 family	16
<b>Floating Point</b>		
Analog Devices	ADSP-21020	32
Motorola	DSP96002	32
Texas Instruments	TMS320 family	32

value. Keeping all of this straight becomes a headache when programming a fixed-point processor. Still, because fixed-point processors are simpler—and thus less expensive—they are common in low-cost DSP systems. **Table 18.2** shows some common DSP chip families.

## DEVELOPMENT TOOLS

Developing DSP systems for Amateur Radio requires the right development tools. Included in these are the hardware that includes a DSP chip, A/D and D/A converters, input and output low-pass filters, and some means of communicating with a PC for loading and testing programs. An assembler and/or a high-level language compiler are needed as well. Debugging software is desirable, too. While industrial-grade DSP development platforms abound, their cost is prohibitive for the amateur. Low-cost development tools are needed. Recently, such tools have become available.

### The Texas Instruments DSP Starter Kits

Texas Instruments provides a DSP Starter Kit (DSK) for both its TMS320C25-series and TMS320C50 series 16-bit, fixed-point processors. Each kit consists of a small PC board that contains the processor, with embedded ROM bootstrap firmware, an audio-frequency codec (integrated A/D, D/A and low-pass filters), and the needed power-supply circuitry, except for the transformer. Also included are a simple assembler and a debugger. Kits are sold by all TI distributors. Call 800-336-5236 for one near you.

The DSK, which costs about \$100, does not use low-grade processors; these are prime, state-of-the-art processors, capable of executing just about any audio-frequency algorithm amateurs are likely to want. The kits also include connector holes (but not the connectors) for attaching external peripheral devices to the processor bus. Although labeled a kit, this product requires no assembly.

### THE TAPR DSP-93

Tucson Amateur Packet Radio, Inc, a not-for-profit organization devoted to the advancement of packet radio, has the DSP-93 kit available. This kit, which requires assembly, is based on the TMS320C25 processor and consists of stackable boards that include 32 kwords of program and data memory, with space for 64 kwords. The analog board includes a codec capable of sampling at 45 ksamples/s, an analog multiplexer to

select from up to 8 audio input sources and an interface for radio keying and frequency-control lines, as well as an RS-232 interface for computer communication. The stackable feature permits later addition of other accessory boards, for use with different analog subsystems, faster interfaces to a PC, or specialized analog circuitry. A shareware assembler is available to facilitate development.

## PC SOUND CARDS

Perhaps one of the most enticing ways of putting DSP development tools in the hands of amateurs is the PC sound card. Recent additions to the market include sound cards with embedded DSP chips. For amateurs, finding the development tools for such boards is the challenge. Sound card manufacturers typically make development packages available, but not at low cost. One set of free tools, and a description of the Analog Devices Personal Sound Architecture chip set used on some of these boards, is described in "Programming a DSP Sound Card for Amateur Radio," by Johan Forrer, KC7WW, *QEX*, August 1994.

# Transmission Lines

## 19

power is rarely generated right where it will be used. A transmitter and the antenna it feeds are a good example. To radiate effectively, the antenna should be high above the ground and should be kept clear of trees, buildings and other objects that might absorb energy. The transmitter, however, is most conveniently installed indoors, where it is out of the weather and is readily accessible. A *transmission line* is used to convey RF energy from the transmitter to the antenna. A transmission line should transport the RF from the source to its destination with as little loss as possible. This chapter was written by Dean Straw, N6BV.

There are three main types of transmission lines used by radio amateurs: coaxial lines, open-wire lines and waveguides. The most common type is the *coaxial* line, usually called *coax*. See Fig 19.1A. Coax is made up of a center conductor, which may be either stranded or solid wire, surrounded by a concentric outer conductor. The outer conductor may be braided shield wire or a metallic sheath. A flexible aluminum foil is employed in some coaxes to improve shielding over that obtainable from a woven shield braid. If the outer conductor is made of solid aluminum or copper, the coax is referred to as *Hardline*.

The second type of transmission line utilizes parallel conductors side by side, rather than the concentric ones used in coax. Typical examples of such *open-wire* lines are 300- $\Omega$  TV ribbon line and 450- $\Omega$  ladder line. See Fig 19.1B. Although open-wire lines are enjoying a sort of renaissance

in recent years due to their inherently lower losses in simple multiband antenna systems, coaxial cables are far more prevalent, because they are much more convenient to use.

The third major type of transmission line is the *waveguide*. While open-wire and coaxial lines are used from power-line frequencies to well into the microwave

region, waveguides are used at microwave frequencies only. Waveguides will be covered at the end of this chapter.

### TRANSMISSION LINE BASICS

In either coaxial or open-wire line, currents flowing in each of the two conductors travel in opposite directions. If the physical spacing between the two parallel

Fig 19.1—In A, coaxial cable transmission line connecting signal generator having source resistance  $R_g$  to reactive load  $R_a \pm jX_a$ , where  $X_a$  is either a capacitive (–) or inductive (+) reactance. Velocity factor (VF) and characteristic impedance ( $Z_0$ ) are properties of the line, as discussed in the text. B shows open-wire balanced transmission line.

conductors in an open-wire line is small in terms of wavelength, the phase difference between the currents will be very close to 180°. If the two currents also have equal amplitudes, the field generated by each conductor will cancel that generated by the other, and the line will not radiate energy, even if it is many wavelengths long.

The equality of amplitude and 180° phase difference of the currents in each conductor in an open-wire line determine the degree of radiation cancellation. If the currents are for some reason unequal, or if the phase difference is not 180°, the line will radiate energy. How such imbalances occur and to what degree they can cause problems will be covered in more detail later.

In contrast to an open-wire line, the outer conductor in a coaxial line acts as a shield, confining RF energy within the line. Because of *skin effect* (see the **Real World** chapter in this *Handbook*), current flowing in the outer conductor of a coax does so mainly on the inner surface of the outer conductor. The fields generated by the currents flowing on the outer surface of the inner conductor and on the inner surface of the outer conductor cancel each other out, just as they do in open-wire line.

In a real (non-ideal) transmission line, the energy actually travels somewhat slower than the speed of light (typically from 65 to 97% of light speed), depending primarily on the dielectric properties of the insulating materials used in the construction of the line. The fraction of the speed of propagation in a transmission line compared to the speed of light in free space is called the *velocity factor* (VF) of the line. The velocity factor causes the line's *electrical* wavelength to be shorter than the wavelength in free space. Eq 1 describes the physical length of an electrical wavelength of transmission line.

$$\lambda = \frac{983.6}{f} \times \text{VF} \quad (1)$$

where

$\lambda$  = wavelength, in ft  
 $f$  = frequency in MHz  
 VF = velocity factor.

Each transmission line has a characteristic velocity factor, related to the specific properties of its insulating materials. The velocity factor must be taken into account when cutting a transmission line to a specific electrical length. **Table 19.1** shows various velocity factors for the transmission lines commonly used by amateurs. For example, if RG-8A, which has a velocity factor of 0.66, were used to make a quarter-wavelength line at 3.5 MHz, the length would be  $(0.66 \times 983.6/3.5)/4 = 46.4$  ft long, instead of the free-space length of 70.3 ft. Open-wire line has a velocity factor of 0.97, close to unity, because it lacks a substantial amount of solid insulating material. Conversely, molded 300- $\Omega$  TV line has a velocity factor of 0.80 to 0.82 because it does use solid insulation between the conductors.

A perfectly lossless transmission line may be represented by a whole series of small inductors and capacitors connected in an infinitely long line, as shown in **Fig 19.2**. (We first consider this special case because we need not consider how the line is terminated at its end, since there is no end.)

Each inductor in Fig 19.2 represents the inductance of a very short section of one wire and each capacitor represents the capacitance between two such short sections. The inductance and capacitance values per unit of line depend on the size of the conductors and the spacing between them. The smaller the spacing between the two conductors and the greater their diameter, the higher the capacitance and the lower the inductance. Each series inductor acts to limit the rate at which current can charge the following shunt capacitor, and in so doing establishes a very important property of a transmission line: its *surge impedance*, more commonly known as its *characteristic impedance*. This is usually abbreviated as  $Z_0$ , and is approximately equal to  $\sqrt{L/C}$ , where  $L$  and  $C$  are the inductance and capacitance per unit length of line.

The characteristic impedance of an air-insulated parallel-conductor line, neglecting the effect of the insulating spacers, is given by

$$Z_0 = 276 \log_{10} \frac{2S}{d} \quad (2)$$

where

$Z_0$  = characteristic impedance  
 $S$  = center-to-center distance between conductors  
 $d$  = diameter of conductor (in same units as  $S$ ).

The characteristic impedance of an air-insulated coaxial line is given by

$$Z_0 = 138 \log_{10} \left( \frac{b}{a} \right) \quad (3)$$

where

$Z_0$  = characteristic impedance  
 $b$  = inside diameter of outer conductors  
 $a$  = outside diameter of inner conductor (in same units as  $b$ ).

It does not matter what units are used for  $S$ ,  $d$ ,  $a$  or  $b$ , so long as they are the same units. A line with closely spaced, large conductors will have a low characteristic impedance, while one with widely spaced, small conductors will have a relatively high characteristic impedance. Practical open-wire lines exhibit characteristic impedances ranging from about 200 to 800  $\Omega$ , while coax cables have  $Z_0$  values between 25 to 100  $\Omega$ .

All practical transmission lines exhibit some power loss. These losses occur in the resistance that is inherent in the conductors that make up the line, and from leakage currents flowing in the dielectric material between the conductors. We'll next consider what happens when a real transmission line, which is not infinitely long, is terminated in real load impedances.

## Matched Lines

Real transmission lines do not extend to infinity, but have a definite length. In use they are connected to, or *terminate* in, a load, as illustrated in **Fig 19.3A**. If the load is a pure resistance whose value equals the characteristic impedance of the line, the line is said to be *matched*. To current traveling along the line, such a load at the end of the line acts as though it were still more transmission line of the same characteristic impedance. In a matched transmission line, energy travels outward along the line from the source until it reaches the load, where it is completely absorbed.

## Mismatched Lines

Assume now that the line in Fig 19.3B is terminated in an impedance  $Z_a$  which is not equal to  $Z_0$  of the transmission line. The line is now a *mismatched* line. RF energy reaching the end of a mismatched line will not be fully absorbed by the load impedance. Instead, part of the energy will be reflected back toward the source. The

\*\*Operating voltage varies widely among manufacturers

**Fig 19.3—At A the coaxial transmission line is terminated with resistance equal to its  $Z_0$ . All power is absorbed in the load. At B, coaxial line is shown terminated in an impedance consisting of a resistance and a capacitive reactance. This is a mismatched line, and a reflected wave will be returned back down the line toward the generator. The reflected wave reacts with the forward wave to produce a standing wave on the line. The amount of reflection depends on the difference between the load impedance and the characteristic impedance of the transmission line.**

amount of reflected versus absorbed energy depends on the degree of mismatch between the characteristic impedance of the line and the load impedance connected to its end.

The reason why energy is reflected at a discontinuity of impedance on a transmission line can best be understood by examining some limiting cases. First, consider the rather extreme case where the line is shorted at its end. Energy flowing to the load will encounter the short at the end, and the voltage at that point will go to zero, while the current will rise to a maximum. Since the current can't develop any power in a dead short, it will all be reflected back toward the source generator.

If the short at the end of the line is replaced with an open circuit, the opposite will happen. Here the voltage will rise to maximum, and the current will by definition go to zero. The phase will reverse, and all energy will be reflected back towards the source. By the way, if this sounds to you like what happens at the end of a half-wave dipole antenna, you are

quite correct. However, in the case of an antenna, energy traveling along the antenna is lost by radiation on purpose, whereas a good transmission line will lose little energy to radiation because of field cancellation between the two conductors.

For load impedances falling between the extremes of short- and open-circuit, the phase and amplitude of the reflected wave will vary. The amount of energy reflected and the amount of energy absorbed in the load will depend on the difference between the characteristic impedance of the line and the impedance of the load at its end.

Now, what actually happens to the energy reflected back down the line? This energy will encounter another impedance discontinuity, this time at the generator. Reflected energy flows back and forth between the mismatches at the source and load. After a few such journeys, the reflected wave diminishes to nothing, partly as a result of finite losses in the line, but mainly because of absorption at the load. In fact, if the load is an antenna, such absorption at the load is desirable, since the energy is actually radiated by the antenna.

If a continuous RF voltage is applied to the terminals of a transmission line, the voltage at any point along the line will consist of a vector sum of voltages, the composite of waves traveling toward the load and waves traveling back toward the source generator. The sum of the waves traveling toward the load is called the *forward* or *incident* wave, while the sum of the waves traveling toward the generator is called the *reflected* wave.

## Reflection Coefficient and SWR

In a mismatched transmission line, the ratio of the voltage in the reflected wave at any one point on the line to the voltage in the forward wave at that same point is defined as the *voltage reflection coefficient*. This has the same value as the current reflection coefficient. The reflection coefficient is a complex quantity (that is, having both amplitude and phase) and is generally designated by the Greek letter  $\rho$  (rho), or sometimes in the professional literature as  $\Gamma$  (Gamma). The relationship between  $R_a$  (the load resistance),  $X_a$  (the load reactance),  $Z_0$  (the line characteristic impedance, whose real part is  $R_0$  and whose reactive part is  $X_0$ ) and the complex reflection coefficient  $\rho$  is

$$\rho = \frac{Z_a - Z_0}{Z_a + Z_0} = \frac{(R_a + jX_a) - (R_0 + jX_0)}{(R_a + jX_a) + (R_0 + jX_0)} \quad (4)$$

For most transmission lines the characteristic impedance  $Z_0$  is almost completely resistive, meaning that  $Z_0 = R_0$  and  $X_0 \approx 0$ .

The magnitude of the complex reflection coefficient in Eq 4 then simplifies to:

$$|\rho| = \sqrt{\frac{(R_a - R_0)^2 + X_a^2}{(R_a + R_0)^2 + X_a^2}} \quad (5)$$

For example, if the characteristic impedance of a coaxial line is  $50 \Omega$  and the load impedance is  $120 \Omega$  in series with a capacitive reactance of  $-90 \Omega$ , the magnitude of the reflection coefficient is

$$|\rho| = \sqrt{\frac{(120 - 50)^2 + (-90)^2}{(120 + 50)^2 + (-90)^2}} = 0.593$$

Note that if  $R_a$  in Eq 4 is equal to  $R_0$  and  $X_a$  is 0, the reflection coefficient,  $\rho$ , is 0. This represents a matched condition, where all the energy in the incident wave is transferred to the load. On the other hand, if  $R_a$  is 0, meaning that the load has no real resistive part, the reflection coefficient is 1.0, regardless of the value of  $R_0$ . This means that all the forward power is reflected since the load is completely reactive. The concept of reflection is often shown in terms of the *return loss*, which is the reciprocal of the reflection coefficient, in dB. In the example above, the return loss is 4.5 dB.

If there are no reflections from the load, the voltage distribution along the line is constant or *flat*. A line operating under these conditions is called either a *matched* or a *flat* line. If reflections do exist, a voltage *standing-wave* pattern will result from the interaction of the forward and reflected waves along the line. For a lossless transmission line, the ratio of the maximum peak voltage anywhere on the line to the minimum value anywhere on the line (which must be at least  $1/4 \lambda$ ) is defined as the *voltage standing-wave ratio*, or VSWR. Reflections from the load also produce a standing-wave pattern of currents flowing in the line. The ratio of maximum to minimum current, or ISWR, is identical to the VSWR in a given line.

In amateur literature, the abbreviation *SWR* is commonly used for standing-wave ratio, as the results are identical when taken from proper measurements of either current or voltage. Since SWR is a ratio of maximum to minimum, it can never be less than one-to-one. In other words, a perfectly flat line has an SWR of 1:1. The SWR is related to the magnitude of the complex reflection coefficient by

$$SWR = \frac{1 + |\rho|}{1 - |\rho|} \quad (6)$$

and conversely the reflection coefficient

magnitude may be defined from a measurement of SWR as

$$|\rho| = \frac{SWR - 1}{SWR + 1} \quad (7)$$

The definitions in Eq 6 and 7 are valid for any line length and for lines which are lossy, not just lossless lines longer than  $1/4 \lambda$  at the frequency in use. Very often the load impedance is not exactly known, since an antenna usually terminates a transmission line, and the antenna impedance may be influenced by a host of factors, including its height above ground, end effects from insulators, and the effects of nearby conductors. We may also express the reflection coefficient in terms of forward and reflected power, quantities which can be easily measured using a directional RF wattmeter. The reflection coefficient may be computed as

$$\rho = \sqrt{\frac{P_r}{P_f}} \quad (8)$$

where

$P_r$  = power in the reflected wave  
 $P_f$  = power in the forward wave.

If a line is not matched (SWR > 1:1) the difference between the forward and reflected powers measured at any point on the line is the net power going toward the load from that point. The forward power measured with a directional wattmeter (often referred to as a reflected power meter or *reflectometer*) on a mismatched line will thus always appear greater than the forward power measured on a flat line with a 1:1 SWR.

## Losses in Transmission Lines

A real transmission line exhibits a certain amount of loss, caused by the resistance of the conductors used in the line and by dielectric losses in the line's insulators. The *matched line loss* for a particular type and length of transmission line, operated at a particular frequency, is the loss when the line is terminated in a resistance equal to its characteristic impedance. The loss in a line is lowest when it is operated as a matched line.

Line losses increase when SWR is greater than 1:1. Each time energy flows from the generator toward the load, or is reflected at the load and travels back toward the generator, a certain amount will be lost along the line. The net effect of standing waves on a transmission line is to increase the average value of current and voltage, compared to the matched line case. An increase in current raises  $I^2R$  (ohmic) losses in the conductors, and an increase in RF voltage increases

$E^2/R$  losses in the dielectric. Line loss rises with frequency, since the conductor resistance is related to skin effect, and also because dielectric losses rise with frequency.

Matched line loss is stated in decibels per hundred feet at a particular frequency. Fig 19.4 shows the matched line loss per hundred feet versus frequency for a number of common types of lines, both coaxial and open-wire balanced types. For example, RG-213 coax cable has a matched line loss of 2.5 dB/100 ft at 100 MHz. Thus, 45 ft of this cable feeding a 50- $\Omega$  load at 100 MHz would have a loss of

$$\text{Matched line loss} = \frac{2.5 \text{ dB}}{100 \text{ ft}} \times 45 \text{ ft} = 1.13 \text{ dB}$$

If a line is not matched, standing waves will cause additional loss beyond the inherent matched line loss for that line. On lines which are inherently lossy, the total line loss (the sum of matched line loss and additional loss due to SWR) can be sur-

prisingly high for high values of SWR.

Total Matched Line Loss (dB)

$$= 10 \log \frac{B^2 - C^2}{B(1 - C^2)} \quad (9)$$

where

$$B = 10^{\left(\frac{L_m}{10}\right)}$$

$$C = \frac{S_L - 1}{S_L + 1}$$

$L_m$  = matched line loss, in dB

$S_L$  = SWR measured at load.

Because of losses in a transmission line, the measured SWR at the input of the line is less than the SWR measured at the load end of the line.

$$\text{SWR at input} = \frac{B + C}{B - C} \quad (10)$$

For example, RG-8A solid-dielectric

coax cable exhibits a matched line loss per 100 ft at 28 MHz of 1.2 dB. A 250-ft length of this cable has a matched line loss of 3.0 dB. Assume that we measure the SWR at the load as 6:1.

$$B = 10^{\left(\frac{2.95}{10}\right)} = 1.972$$

$$C = \frac{6.0 - 1}{6.0 + 1} = 0.714$$

$$\text{Total Loss} = 10 \log \frac{1.972^2 - 0.714^2}{1.972(1 - 0.714^2)} = 5.4 \text{ dB}$$

$$\text{SWR}_{\text{in}} = \frac{1.972 + 0.714}{1.972 - 0.714} = 2.1$$

The additional loss due to the 6:1 SWR at 28 MHz is  $5.4 - 3.0 = 2.4$  dB. The SWR at the input of the 250-ft line is only 2.1:1, because line loss has masked the true extent of the SWR (6:1) at the load end of the line.

The losses become larger if coax with a larger matched line loss is used under the

Fig 19.4—This graph displays the matched line attenuation in decibels per 100 ft for many popular transmission lines. The vertical axis represents attenuation and the horizontal axis frequency. Note that these loss figures are only accurate for properly matched transmission lines.

**Table 19.2**  
**Matched-Line Loss for 250 ft of Three Common Coaxial Cables**

Comparisons of line losses versus frequency for 250-ft lengths of three different coax cable types: small-diameter RG-58A, medium-diameter RG-8A, and  $\frac{3}{4}$ -inch OD 50- $\Omega$  Hardline. At VHF, the losses for the small-diameter cable are very large, while they are moderate at 3.5 MHz.

Xmsn Line	3.5 MHz Matched- Line Loss, dB	3.5 MHz Loss, 6:1 SWR, dB	28 MHz Matched- Line Loss, dB	28 MHz Loss, 6:1 SWR, dB	145 MHz Matched- Line Loss, dB	146 MHz Loss 6:1 SWR, dB
RG-58A	1.9	4.0	6.3	9.3	16.5	19.6
RG-8A	0.9	2.2	3.0	5.4	7.8	10.8
$\frac{3}{4}$ " 50- $\Omega$ Hardline	0.2	0.5	0.7	1.8	2.1	4.2

**Fig 19.5—Increase in line loss because of standing waves (SWR measured at the load). To determine the total loss in decibels in a line having an SWR greater than 1, first determine the matched line loss for the particular type of line, length and frequency, on the assumption that the line is perfectly matched (from Fig 19.4). For example, Belden 9913 has a matched line loss of 0.49 dB/100 ft at 14 MHz. Locate 0.49 dB on the horizontal axis. For an SWR of 5:1, move up to the curve corresponding to this SWR. The increase in loss due to SWR is 0.65 dB beyond the matched line loss.**

same conditions. For example, RG-58A coaxial cable is about one-half the diameter of RG-8A, and it has a matched line loss of 2.5 dB/100 ft at 28 MHz. A 250-ft length of RG-58A has a total matched line loss of 6.3 dB. With a 6:1 SWR at the load, the additional loss due to SWR is 3.0 dB, for a total loss of 9.3 dB. The additional cable loss due to the mismatch reduces the SWR at the input of the line to 1.4:1. An unsuspecting operator measuring the SWR at his transmitter might well believe that everything is just fine, when in truth

only about 12% of the transmitter power is getting to the antenna! Be suspicious of very low SWR readings for an antenna fed with a long length of coaxial cable, especially if the SWR remains low across a wide frequency range. Most antennas have narrow SWR bandwidths, and the SWR *should* change across a band.

On the other hand, if expensive  $\frac{3}{4}$ -inch diameter 50- $\Omega$  Hardline cable is used at 28 MHz, the matched line loss is only 0.28 dB/100 ft. For 250 ft of Hardline the matched line loss is 0.7 dB, and the additional loss due to a 6:1 SWR is 1.1 dB. The total loss is 1.8 dB. See **Table 19.2** for a summary of the losses for 250 ft of the three types of coax as a function of frequency for matched line and 6:1 SWR conditions.

At the upper end of the HF spectrum, when the transmitter and antenna are separated by a long transmission line, the use of bargain coax may prove to be a very poor cost-saving strategy. A 7.5 dB linear amplifier, to offset the loss in RG-58A compared to Hardline, would cost a great deal more than higher-quality coax. Furthermore, no *transmitter* amplifier can boost *receiver* sensitivity—loss in the line has the same effect as putting an attenuator in front of the receiver.

At the low end of the HF spectrum, say 3.5 MHz, the amount of loss in common coax lines is less of a problem for the range of SWR values typical on this band. For example, consider an 80-m dipole cut for the middle of the band at 3.75 MHz. It exhibits an SWR of about 6:1 at the 3.5 and 4.0 MHz ends of the band. At 3.5 MHz, 250 ft of RG-58A small-diameter coax has an additional loss of 2.1 dB for this SWR, giving a total line loss of 4.0 dB. If larger-diameter RG-8A coax is used instead, the additional loss due to SWR is 1.3 dB, for a total loss of 2.2 dB. This is an acceptable level of loss for most 80-m operators.

However, the loss situation gets

dramatically worse as the frequency increases into the VHF and UHF regions. At 146 MHz, the total loss in 250 ft of RG-58A with a 6:1 SWR at the load is 16.5 dB, 10.8 dB for RG-8A, and 4.2 dB for  $\frac{3}{4}$ -inch 50- $\Omega$  Hardline. At VHF and UHF, a low SWR is essential to keep line losses low, even for the best coaxial cable. The length of transmission line must be kept as short as practical at these frequencies.

The effect of SWR on line loss is shown graphically in **Fig 19.5**. The horizontal axis is the attenuation, in decibels, of the line when perfectly matched. The vertical axis gives the additional attenuation due to SWR. If long coaxial-cable transmission lines are necessary, the matched loss of the coax used should be kept as low as possible, meaning that the highest-quality, largest-diameter cable should be used.

### Coax Versus Open-Wire Transmission Lines, an Illustration

It is no accident that coaxial cable became as popular as it has since it was first widely used during World War II. Coax is mechanically much easier to use than open-wire line. Because of the excellent shielding afforded by its outer shield, coax can be run up a metal tower leg, taped together with numerous other cables, with virtually no interaction or crosstalk between the cables. At the top of a tower, coax can be used with a rotatable Yagi or quad antenna without worrying about shorting or twisting the conductors, which might happen with an open-wire line. Coax can even be buried underground, especially if it is run in plastic piping so that ground water and soil chemicals cannot easily deteriorate the cable.

Open-wire line must be carefully spaced away from nearby conductors, by at least several times the spacing between its conductors, to minimize possible electrical imbalances between the two parallel conductors. Such imbalances lead to line radiation and extra losses. One popular type of open-wire line is called *ladder line* because the insulators used to separate the two parallel, uninsulated conductors of the line resemble the steps of a ladder. Long lengths of ladder line can twist together in the wind and short out if not properly supported.

Despite the mechanical difficulties associated with open-wire line, there are some compelling reasons for its use, especially in simple multiband antenna systems. Every antenna system, no matter what its physical form, exhibits a definite value of impedance at the point where the transmission line is connected. Although the input impedance of an antenna system

**Table 19.3**  
**Modeled Data for a 100-ft Flat-Top Antenna**

100-ft long, 50-ft high, center-fed dipole over average ground, using coaxial or open-wire transmission lines. Antenna impedance computed using *NEC2* computer program, with ground relative permittivity of 13, ground conductivity of 5 mS/m and Sommerfeld/Norton ground model. Note the extremely reactive impedance levels at many frequencies, but especially at 1.8 MHz. If this antenna is fed directly with RG-8A coax, the losses are unacceptably large on 160 m, and undesirably high on most other bands also. The RF voltage at 3.8 MHz for high-power operation with open-wire line is extremely high also, and would probably result in arcing either on the line itself, or more likely in the Transmatch. Each transmission line is 100 ft long.

Frequency (MHz)	Antenna Impedance (Ohms)	SWR RG-8A Coax	Loss 100 ft RG-8A Coax	Loss 100 ft 450-Ω Line	Max Volt. RG-8A 1500 W	Max Volt. 450-Ω Line 1500 W
1.8 MHz	4.5 - j 1673	1818:1	17.1 dB	6.6 dB	4283	14328
3.8 MHz	38.9 - j 362	63:1	5.6 dB	0.8 dB	1181	3192
7.1 MHz	481 + j 964	49:1	6.0 dB	0.4 dB	943	1957
10.1 MHz	2584 - j 3292	134:1	10.5 dB	1.0 dB	936	2869
14.1 MHz	85.3 - j 123.3	6.0:1	1.9 dB	0.4 dB	534	1863
18.1 MHz	2097 + j 1552	65:1	9.0 dB	0.6 dB	746	2074
21.1 MHz	345 - j 1073	73:1	9.8 dB	0.8 dB	726	2295
24.9 MHz	202 + j 367	18:1	5.2 dB	0.4 dB	630	1563
28.4 MHz	2493 - j 1375	65:1	10.0 dB	0.7 dB	664	2051

is seldom known exactly, it is often possible to make a close estimate of its value, especially since sophisticated computer-modeling programs have become available to the radio amateur. As an example, **Table 19.3** lists the computed characteristics versus frequency for a multiband, 100-ft long center-fed dipole, placed 50 ft above average ground having a dielectric constant of 13 and a conductivity of 10 mS/m.

These values were computed using a complex program called *NEC2* (Numerical Electromagnetic Code), which incorporates a sophisticated Sommerfeld/Norton ground-modeling algorithm for antennas close to real earth. A nonresonant 100-ft length was chosen as an illustration of a practical size that many radio amateurs could fit into their backyards, although nothing in particular recommends this antenna over other forms. It is merely used as an example.

Examine Table 19.3 carefully in the following discussion. Columns four and five show the SWR on a 50-Ω RG-8A coaxial transmission line directly connected to the antenna, followed by the total loss in 100 ft of this cable. The impedance for this nonresonant, 100-ft long antenna varies over a very wide range for the nine operating frequencies. The SWR on a 50-Ω coax connected directly to this antenna would be *extremely* high on some frequencies, particularly at 1.8 MHz, where the antenna is highly capacitive because it is much short of resonance. The loss for an SWR of 1818:1 in 100 ft of RG-8A at 1.8 MHz is a staggering 17.1 dB.

Contrast this to the loss in 100 ft of 450-Ω open-wire line. Here, the loss at 1.8 MHz is 6.6 dB. While 6.6 dB of loss is not particularly desirable, it is almost

12 dB better than the coax! Note that the RG-8A coax exhibits a good deal of loss on almost all the bands due to mismatch. Only on 14 MHz does the loss drop down to 1.9 dB, where the antenna is just past  $3/2\lambda$  resonance. From 3.8 to 28.4 MHz the open-wire line has a maximum loss of only 1.0 dB.

Columns six and seven in Table 19.3 list the maximum RMS voltage for 1500 W of RF power on the 50-Ω coax and on the 450-Ω open-wire line. The maximum RMS voltage for 1500 W on the open-wire line is extremely high, at 14328 V at 1.8 MHz. The voltage for a 100-W transmitter would be reduced by a ratio of  $\sqrt{1500/100} = 3.87:1$ . This is 3702 V, still high enough to cause arcing in many Transmatches.

In general, such a nonresonant antenna is a proven, practical multiband radiator when fed with 450-Ω open-wire ladder line connected to a Transmatch, although a longer antenna would be preferable for more efficient 160-m operation, even with open-wire line. The Transmatch and the line itself must be capable of handling the high RF voltages and currents involved for high-power operation. On the other hand, if such a multiband antenna is fed directly with coaxial cable, the losses on most frequencies are prohibitive. Coax is most suitable for antennas whose resonant feed-point impedances are close to the characteristic impedance of the feed line.

### The Transmission Line as Impedance Transformer

If the complex mechanics of reflections, SWR and line losses are put aside momentarily, a transmission line can very simply be considered as an impedance transformer. A certain value of load imped-

ance, consisting of a resistance and reactance, at the end of the line is transformed into another value of impedance at the input of the line. The amount of transformation is determined by the electrical length of the line, its characteristic impedance, and by the losses inherent in the line. The input impedance of a real, lossy transmission line is computed using the following equation

$$Z_{in} = Z_0 \times \frac{Z_L \cosh(\eta\ell) + Z_0 \sinh(\eta\ell)}{Z_L \sinh(\eta\ell) + Z_0 \cosh(\eta\ell)} \quad (11)$$

where

$Z_{in}$  = complex impedance at input of line  
=  $R_{in} \pm jX_{in}$

$Z_L$  = complex load impedance at end of line  
=  $R_a \pm jX_a$

$Z_0$  = characteristic impedance of line  
=  $R_0 \pm jX_0$

$\eta$  = complex loss coefficient =  $\alpha + j\beta$

$\alpha$  = matched line loss attenuation constant, in nepers/unit length  
(1 neper = 8.688 dB; most cables are rated in dB/100 ft)

$\beta$  = phase constant of line in radians/unit length (related to physical length of line by the fact that 2 radians = 1 wavelength, and by Eq 1)

$\ell$  = electrical length of line in same units of length measurement as  $\alpha$  or above.

Solving this equation manually is tedious, since it incorporates hyperbolic cosines and sines of the complex loss coefficient, but it may be solved using a traditional paper Smith Chart or a computer program. *The ARRL Antenna Book* has a chapter detailing the use of the Smith Chart. *MicroSmith* is a sophisticated

graphical Smith Chart program written for the IBM PC, and is available through the ARRL. *TL* (Transmission Line) is another ARRL program that performs this transformation, but without Smith Chart graphics. *TL.EXE* is available from the ARRL BBS. See *QST* for the BBS telephone number.

### Lines as Stubs

The impedance-transformation proper-

ties of a transmission line are useful in a number of applications. If the terminating resistance is zero (that is, a short) at the end of a low-loss transmission line which is less than  $\frac{1}{4}\lambda$ , the input impedance consists of a reactance, which is given by a simplification of Eq 11.

$$X_{in} \cong Z_0 \tan \ell \quad (12)$$

If the line termination is an open circuit,

the input reactance is given by

$$X_{in} \cong Z_0 \cot \ell \quad (13)$$

The input of a short (less than  $\frac{1}{4}\lambda$ ) length of line with a short circuit as a terminating load appears as an inductance, while an open-circuited line appears as a capacitance. This is a useful property of a transmission line, since it can be used as a

## Reflections on the Smith Chart

Although most radio amateurs have seen the Smith Chart, it is often regarded with trepidation. It is supposed to be complicated and subtle. However, the chart is extremely useful in circuit analysis, especially when transmission lines are involved. The Smith Chart is not limited to transmission-line and antenna problems.

The basis for the chart is Eq 4 in the main text relating reflection coefficient to a terminating impedance. Eq 4 is repeated here:

$$\rho = \frac{Z - Z_0}{Z + Z_0} \quad (1)$$

where  $Z_0$  is the characteristic impedance of the chart, and  $Z = R + jX$  is a complex terminating impedance.  $Z$  might be the feed-point impedance of an antenna connected to a  $Z_0$  transmission line.

It is useful to define a normalized impedance  $z = Z/Z_0$ . The normalized

resistance and reactance become  $r = R/Z_0$  and  $x = X/Z_0$ . Inserting these into Eq 1 yields:

$$\rho = \frac{z - 1}{z + 1} \quad (2)$$

where  $\rho$  and  $z$  are both complex, each having a magnitude and a phase when expressed in polar coordinates, or a real and an imaginary part in XY coordinates.

Eq 1 and 2 have some interesting and useful properties, characteristics that make them physically significant:

- Even though the components of  $z$  (and  $Z$ ) may take on values that are very large, the reflection coefficient  $\rho$ , is restricted to always having a magnitude between zero and one if  $z$  has a real part,  $r$ , that is positive.
- If all possible values for  $\rho$  are examined and plotted in polar coordinates, they will lie within a

circle with a radius of one. This is termed *the unit circle*. A plot is shown in Fig A.

- An impedance that is perfectly matched to  $Z_0$ , the characteristic value for the chart, will produce a  $\rho$  at the center of the unit circle.
- Real  $Z$  values, ones that have no reactance, "map" onto a horizontal line that divides the top from the bottom of the unit circle. By convention, a polar variable with an angle of zero is on the x axis, to the right of the origin.
- Impedances with a reactive part produce  $\rho$  values away from the dividing line. Inductive impedances with the imaginary part greater than zero appear in the upper half of the chart, while capacitive impedances appear in the lower half.
- Perhaps the most interesting and exciting property of the reflection coefficient is the way it describes

**Fig A—Plot of polar reflection coefficient.** Circles represent contours of constant  $\rho$ . The starting "feedpoint" value, 0.5 at  $+45^\circ$ , represents an antenna impedance of  $69.1 + j65.1 \Omega$  with  $Z_0 = 50 \Omega$ . The arc represents a 15-ft section of 50- $\Omega$ , VF 0.66 transmission line at 7 MHz, yielding a shack  $\rho$  of 0.5 at  $-71.3^\circ$ . The shack  $z$  is calculated as  $40.3 - j50.9$ .

**Fig B—This plot shows a Smith Chart.** The circles now represent contours of constant normalized resistance or reactance. Note the arc with the markers: This illustrates the same antenna and line used in the previous figure. The plot is the same on the two charts; only the scale details have changed.

low-loss inductor or capacitor in matching networks. Such lines are often referred to as *stubs*.

A line that is an electrical quarter wavelength is a special kind of a stub. When a quarter-wave line is short circuited at its load end, it presents an open circuit at its input. Conversely, a quarter-wave line with an open circuit at its load end presents a short circuit at its input. Such a line

inverts the sense of a short or an open circuit at the frequency for which the line is a quarter-wave long. This is also true for frequencies that are odd multiples of the quarter-wave frequency. However, for frequencies where the length of the line is a half wavelength, or integer multiples thereof, the line will duplicate the termination at its end.

For example, if a shorted line is cut to be

a quarter wavelength at 7.1 MHz, the impedance looking into the input of the cable will be an open circuit. The line will have no effect if placed in parallel with a transmitter's output terminal. However, at twice the frequency, 14.2 MHz, that same line is now a half wavelength, and the line looks like a short circuit. The line, often dubbed a *quarter-wave stub* in this application, will act as a trap for not only the

the impedance-transforming properties of a transmission line, presented in closed mathematical form in the main text as Eq 11. Neglecting loss effects, a transmission line of electrical length  $\theta$  will transform a normalized impedance represented by  $p$  to another with the same magnitude and a new angle that differs from the original by  $-2\theta$ . This rotation is clockwise.

Clearly, the reflection coefficient is more than an intermediate step in a mathematical development. It is a useful, alternative description of complex impedance. However, our interest is still focused on impedance; we want to know, for example, what the final  $z$  is after transformation with a transmission line. This is the problem that Phillip Smith solved in creating the Smith Chart. Smith observed that the unit circle, a graph of reflection coefficient, could be labeled with lines representing *normalized impedance*. A Smith Chart is shown in Fig B. All of the lines on the chart are complete or partial circles representing a line of constant normalized resistance and reactance.

How might we use the Smith Chart? A classic application relates antenna feed-point impedance to the impedance seen at the end of the "shack" end of the line. Assume that the antenna impedance is known,  $Z_a = R_a + jX_a$ . This complex value is converted to normalized impedance by dividing  $R_a$  and  $X_a$  by  $Z_0$  to yield  $r_a + jx_a$ , and is plotted on the chart. A compass is then used to draw an arc of a circle centered at the origin of the chart. The arc starts at the normalized antenna impedance and proceeds in a clockwise direction for  $2\theta$ , where  $\theta$  is the electrical degrees, derived from the physical length and velocity factor of the transmission line. The end of the arc represents the normalized impedance at the end of the line in the

shack; it is denormalized by multiplying the real and imaginary parts by  $Z_0$ .

Antenna feedpoint  $Z$  can also be inferred from an impedance measurement at the shack end of the line. A similar procedure is followed. The only difference is that rotation is now in a counterclockwise direction. The Smith Chart is much more powerful than depicted in this brief summary. A detailed treatment is given by Phillip H. Smith in his classic book: *Electronic Applications of the Smith Chart*

(McGraw-Hill, 1969). I also recommend his article "Transmission Line Calculator" in Jan 1939 *Electronics*. Joseph White presented a wonderful summary of the chart in a short but outstanding paper: "The Smith Chart: An Endangered Species?" Nov 1979 *Microwave Journal*. *MicroSmith* is available from ARRL for \$39. The impedance matching tutorial is included, or may be obtained by dialing 203-666-0578.—Wes Hayward, W7ZOI

Fig C—The Smith Chart shown in Fig B was computer generated with *MicroSmith*. A much more detailed plot is presented here; this is the chart form used by Smith, suitable for graphic applications. Numbers are calculated by the computer in *MicroSmith*. This chart is used with the permission of Analog Instruments.

second harmonic, but also for higher even-order harmonics, such as the fourth or sixth harmonics.

Quarter-wave stubs made of good-quality coax, such as RG-213, offer a convenient way to lower transmitter harmonic levels. Despite the fact that the exact amount of harmonic attenuation depends on the impedance (often unknown) into which they are working at the harmonic frequency, a quarter-wave stub will typically yield 20 to 25 dB of attenuation of the second harmonic when placed directly at the output of a transmitter feeding common amateur antennas. Because different manufacturing runs of coax will have slightly different velocity factors, a quarter-wave stub is usually cut a little longer than calculated, and then carefully pruned by snipping off short pieces, while monitoring the response at the fundamental frequency, using a grid-dip meter or a receiver noise bridge. Because the end of the coax is an open circuit while pieces are being snipped away, the input of a quarter-wave line will show a short circuit exactly at the fundamental frequency. Once the coax has been pruned to frequency, a short jumper is soldered across the end, and the response at the second harmonic frequency is measured.

We will examine further applications of quarter-wave transmission lines later in the next section.

### Matching the Antenna to the Line

When transmission lines are used with a transmitter, the most common load is an antenna. When a transmission line is connected between an antenna and a receiver, the receiver input circuit is the load, not the antenna, because the power taken from a passing wave is delivered to the receiver.

Whatever the application, the conditions existing at the load, and *only* the load, determine the reflection coefficient, and hence the standing-wave ratio, on the line. If the load is purely resistive and equal to the characteristic impedance of the line, there will be no standing waves. If the load is not purely resistive, or is not equal to the line  $Z_0$ , there will be standing waves. No adjustments can be made at the input end of the line to change the SWR at the load. Neither is the SWR affected by changing the line length, except as previously described when the SWR at the input of a lossy line is masked by the attenuation of the line.

Only in a few special cases is the antenna impedance the exact value needed to match a practical transmission line. In all other cases, it is necessary either to operate with a mismatch and accept the SWR that results, or else to bring about a

match between the line and the antenna.

Technical literature sometimes uses the term *conjugate match* to describe the condition where the reactance seen looking toward the load from any point on the line is the complex conjugate of the impedance seen looking toward the source. A conjugate match is necessary to achieve the maximum power gain possible from a small-signal amplifier. For example, if a small-signal amplifier at 14.2 MHz has an output impedance of  $25.8 - j11.0 \Omega$ , then the maximum power possible will be generated from that amplifier when the output load is  $25.8 + j11.0 \Omega$ . The amplifier and load system is resonant because the  $\pm 11.0\text{-}\Omega$  reactances cancel.

Now, assume that 100 ft of 50- $\Omega$  RG-213 coax at 14.2 MHz just happens to be terminated in an impedance of  $115 - j25 \Omega$ . Eq 11 calculates that the impedance looking into the input of the line is  $25.8 - j11.0 \Omega$ . If this transmission line is connected directly to the small-signal amplifier above, then a conjugate match is created, and the amplifier generates the maximum possible amount of power it can generate.

However, if the impedance at the output of the amplifier is not  $25.8 - j11.0 \Omega$ , then a matching network is needed between the amplifier and its load for maximum power gain. For example, if 50 ft of RG-213 is terminated in a  $72 - j34 \Omega$  antenna impedance, the impedance at the line input becomes  $35.9 - j21.6 \Omega$ . A matching network is designed to transform  $35.9 - j21.6 \Omega$  to  $25.8 + j11.0 \Omega$ , so that once again a conjugate match is created for the small-signal amplifier.

Now, let us consider what happens with amplifiers where the power level is higher than the milliwatt level of small-signal amplifiers. Most modern transmitters are designed to work into a 50- $\Omega$  load. Most will reduce power automatically if the load is not 50  $\Omega$ —this protects them against damage and ensures linear operation without distortion.

Many amateurs use an *antenna tuner* between their transmitter and the transmission line feeding the antenna. The antenna tuner's function is to transform the impedance, whatever it is, at the shack-end of the transmission line into the 50  $\Omega$  required by their transmitter. Note that the SWR on the transmission line between the antenna and the output of the antenna tuner is rarely exactly 1:1, even though the SWR on the short length of line between the tuner and the transmitter is 1:1.

Therefore, some loss is unavoidable: additional loss due to the SWR on the line, and loss in the antenna tuner itself. How-

ever, most amateur antenna installations use antennas that are reasonably close to resonance, making these types of losses small enough to be acceptable.

Despite the inconvenience, if the antenna tuner could be placed at the antenna rather than at the transmitter output, it can transform the  $72 - j34 \Omega$  antenna impedance to a nonreactive 50  $\Omega$ . Then the line SWR is 1:1.

Impedance matching networks can take a variety of physical forms, depending on the circumstances.

### Matching the Antenna to the Line, at the Antenna

This section describes methods by which a network can be installed at the antenna itself to provide matching to a transmission line. Having the matching system up at the antenna rather than down in the shack at the end of a long transmission line does seem intuitively desirable, but it is not always very practical, especially in multiband antennas.

If a highly reactive antenna can be tuned to resonance, even without special efforts to make the resistive portion equal to the line's characteristic impedance, the resulting SWR is often low enough to minimize additional line loss due to SWR. For example, the multiband dipole in Table 19.3 has an antenna impedance of  $4.5 - j1673 \Omega$  at 1.8 MHz. Assume that the antenna reactance is tuned out with a network consisting of two symmetrical inductors whose reactance is  $+836.5 \Omega$  each, with a Q of 200. The inductors are made up of 73.95  $\mu\text{H}$  coils in series with inherent loss resistors of  $836.5/200 = 4.2 \Omega$ . The total series resistance is thus  $4.5 + 2 \times (4.2) = 12.9 \Omega$ , and the antenna reactance and inductor reactance cancel out. See Fig 19.6.

If this tuned system is fed with 50- $\Omega$  coaxial cable, the SWR is  $50/12.9 = 3.88:1$ , and the loss in 100 ft of RG-8A cable would be 0.47 dB. The radiation efficiency is  $4.5/12.9 = 34.9\%$ . Expressed another way, there is 4.57 dB of loss. Adding the 0.47 dB of loss in the line yields an overall system loss of 5.04 dB. Compare this to the loss of 17.1 dB if the RG-8A coax is used to feed the antenna directly, without any matching at the antenna. The use of a moderately high-Q resonator has yielded almost 12 dB of "gain" (that is, less loss) compared to the nonresonator case. The drawback of course is that the antenna is now resonated on only one frequency, but it certainly is a lot more efficient on that one frequency.

### The Quarter-Wave Transformer or "Q" Section

The range of impedances presented to

the transmission line is usually relatively small on a typical amateur antenna, such as a dipole or a Yagi when it is operated close to resonance. In such antenna systems, the impedance transforming properties of a quarter-wave section of transmission line are often utilized to match the transmission line at the antenna.

One example of this technique is an array of stacked Yagis on a single tower. Each antenna is resonant and is fed in parallel with the other Yagis, using equal lengths of coax to each antenna. A stacked array is used to produce not only gain, but also a wide vertical elevation pattern, suitable for coverage of a broad geographic area. (See *The ARRL Antenna Book* for details about Yagi stacking.) The feed-point impedance of two 50-Ω Yagis fed with equal lengths of feed line connected in parallel is 25 Ω (50 Ω/2); three in parallel yield 16.7 Ω; four in parallel yield 12.5 Ω. The nominal SWR for a stack of four Yagis is 4:1 (50 Ω/12.5 Ω). This level of SWR does not cause excessive line loss, provided that low-loss coax feed line is used. However, many station designers want to be able to select, using relays, any individual antenna in the array, without having the load seen by the transmitter change. Perhaps they might wish to turn one antenna in the stack in a different direction and use it by itself. If the load changes, the amplifier must be retuned, an inconvenience at best.

See Fig 19.7. If the antenna impedance and the characteristic impedance of a feed line to be matched are known, the characteristic impedance needed for a quarter-wave matching section of low-loss cable is expressed by another simplification of Eq 11.

$$Z = \sqrt{Z_1 Z_0} \quad (14)$$

where

$Z$  = characteristic impedance needed for matching section

$Z_1$  = antenna impedance

$Z_0$  = characteristic impedance of the line to which it is to be matched.

Example: To match a 50-Ω line to a Yagi stack consisting of two antennas fed in parallel to produce a 25-Ω load, the quarter-wave matching section would require a characteristic impedance of

$$Z = \sqrt{50 \times 25} = 35.4 \Omega$$

A transmission line with a characteristic impedance of 35 Ω could be closely approximated by connecting two equal lengths of 75-Ω cable (such as RG-11A) in parallel to yield the equivalent of a 37.5-Ω cable. Three Yagis fed in parallel would require a quarter-wave transformer

**Fig 19.6**—The efficiency of the dipole in Table 19.3 can be improved at 1.8 MHz with a pair of inductors inserted symmetrically at the feedpoint. Each inductor is assumed to have a  $Q$  of 200. By resonating the dipole in this fashion the system efficiency, when fed with RG-8A coax, is almost 20 dB better than using this same antenna without the resonator. The disadvantage is that the formerly multiband antenna can only be used on a single band.

**Fig 19.7**—Array of two stacked Yagis, illustrating use of quarter-wave matching sections. At the junction of the two equal lengths of 50-Ω feed line the impedance is 25 Ω. This is transformed back to 50 Ω by the two paralleled 75-Ω, quarter-wave lines, which together make a net characteristic impedance of 37.5 Ω. This is close to the 35.4 Ω value computed by the formula  $\sqrt{25 \times 50}$ .

made using a cable having a characteristic impedance of

$$\sqrt{16.7 \times 50} = 28.9 \Omega$$

This is approximated by using a quarter-wave section of 50-Ω cable in parallel with a quarter-wave section of 75-Ω cable, yielding a net impedance of 30 Ω, quite close enough to the desired 28.9 Ω. Four Yagis fed in parallel would require a quarter-wave transformer made up using cable with a characteristic impedance of 25 Ω, easily created by using two 50-Ω

cables in parallel.

### T- and Gamma-Match Sections

Many types of antennas exhibit a feed-point impedance lower than the 50-Ω characteristic impedance of commonly available coax cable. Both the so-called *T-Match* and the *Gamma-Match* are used extensively on Yagi and quad beam antennas to increase the antenna feed impedance to 50 Ω.

The method of matching shown in Fig 19.8 is based on the fact that the im-

pedance between any two points equidistant from the center along a resonant antenna is resistive, and has a value that depends on the spacing between the two points. It is therefore possible to choose a pair of points between which the impedance will have the right value to match a transmission line. In practice, the line cannot be connected directly at these points because the distance between them is much greater than the conductor spacing of a practical transmission line. The T arrangement in Fig 19.8A overcomes this difficulty by using a second conductor paralleling the antenna to form a matching section to which the line may be connected.

The T is particularly well suited to use with parallel-conductor feed line. The operation of this system is somewhat complex. Each T conductor (Y in the drawing) forms a short section of transmission line with the antenna conductor opposite it. Each of these transmission-line sections can be considered to be terminated in the impedance that exists at the point of connection to the antenna. Thus, the part of the antenna between the two points carries a transmission-line current in addition to the normal antenna current. The two transmission-line matching sections are in series, as seen by the main transmission line.

If the antenna by itself is resonant at the operating frequency, its impedance will be purely resistive. In this case the matching-section lines are terminated in a resistive

load. As transmission-line sections however, these matching sections are terminated in a short, and are shorter than a quarter wavelength. Thus their input impedance, the impedance seen by the main transmission line looking into the matching-section terminals, will be inductive as well as resistive. The reactive component of the input impedance must be tuned out before a proper match can be obtained.

One way to do this is to detune the antenna just enough, by shortening its length, to cause capacitive reactance to appear at the input terminals of the matching section, thus canceling the reactance introduced. Another method, which is considerably easier to adjust, is to insert a variable capacitor in series with each matching section where it connects to the transmission line, as shown in the chapter on **Antennas**. The capacitors must be protected from the weather.

When the series-capacitor method of reactance compensation is used, the antenna should be the proper length for resonance at the operating frequency. Trial positions of the matching-section taps are then taken, each time adjusting the capacitor for minimum SWR, until the lowest possible SWR has been achieved. The unbalanced (gamma) arrangement in Fig 19.8B is similar in principle to the T, but is adapted for use with single coax line. The method of adjustment is the same.

### The Hairpin Match

In beam antennas such as Yagis or quads, which utilize parasitic directors and

reflectors to achieve directive gain, the mutual impedance between the parasitic and the driven elements lowers the resistive component of the driven-element impedance, typically to a value between 10 and 30  $\Omega$ . If the driven element is purposely cut slightly shorter than its half-wave resonant length, it will exhibit a capacitive reactance at its feedpoint. A shunt inductor as shown in Fig 19.9 placed across the feed-point center insulator can be used to transform the antenna resistance to match the characteristic impedance of the transmission line, while canceling out the capacitive reactance simultaneously. The antenna's capacitive reactance and the hairpin shunt inductor form an L network.

For mechanical convenience, the shunt inductor is often constructed using heavy-gauge aluminum wire bent in the shape of a hairpin. The center of the hairpin, the end farthest from the driven element, is grounded to the boom, since this point in a balanced feed system is equidistant from the antenna feed terminals. This gives some protection against static buildup and a certain measure of lightning protection. The disadvantage of the Hairpin match is that it does require that the driven element be split and insulated at its center. Since only the length of the driven element and the value of shunt inductance can be varied in the Hairpin, the SWR often cannot be brought down to exactly 1:1 at a desired frequency in the band, as it can be with the T or Gamma matches previously described.

### Matching the Line to the Transmitter

So far we have been concerned mainly with the measures needed to achieve acceptable amounts of loss and a low SWR when real coax lines are connected to real antennas. Not only is feed-line loss minimized when the SWR is kept within reasonable bounds, but also the transmitter is able to deliver its rated output power, at its rated level of distortion, when it sees the load resistance it was designed to feed.

Most modern amateur transmitters use broadband, untuned solid-state final amplifiers designed to work into a 50- $\Omega$  load. Such a transmitter very often utilizes built-in protection circuitry, which automatically reduces output power if the SWR rises to more than about 2:1. Protective circuits are needed because many solid-state devices will willingly and almost instantly destroy themselves attempting to deliver power into low-impedance loads. Solid-state devices are a lot less forgiving than vacuum tube amplifiers, which can survive momentary overloads without being destroyed instantly. Pi networks used

Fig 19.8—The T match (A) and gamma match (B).

Fig 19.9—Hairpin match, sometimes called the Beta match. The "hairpin" is a shunt inductor, which together with the series capacitive reactance of an electrically short driven element, forms an L network. This L network transforms the antenna resistive component to 50  $\Omega$ .

in vacuum-tube amplifiers typically have the ability to match a surprisingly wide range of impedances on a transmission line. See the **Amplifiers** chapter in this *Handbook*.

Besides the rather limited option of using only inherently low-SWR antennas to ensure that the transmitter sees the load for which it was designed, we radio amateurs have another alternative. We can use a *Transmatch*. This is a coined word, referring to a "Transmitter Matching" network. The function of a Transmatch is to transform the impedance at the input end of the transmission line, whatever it may be, to the  $50\ \Omega$  needed to keep the transmitter loaded properly. Do not forget: A Transmatch does not alter the SWR on the transmission line going to the antenna; it only keeps the transmitter looking into the load for which it was designed. Indeed, some solid-state transmitters incorporate (usually at extra cost) automatically tuned *antenna couplers* (another name for Transmatch), so that they too can cope with practical antennas and transmission lines that are not perfectly flat. The range of impedances which can be matched is typically rather limited, however, especially at lower frequencies.

Over the years, radio amateurs have derived a number of circuits for use as Transmatches. At one time, when open-wire transmission line was more widely used, link coupled tuned circuits were in vogue. See Fig 19.10. With the increasing popularity of coaxial cable used as feed lines, other circuits have become more prevalent. The most common form of Transmatch in recent years is some variation of a T configuration, as shown in Fig 19.11A.

The T network can be visualized as being two L networks back to front, where the common element has been conceptually broken down into two inductors in parallel. See Fig 19.11B. The L network connected to the load transforms the output impedance  $R_a \pm jX_a$  into its parallel

equivalent by means of the series output capacitor  $C_2$ . The first L network then transforms the parallel equivalent back into the series equivalent and resonates the reactance with the input series capacitor  $C_1$ .

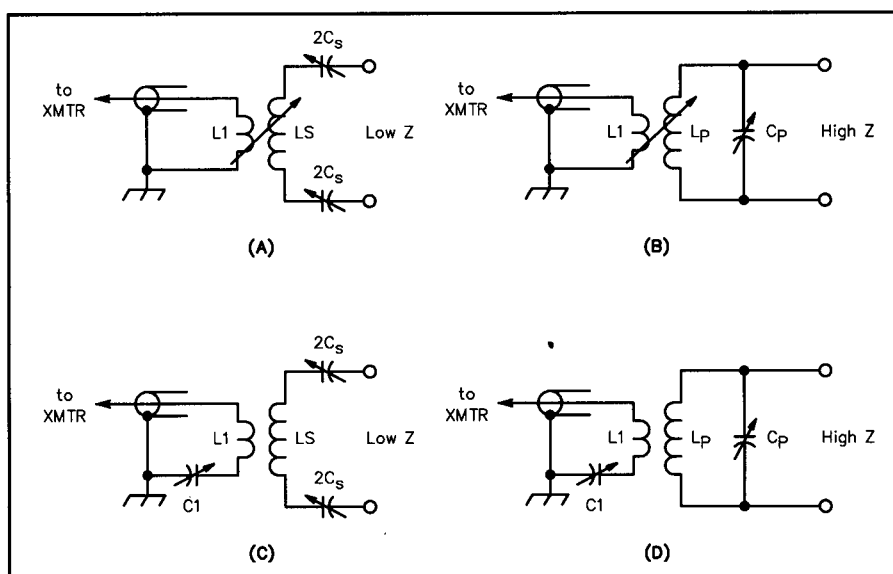

Note that the equivalent parallel resistance  $R_p$  across the shunt inductor can be a very large value for highly reactive loads, meaning that the voltage developed at this point can be very high. For example, assume that the load impedance at 3.8 MHz presented to the Transmatch is  $Z_a = 20 - j1000$ . If  $C_2$  is 300 pF, then the equivalent parallel resistance across  $L_1$  is  $66326\ \Omega$ . If 1500 W appears across this parallel resistance, a peak voltage of 14106 V is produced, a very substantial level indeed. Highly reactive loads can produce very high voltages across components in a Transmatch.

The ARRL computer program *TL* calculates and shows graphically the Transmatch values for operator selected antenna impedances transformed through lengths of various types of practical transmission lines. The **Station Accessories** chapter includes a Transmatch project, and *The ARRL Antenna Book* contains detailed information on Transmatch design and construction.

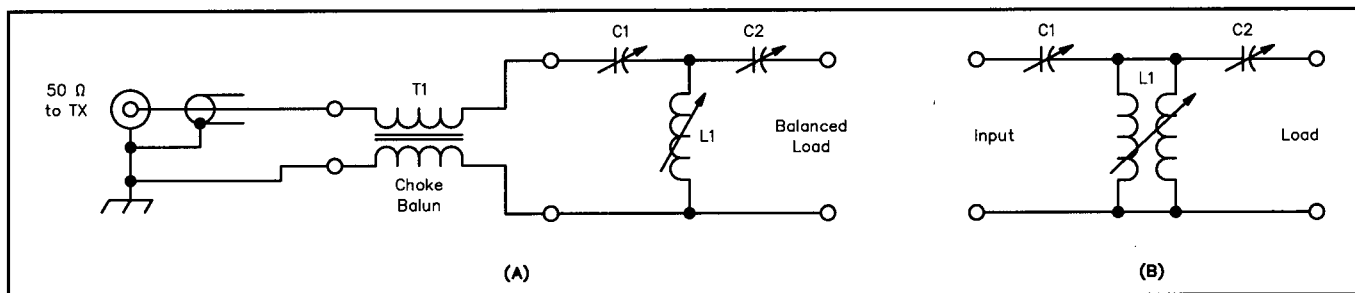

### Myths About SWR

This is a good point to stop and mention that there are some enduring and quite misleading myths in Amateur Radio concerning SWR.

Despite some claims to the contrary, a high SWR *does not by itself* cause RFI, or TVI or telephone interference. While it is true that an antenna located close to such devices can cause overload and inter-

**Fig 19.10—Simple Transmatches for coupling a transmitter to a balanced line presenting a load different from the transmitter's design load impedance, usually  $50\ \Omega$ . A and B, respectively, are series and parallel tuned circuits using variable inductive coupling between coils. C and D are similar but use fixed inductive coupling and a variable series capacitor,  $C_1$ . A series tuned circuit works well with a low-impedance load; the parallel circuit is better with high impedance loads (several hundred ohms or more).**

**Fig 19.11—Transmatch network in T configuration. This network has become popular because it has the capability of matching a wide range of impedances. At A, the balun transformer at the input of the Transmatch preserves balance when feeding a balanced transmission line. At B, the T configuration is shown as two L networks back to back.**

ference, the SWR on the feed line to that antenna has nothing to do with it, providing of course that the Transmatch, feed line or connectors are not arcing. The antenna is merely doing its job, which is to radiate. The transmission line is doing its job, which is to convey power from the transmitter to the radiator.

A second myth, often stated in the same breath as the first one above, is that a high SWR will cause excessive radiation from a transmission line. SWR has nothing to do with excessive radiation from a line. *Imbalances* in open-wire lines cause radiation, but such imbalances are not related to SWR. This subject will be covered more in the section on baluns.

A third and perhaps even more prevalent myth is that you can't "get out" if the SWR on your transmission line is higher than 1.5:1, or 2:1 or some other such arbitrary figure. On the HF bands, if you use reasonable lengths of good coaxial cable (or even better yet, open-wire line), the truth is that you need not be overly concerned if the SWR at the load is kept below about 6:1. This sounds pretty radical to some amateurs who have heard horror story after horror story about SWR. The fact is that if you can load up your transmitter without any arcing inside,

or if you use a Transmatch to make sure your transmitter is operating into its rated load resistance, you can enjoy a very effective station, using antennas with feed lines having high values of SWR on them. For example, a 450- $\Omega$  open-wire line connected to the multiband dipole shown in Table 19.3 would have a 19:1 SWR on it at 3.8 MHz. Yet time and again this antenna has proven to be a great performer at many installations.

Fortunately or unfortunately, SWR is one of the few antenna and transmission-line parameters easily measured by the average radio amateur. Ease of measurement does not mean that a low SWR should become an end in itself! The hours spent pruning an antenna so that the SWR is reduced from 1.5:1 down to 1.3:1 could be used in far more rewarding ways—making QSOs, for example, or studying transmission-line theory.

### Loads and Balancing Devices

Center-fed dipoles and loops are *balanced*, meaning that they are electrically symmetrical with respect to the feedpoint. A balanced antenna should be fed by a balanced feeder system to preserve this electrical symmetry with respect to ground, thereby avoiding difficulties with

unbalanced currents on the line and undesirable radiation from the transmission line itself. Line radiation can be prevented by a number of devices which detune or *decouple* the line for currents radiated by the antenna back onto the line that feeds it, greatly reducing the amplitude of such *antenna currents*.

Many amateurs use center-fed dipoles or Yagis, fed with unbalanced coaxial line. Some method should be used for connecting the line to the antenna without upsetting the symmetry of the antenna itself. This requires a circuit that will isolate the balanced load from the unbalanced line, while still providing efficient power transfer. Devices for doing this are called *baluns* (a contraction for "balanced to unbalanced"). A balanced antenna fed with balanced line, such as two-wire ladder line, will maintain its inherent balance, so long as external causes of unbalance are avoided. However, even they will require some sort of balun at the transmitter, since modern transmitters have unbalanced (coax) outputs.

If a balanced antenna is fed at the center through a coaxial line without a balun, as indicated in **Fig 19.12A**, the inherent symmetry and balance is upset because one side of the radiator is connected to the shield while the other is connected to the inner conductor. On the side connected to the shield, current can be diverted from flowing into the antenna, and instead can flow down over the outside of the coaxial shield. The field thus set up cannot be canceled by the field from the inner conductor because the fields inside the cable cannot escape through the shielding of the outer conductor. Hence currents flowing on the outside of the line will be responsible for some radiation from the line.

This is a good point to say that striving for perfect balance in a line and antenna system is not always absolutely mandatory. For example, if a nonresonant center fed dipole is fed with open-wire line and a Transmatch for multiband operation, the most desirable radiation pattern for general-purpose communication is actually an omnidirectional pattern. A certain amount of feed-line radiation might actually help fill in otherwise undesirable nulls in the azimuthal pattern of the antenna itself. Furthermore, the radiation pattern of a coaxial-fed dipole that is only a few tenths of a wavelength off the ground (50 ft high on the 80-m band, for example) is not very directional anyway, because of its severe interaction with the ground.

Purists may cry out in dismay, but there are many thousands of coaxial-fed dipoles in daily use worldwide that perform very effectively without the benefit of a balun.

**Fig 19.12—Quarter-wave baluns. Radiator with coaxial feed (A) and methods of preventing unbalanced currents from flowing on the outside of the transmission line (B and C). The  $\frac{1}{2} \lambda$ -phasing section shown at D is used for coupling to an unbalanced circuit when a 4:1 impedance ratio is desired or can be accepted.**

However, some form of balun should be used to preserve the pattern of an antenna that is purposely designed to be highly directional, such as a Yagi or a quad.

### Quarter-Wave Baluns

Fig 19.12B shows a balun arrangement known as a *bazooka*, which uses a sleeve over the transmission line. The sleeve, together with the outside portion of the outer coax conductor, forms a shorted quarter-wave line section. The impedance looking into the open end of such a section is very high, so the end of the outer conductor of the coaxial line is effectively isolated from the part of the line below the sleeve. The length is an electrical quarter wave, and because of the velocity factor may be physically shorter if the insulation between the sleeve and the line is not air. The bazooka has no effect on antenna impedance at the frequency where the quarter-wave sleeve is resonant. However, the sleeve adds inductive shunt reactance at frequencies lower, and capacitive shunt reactance at frequencies higher than the quarter-wave-resonant frequency. The bazooka is mostly used at VHF, where its physical size does not present a major problem. On HF a quarter-wavelength rigid sleeve becomes considerably more challenging to construct, especially for a rotary antenna such as a Yagi.

Another method that gives an equivalent effect is shown at Fig 19.12C. Since the voltages at the antenna terminals are equal and opposite (with reference to ground), equal and opposite currents flow on the surfaces of the line and second conductor. Beyond the shorting point, in the direction of the transmitter, these currents combine to cancel out. The balancing section acts like an open circuit to the antenna, since it is a quarter-wave parallel-conductor line shorted at the far end, and thus has no effect on normal antenna operation. This is not essential to the line balancing function of the device, however, and baluns of this type are sometimes made shorter than a quarter wavelength to provide a shunt inductive reactance required in certain matching systems (such as the Hairpin).

Fig 19.12D shows a third balun, in which equal and opposite voltages, balanced to ground, are taken from the inner conductors of the main transmission line and half-wave phasing section. Since the voltages at the balanced end are in series while the voltages at the unbalanced end are in parallel, there is a 4:1 step down in impedance from the balanced to the unbalanced side. This arrangement is useful for coupling between a 300- $\Omega$  balanced line and a 75- $\Omega$  unbalanced coaxial line.

### Broadband Baluns

At HF and even at VHF, broadband baluns are generally used nowadays. These can be divided into two distinct categories: voltage baluns and choke (or current) baluns. Examples of the two types of bal-

uns are shown in Fig 19.13.

The voltage baluns of Fig 19.13A and Fig 19.13B cause equal and opposite voltages to appear at the two output terminals, relative to the voltage at the "cold" (coax cable ground) side of the input. If the two

Fig 19.13—Broadband baluns. (A) 1:1 voltage balun; (B) 4:1 voltage balun; (C) 1:1 current balun; and (D) 4:1 current transformer. (D) is wound on two cores, which are separated.

antenna halves are perfectly balanced in impedance with respect to ground, the balun will force the voltages to be equal, and the currents flowing from the balun's output terminals will be equal and opposite. No antenna current will flow on the feed line, and the feed line will not radiate. If the load is balanced, the 1:1 voltage balun of Fig 19.13A performs exactly the same function as the current balun of Fig 19.13C, as there is no net current in winding b. If the antenna isn't perfectly symmetrical, however, unequal currents will appear at the balun output, despite equal voltages, causing antenna current to flow on the line, an undesirable condition leading to line radiation.

Another potential shortcoming of the 1:1 voltage balun is that the windings appear across the line. If the windings have insufficient inductive reactance (a common problem, particularly near the lower-frequency end of its range), the system SWR will be degraded. The choke, or current balun, is generally recommended for use at the junction of the antenna and feed line. However, voltage baluns are still commonly used in this application and serve a useful function if the user is aware of their shortcomings.

While voltage baluns cause equal and opposite voltages to appear at their outputs, choke or current baluns force equal and opposite currents to flow. The result is that currents radiated back onto the transmission line by the antenna are effectively reduced, or "choked off," even if the antenna is not perfectly balanced. If winding inductive reactance becomes marginal at lower frequencies, the balun's ability to eliminate antenna currents is reduced, but (for the 1:1 balun) no winding impedance appears across the line.

For either type of balun, if induced current on the line is a problem, perhaps because the feed line must be run in parallel with the antenna for some portion of its length, additional baluns can be placed at

approximately  $\frac{1}{4}\lambda$  intervals along the line. Current baluns are particularly useful for feeding asymmetrical antennas with balanced line.

### Broadband Balun Construction

Either type of broadband balun can be constructed using a variety of techniques. Construction of choke (current) baluns is described here. The objective is to obtain a high impedance for currents that tend to flow on the line. Values from a few hundred to over a thousand ohms of inductive reactance are readily achieved. These baluns work best with antennas having resonant feed-point impedances less than 100  $\Omega$  or so (400  $\Omega$  for 4:1 baluns). This is because the winding inductive reactance must be high relative to the antenna impedance for effective operation. A rule of thumb is that the inductive reactance should be four times higher than the antenna impedance. High impedances are difficult to achieve over a wide frequency range. Any sort of transformer which is operated at impedances for which it was not designed can fail, sometimes spectacularly.

The simplest construction method for a 1:1 balun for coaxial line is simply to wind a portion of the line into a coil. See Fig 19.14. This type of choke balun is simple, cheap and effective. Currents on the outside of the line encounter the coil's impedance, while currents on the inside are unaffected. A flat coil (like a coil of rope) shows a broad resonance that easily covers three bands, making it reasonably effective over the entire HF range. If particular problems are encountered on a single band, a coil that is resonant at that band may be added. The coils shown in Table 19.4 were constructed to have a high impedance at the indicated frequencies, as measured with an impedance meter. Many other geometries can also be effective. This construction technique is not effective with open-wire or twin-lead line be-

cause of coupling between adjacent turns. An air-core 4:1 choke balun is shown in Fig 19.15.

Ferrite-core baluns can provide a high impedance over the entire HF range. They may be wound either with two conductors in bifilar fashion, or with a single coaxial cable. Rod or toroidal cores may be used. Current through a choke balun winding is the "antenna current" on the line; if the balun is effective, this current is small.

Fig 19.14—RF choke formed by coiling the feed line at the point of connection to the antenna. The inductance of the choke isolates the antenna from the remainder of the feed line.

Table 19.4  
Effective Choke (Current Baluns)

Wind the indicated length of coaxial feed line into a coil (like a coil of rope) and secure with electrical tape. The balun is most effective when the coil is near the antenna. Lengths are not critical.

#### Single Band (Very Effective)

Freq MHz	RG-213, RG-8	RG-58
3.5	22 ft, 8 turns	20 ft, 6-8 turns
7	22 ft, 10 turns	15 ft, 6 turns
10	12 ft, 10 turns	10 ft, 7 turns
14	10 ft, 4 turns	8 ft, 8 turns
21	8 ft, 6-8 turns	6 ft, 8 turns
28	6 ft, 6-8 turns	4 ft, 6-8 turns

#### Multiple Band

Freq, MHz	RG-8, 58, 59, 8X, 213
3.5-30	10 ft, 7 turns
3.5-10	18 ft, 9-10 turns
14-30	8 ft, 6-7 turns

Fig 19.15—4:1 air-core current balun. This balun is rarely encountered nowadays, having been supplanted at HF by more compact broadband balun transformers wound on toroidal cores.

Fig 19.16—W2DU bead balun consisting of 50 FB-73-2401 ferrite beads over a length of RG-303 coax. See text for details.

Baluns used for high-power operation should be tested by checking for temperature rise before use. If the core overheats, add turns or use a larger or lower-loss core. It also would be wise to investigate the imbalance causing such high line antenna currents.

Type 72, 73 or 77 ferrite gives the greatest impedance over the HF range. Type 43 ferrite has lower loss, but somewhat less impedance. Core saturation is not a problem with these ferrites at HF; since they overheat due to loss at flux levels well below saturation. The loss occurs because there is insufficient inductive reactance at lower frequencies. Eight to ten turns on a toroidal core or 10 to 15 turns on a rod are typical for the HF range. Winding impedance increases approximately as the square of the number of turns.

Another type of choke balun that is very effective was originated by M. Walter Maxwell, W2DU. A number of ferrite toroids are strung, like beads on a string, directly onto the coax where it is connected to the antenna. The "bead" balun in Fig 19.16 consists of 50 FB73-2401 ferrite beads slipped over a 1-ft length of RG-303 coax. The beads fit nicely over the insulating jacket of the coax and occupy a total length of 9 1/2 inches. Twelve, FB-77-1024 or equivalent beads will come close to doing the same job using RG-8A or RG-213 coax. Type-73 material is recommended for 1.8 to 30 MHz use, but type-77 material may be substituted; use type-43 material for 30 to 250 MHz.

The cores present a high impedance to any RF current that would otherwise flow on the outside of the shield. The total impedance is in approximate proportion to the stacked length of the cores. The impedance stays fairly constant over a wide range of frequencies. Again, 70-series ferrites are a good choice for the HF range; use type-43 if heating is a problem. Type-43 or -61 is the best choice for the VHF range. Cores of various materials can be used in combination, permitting construction of baluns effective over a very wide frequency range, such as from 2 to 250 MHz.

## WAVEGUIDES

A waveguide is a hollow, conducting tube, through which microwave energy is transmitted in the form of electromagnetic waves. The tube does not carry a current in the same sense that the wires of a two-conductor line do. Instead, it is a boundary that confines the waves to the enclosed space. Skin effect on the inside walls of the waveguide confines electromagnetic energy inside the guide, in much the same manner that the shield of a coaxial cable

**Fig 19.17**—At its cutoff frequency a rectangular waveguide can be analyzed as a parallel two-conductor transmission line supported from top and bottom by an infinite number of quarter-wavelength stubs.

confines energy within the coax. Microwave energy is injected at one end (either through capacitive or inductive coupling or by radiation) and is received at the other end. The waveguide merely confines the energy of the fields, which are propagated through it to the receiving end by means of reflections off its inner walls.

## Evolution of a Waveguide

Suppose an open-wire line is used to carry UHF energy from a generator to a load. If the line has any appreciable length, it must be well insulated from the supports to avoid high losses. Since high-quality insulators are difficult to make for microwave frequencies, it is logical to support the transmission line with quarter-wavelength stubs, shorted at the far end. The open end of such a stub presents an infinite impedance to the transmission line, provided that the shorted stub is nonreactive. However, the shorting link has finite length and, therefore, some inductance. This inductance can be nullified by making the RF current flow on the surface of a plate rather than through a thin wire. If the plate is large enough, it will prevent the magnetic lines of force from encircling the RF current.

An infinite number of these quarter-wave stubs may be connected in parallel without affecting the standing waves of voltage and current. The transmission line may be supported from the top as well as the bottom, and when infinitely many supports are added, they form the walls of a waveguide at its cutoff frequency. Fig 19.17 illustrates how a rectangular waveguide evolves from a two-wire parallel transmission line. This simplified analysis also shows why the cutoff dimension is a half wavelength.

While the operation of waveguides is

**Fig 19.18**—Field distribution in a rectangular waveguide. The  $TE_{1,0}$  mode of propagation is depicted.

**Table 19.5**  
**Wavelength Formulas for Waveguide**

	Rectangular	Circular
Cut-off wavelength	$2X$	$3.41R$
Longest wavelength transmitted with little attenuation	$1.6X$	$3.2R$
Shortest wavelength before next mode becomes possible	$1.1X$	$2.8R$

usually described in terms of fields, current does flow on the inside walls, just as fields exist between the conductors of a two-wire transmission line. At the waveguide cutoff frequency, the current is concentrated in the center of the walls, and disperses toward the floor and ceiling as the frequency increases.

Analysis of waveguide operation is based on the assumption that the guide material is a perfect conductor of electricity. Typical distributions of electric and magnetic fields in a rectangular guide are shown in Fig 19.18. The intensity of the electric field is greatest (as indicated by closer spacing of the lines of force in Fig 19.18B) at the center along the X dimension and diminishes to zero at the end walls. Zero field intensity is a necessary condition at the end walls, since the existence of any electric field parallel to any wall at the surface would cause an infinite current to flow in a perfect conductor, which is an impossible situation.

### Modes of Propagation

Fig 19.18 represents a relatively simple distribution of the electric and magnetic fields. An infinite number of ways exist in which the fields can arrange themselves in a guide, as long as there is no upper limit to the frequency to be transmitted. Each field configuration is called a mode. All modes may be separated into two general groups. One group, designated TM (transverse magnetic), has the magnetic field entirely crosswise to the direction of propagation, but has a component of electric field in the propagation direction. The other type, designated TE (transverse electric) has the electric field entirely crosswise to the direction of propagation, but has a component of magnetic field in the direction of propagation. TM waves are

**Fig 19.19—Coupling to waveguide and resonators. The probe at A is an extension of the inner conductor of coax line. At B an extension of the coax inner conductor is grounded to the waveguide to form a coupling loop.**

sometimes called E waves, and TE waves are sometimes called H waves. The TM and TE designations are preferred, however.

The particular mode of transmission is identified by the group letters followed by subscript numbers; for example  $TE_{1,1}$ ,  $TM_{1,1}$  and so on. The number of possible modes increases with frequency for a given size of guide. There is only one possible mode (called the *dominant mode*) for the lowest frequency that can be transmitted. The dominant mode is the one normally used in practical work.

### Waveguide Dimensions

In rectangular guides the critical dimension (shown as X in Fig 19.18C) must be more than one-half wavelength at the lowest frequency to be transmitted. In practice, the Y dimension is usually made about equal to  $1/2$  X to avoid the possibility of operation at other than the dominant mode. Cross-sectional shapes other than rectangles can be used; the most important is the circular pipe.

Table 19.5 gives dominant-mode wave-

length formulas for rectangular and circular guides. X is the width of a rectangular guide, and R is the radius of a circular guide.

### Coupling to Waveguides

Energy may be introduced into or extracted from a waveguide or resonator by means of either the electric or magnetic field. The energy transfer frequently takes place through a coaxial line. Two methods for coupling are shown in Fig 19.19. The probe at A is simply a short extension of the inner conductor of the feed coaxial line, oriented so that it is parallel to the electric lines of force. The loop shown at B is arranged to enclose some of the magnetic lines of force. The point at which maximum coupling will be obtained depends on the particular mode of propagation in the guide or cavity; the coupling will be maximum when the coupling device is in the most intense field.

Coupling can be varied by rotating the probe or loop through  $90^\circ$ . When the probe is perpendicular to the electric lines the coupling will be minimum; similarly, when the plane of the loop is parallel to the magnetic lines, the coupling will be minimum. See *The ARRL Antenna Book* for more information on waveguides.

## 20

### ANTENNA BASICS

Every ham needs at least one antenna, and most hams have built one. This chapter, by Chuck Hutchinson, K8CH, covers theory and construction of antennas for most radio amateurs. Here you'll find simple verticals and dipoles, as well as quad and Yagi projects and other antennas that you can build and use.

The amount of available space should be high on the list of factors to consider when selecting an antenna. Those who live in urban areas often must accept a compromise antenna for the HF bands because a city lot won't accommodate full-size wire dipoles, end-fed systems or high supporting structures. Other limitations are imposed by the amount of money available for an antenna system (including supporting hardware), the number of amateur bands to be worked and local zoning ordinances.

Operation objectives also come into play. Do you want to dedicate yourself to serious contesting and DXing? Are you looking for general-purpose operation that will yield short- and long-haul QSOs during periods of good propagation? Your answers should result in selecting an antenna that will meet your needs. You might want to erect the biggest and best collection of antennas that space and finances will allow. If a modest system is the order of the day, then use whatever is practical

and accept the performance that follows. Practically any radiator works well under some propagation conditions, assuming the radiator is able to accept power and radiate it at some useful angle. Any antenna is a good one if it meets your needs!

In general, the height of the antenna above ground is the most critical factor at the higher end of the HF spectrum, that is from roughly 14 through 30 MHz. This is because the antenna should be clear of conductive objects such as power lines, phone wires, gutters and the like, plus high enough to have a low radiation angle. Lower frequency antennas, operating between 2 and 10 MHz, should also be kept well away from conductive objects and as high above ground as possible if you want good performance.

### Antenna Polarization

Most HF-band antennas are either vertically or horizontally polarized, although circular polarization is possible, just as it is at VHF and UHF. *Polarization* is determined by the position of the radiating element or wire with respect to the earth. Thus a radiator that is parallel to the earth radiates horizontally, while an antenna at a right angle to the earth (vertical) radiates a vertical wave. If a wire antenna is slanted above earth, it radiates waves that have both a vertical and a horizontal component.

For best results in line-of-sight commu-

nications, antennas at both ends of the circuit should have the same polarity; cross polarization results in many decibels of signal reduction. It is not essential for both stations to use the same antenna polarity for ionospheric propagation (sky wave). This is because the radiated wave is bent and it tumbles considerably during its travel through the ionosphere. At the far end of the communications path the wave may be horizontal, vertical or somewhere in between at any given instant. On multihop transmissions, in which the signal is refracted more than once from the ionosphere, and subsequently reflected from the Earth's surface during its travel, considerable polarization shift will occur. For that reason, the main consideration for a good DX antenna is a low angle of radiation rather than the polarization.

### Antenna Bandwidth

The *bandwidth* of an antenna refers generally to the range of frequencies over which the antenna can be used to obtain good performance. The bandwidth is often referenced to some SWR value, such as, "The 2:1 SWR bandwidth is 3.5 to 3.8 MHz." Popular amateur usage of the term "bandwidth" most often refers to the 2:1 SWR bandwidth. Other specific bandwidth terms are also used, such as the *gain bandwidth* and the *front-to-back ratio bandwidth*.

For the most part, the lower the operat-

ing frequency of a given antenna design, the narrower is the bandwidth. This follows the rule that the bandwidth of a resonant circuit doubles as the frequency of operation is doubled, assuming the Q is the same for each case. Therefore, it is often difficult to cover all of the 160 or 80-m band for a particular level of SWR with a dipole antenna. It is important to recognize that SWR bandwidth does not always relate directly to gain bandwidth. Depending on the amount of feed-line loss, an 80-m dipole with a relatively narrow 2:1 SWR bandwidth can still radiate a good signal at each end of the band, provided that an antenna tuner is used to allow the transmitter to load properly.

**Fig 20.1—Curves showing the radiation resistance of vertical and horizontal half-wavelength dipoles at various heights above ground. The broken-line portion of the curve for a horizontal dipole shows the resistance over “average” real earth, the solid line for perfectly conducting ground.**

**Fig 20.2—Effect of antenna diameter on length for half-wavelength resonance, shown as a multiplying factor, K, to be applied to the free-space, half-wavelength equation (Eq 1 in text). The effect of conductor diameter on the resistive component of the center feed-point impedance is shown here also.**

Broadbanding techniques, such as fanning the far ends of a dipole to simulate a conical type of dipole, can help broaden the SWR response curve.

### Current and Voltage Distribution

When power is fed to an antenna, the current and voltage vary along its length. The current is nearly zero (a current *node*) at the ends. The current does not actually reach zero at the current nodes, because of capacitance at the antenna ends. Insulators, loops at the antenna ends, and support wires all contribute to this capacitance, which is also called the “end effect.” In the case of a half-wave antenna there is a current maximum (a current *loop*) at the center.

The opposite is true of the RF voltage. That is, there is a voltage loop at the ends, and in the case of a half-wave antenna there is a voltage minimum (node) at the center. The voltage is not zero at its node because of the resistance of the antenna, which consists of both the RF resistance of the wire (ohmic loss resistance) and the *radiation resistance*. The radiation resistance is the equivalent resistance that would dissipate the power the antenna radiates, with a current flowing in it equal to the antenna current at a current loop (maximum). The loss resistance of a half-wave antenna is ordinarily small, compared with the radiation resistance, and can usually be neglected for practical purposes.

### Impedance

The *impedance* at a given point in the antenna is determined by the ratio of the voltage to the current at that point. For example, if there were 100 V and 1.4 A of RF current at a specified point in an antenna and if they were in phase, the impedance would be approximately 71 Ω.

Antenna impedance may be either resistive or complex (that is, containing resistance and reactance). This will depend on whether or not the antenna is *resonant* at the operating frequency. You need to know the impedance in order to match the feeder to the feedpoint. Some operators mistakenly believe that a mismatch, however small, is a serious matter. This is not true. The importance of a matched line is described in detail in the **Transmission Lines** chapter of this book. The significance of a perfect match becomes more pronounced only at VHF and higher, where feed-line losses are a major factor.

Some antennas possess a theoretical input impedance at the feedpoint close to that of certain transmission lines. For example, a 0.5-λ (or half wave) center-fed dipole, placed at a correct height above ground, will have a feedpoint impedance of approxi-

mately 75 Ω. In such a case it is practical to use a 75-Ω coaxial or balanced line to feed the antenna. But few amateur half-wave dipoles actually exhibit a 75-Ω impedance. This is because at the lower end of the high-frequency spectrum the typical height above ground is rarely more than  $\frac{1}{4}\lambda$ . The 75-Ω feed-point impedance is most likely to be realized in a practical installation when the horizontal dipole is approximately  $\frac{1}{2}$ ,  $\frac{3}{4}$  or 1 wavelength above ground. Coax cable having a 50-Ω characteristic impedance is the most common transmission line used in amateur work.

**Fig 20.1** shows the difference between the effects of perfect ground and typical earth at low antenna heights. The effect of height on the radiation resistance of a horizontal half-wave antenna is not drastic so long as the height of the antenna is greater than  $0.2\lambda$ . Below this height, while decreasing rapidly to zero over perfectly conducting ground, the resistance decreases less rapidly with height over actual ground. At lower heights the resistance stops decreasing at around  $0.15\lambda$ , and thereafter increases as height decreases further. The reason for the increasing resistance is that more and more of the induction field of the antenna is absorbed by the earth as the height drops below  $\frac{1}{4}\lambda$ .

### Conductor Size

The impedance of the antenna also depends on the diameter of the conductor in relation to the wavelength, as indicated in **Fig 20.2**. If the diameter of the conductor is increased, the capacitance per unit length increases and the inductance per unit length decreases. Since the radiation resistance is affected relatively little, the decreased L/C ratio causes the Q of the antenna to decrease so that the resonance curve becomes less sharp with change in frequency. This effect is greater as the diameter is increased, and is a property of some importance at the very high frequencies where the wavelength is small.

### Directivity and Gain

All antennas, even the simplest types, exhibit directive effects in that the intensity of radiation is not the same in all directions from the antenna. This property of radiating more strongly in some directions than in others is called the *directivity* of the antenna.

The *gain* of an antenna is closely related to its directivity. Because directivity is based solely on the shape of the directive pattern, it does not take into account any power losses that may occur in an actual antenna system. Gain takes into account those losses.

Gain is usually expressed in decibels,

and is based on a comparison with a “standard” antenna—usually a dipole or an *isotropic radiator*. An isotropic radiator is a theoretical antenna that would, if placed in the center of an imaginary sphere, evenly illuminate that sphere with radiation. The isotropic radiator is an unambiguous standard, and so is frequently used as the comparison for gain measurements. When the standard is the isotropic radiator in free space, gain is expressed in dBi. When the standard is a dipole, *also located in free space*, gain is expressed in dBd.

The more the directive pattern is compressed—or focused—the greater the power gain of the antenna. This is a result of power being concentrated in some directions at the expense of others. The directive pattern, and therefore the gain, of an antenna at a given frequency is determined by the size and shape of the antenna, and on its position and orientation relative to the Earth.

### Elevation Angle

For HF communication, the vertical (elevation) angle of maximum radiation is of considerable importance. You will want to erect your antenna so that it radiates at desirable angles. **Tables 20.1, 20.2 and 20.3** show optimum elevation angles from locations in the continental US. These figures are based on statistical averages over all portions of the solar sunspot cycle.

Since low angles usually are most effective, this generally means that horizontal antennas should be high—higher is usually better. Experience shows that satisfactory results can be attained on the bands above 14 MHz with antenna heights between 40 and 70 ft. **Fig 20.3** shows this effect at work in horizontal dipole antennas.

### Imperfect Ground

Earth conducts, but is far from being a perfect conductor. This influences the radiation pattern of the antennas that we use. The effect is most pronounced at high vertical angles (the ones that we’re least interested in for long-distance communications) for horizontal antennas. The consequences for vertical antennas are greatest at low angles, and are quite dramatic as can be clearly seen in **Fig 20.4**, where the elevation pattern for a 40-m vertical half-wave dipole located over average ground is compared to one located over saltwater. At 10° elevation, the salt-water antenna has about 7 dB more gain than its landlocked counterpart.

A vertical antenna may work well at HF for a ham living in the area between Dallas, Texas and Lincoln, Nebraska. This area is pastoral, has low hills, and rich soil. Ground of this type has very good conduc-

**Fig 20.3—Elevation patterns for two 40-m dipoles over average ground** (conductivity of 5 mS/m and dielectric constant of 13) at  $\frac{1}{4}\lambda$  (33 ft) and  $\frac{1}{2}\lambda$  (66 ft) heights. The higher dipole has a peak gain of 7.1 dBi at an elevation angle of about 26°, while the lower dipole has more response at high elevation angles.

**Fig 20.4—Elevation patterns for a vertical dipole over sea water compared to average ground.** In each case the center of the dipole is just over  $\frac{1}{4}\lambda$  high. The low-angle response is greatly degraded over average ground compared to sea water, which is virtually a perfect ground.

tivity. By contrast a ham living in New Hampshire, where the soil is rocky and a

poor conductor, may not be satisfied with the performance of a vertical HF antenna.

# Dipoles and the Half-Wave Antenna

A fundamental form of antenna is a wire whose length is half the transmitting wavelength. It is the unit from which many more complex forms of antennas are constructed and is known as a *dipole antenna*. The length of a half-wave in free space is

$$\text{Length (ft)} = \frac{492}{f(\text{MHz})} \quad (1)$$

The actual length of a resonant  $\frac{1}{2}\lambda$  antenna will not be exactly equal to the half wavelength in space, but depends on the thickness of the conductor in relation to the wavelength. The relationship is shown in Fig 20.2, where K is a factor that must be multiplied by the half wavelength in free space to obtain the resonant antenna length. An additional shortening effect occurs with wire antennas supported by insulators at the ends because of the capacitance added to the system by the insulators (end effect). The following formula is sufficiently accurate for wire antennas for frequencies up to 30 MHz.

$$\begin{aligned} \text{Length of half-wave antenna (ft)} \\ = \frac{492 \times 0.95}{f(\text{MHz})} = \frac{468}{f(\text{MHz})} \end{aligned} \quad (2)$$

Example: A half-wave antenna for 7150 kHz (7.15 MHz) is  $468/7.15 = 65.45$  ft, or 65 ft 5 inches.

Above 30 MHz use the following formulas, particularly for antennas constructed from rod or tubing. K is taken from Fig 20.2.

**Fig 20.5—Response of a dipole antenna in free space, where the conductor is along 90° to 270° axis, solid line. If the currents in the halves of the dipole are not in phase, slight distortion of the pattern will occur, broken line. This illustrates case where balun is not used on a balanced antenna fed with unbalanced line.**

$$\begin{aligned} \text{Length of half-wave antenna (ft)} \\ = \frac{492 \times K}{f(\text{MHz})} \end{aligned} \quad (3)$$

$$\text{length (in.)} = \frac{5904 \times K}{f(\text{MHz})} \quad (4)$$

Example: Find the length of a half-wave antenna at 50.1 MHz, if the antenna is made of  $\frac{1}{2}$ -inch-diameter tubing. At 50.1 MHz, a half wavelength in space is

$$\frac{492}{50.1} = 9.82 \text{ ft}$$

**Fig 20.6—At A, elevation response pattern of a dipole antenna placed  $\frac{1}{2}\lambda$  above a perfectly conducting ground. At B, the pattern for the same antenna when raised to one wavelength. For both A and B, the conductor is coming out of the paper at right angle. C shows the azimuth patterns of the dipole for the two heights at the most-favored elevation angle, the solid-line plot for the  $\frac{1}{2}\lambda$  height at an elevation angle of 30°, and the broken-line plot for the  $1\lambda$  height at an elevation angle of 15°. The conductor in C lies along 90° to 270° axis.**

From equation 1 the ratio of half wavelength to conductor diameter (changing wavelength to inches) is

$$\frac{(9.82 \times 12)}{0.5 \text{ inch}} = 235.7$$

From Fig 20.2,  $K = 0.965$  for this ratio. The length of the antenna, from equation 3 is

$$\frac{492 \times 0.965}{50.1} = 9.48 \text{ ft}$$

or 9 ft  $5\frac{3}{4}$  inches. The answer is obtained directly in inches by substitution in equation 4

$$\frac{5904 \times 0.965}{50.1} = 113.7 \text{ inches}$$

The length of a half-wave antenna is also affected by the proximity of the dipole ends to nearby conductive and semiconductive objects. In practice, it is often necessary to do some experimental "pruning" of the wire after cutting the antenna to the computed length, lengthening or shortening it in increments to obtain a low SWR. When the lowest SWR is obtained for the desired part of an amateur band, the antenna is resonant at that frequency. The value of the SWR indicates the quality of the match between the antenna and the feed line. If the lowest SWR obtainable is too high for use with solid-state rigs, a Transmatch or line-input matching network may be used, as described in the **Transmission Lines and Station Setup** chapters.

## Radiation Characteristics

The radiation pattern of a dipole antenna in free space is strongest at right angles to the wire (**Fig 20.5**). This figure-8 pattern appears in the real world if the dipole is  $\frac{1}{2}\lambda$  or greater above earth and is not degraded by nearby conductive objects. This assumption is based also on a symmetrical feed system. In practice, a coaxial feed line may distort this pattern slightly, as shown in Fig 20.5. Minimum horizontal radiation occurs off the ends of the dipole if the antenna is parallel to the earth.

As an antenna is brought closer to ground, the elevation pattern peaks at a higher elevation angle as shown in Fig 20.3. **Fig 20.6** illustrates what happens to the directional pattern as antenna height changes. Fig 20.6C shows that there is significant radiation off the ends of a low horizontal dipole. For the  $\frac{1}{2}\lambda$  height (solid line), the radiation off the ends is only 7.6 dB lower than that in the broadside direction.

## Feed Methods

Most amateurs use either *coax* or *open-*

wire transmission line. Coax is the common choice because it is readily available, its characteristic impedance is close to that of the antenna and it may be easily routed through or along walls and among other cables. The disadvantages of coax are increased RF loss and low working voltage (compared to that of open-wire line). Both disadvantages make coax a poor choice for higher-SWR systems.

Take care when choosing coax. Use 1/4-inch foam-dielectric cables only for low power (25 W or less) HF transmissions. Solid-dielectric 1/4-inch cables are okay for 300 W if the SWR is low. For high-power installations, use 1/2-inch or larger cables.

The most common two-wire transmission lines are *ladder line* and *twin lead*. Since the conductors are not shielded, two-wire lines are affected by their environment. Use standoffs and insulators to keep the line several inches from structures or other conductors. Ladder line has very low loss (twin lead has a little more), and it can stand very high voltages (SWR) as long as the insulators are clean.

Two-wire lines are usually used in balanced systems, so they should have a balun at the transition to an unbalanced transmitter or coax. A Transmatch will be needed to match the line input impedance to the transmitter.

### Baluns

A balun is a device for feeding a balanced load with an unbalanced line, or vice versa (see the **Transmission Lines** chapter of this book). Because dipoles are balanced (electrically symmetrical about their feed-points), a balun should be used at the feed-point when a dipole is fed with coax. When coax feeds a dipole directly (as in Fig 20.7), current flows on the outside of the cable shield. The shield can conduct RF onto the transmitter chassis and induce RF onto metal objects near the system. Shield currents can impair the function of instruments connected to the line (such as SWR meters and SWR-protection circuits in the transmitter). The shield current also produces some feed-line radiation, which changes the antenna radiation pattern, and allows objects near the cable to affect the antenna-system performance.

The consequences may be negligible: A slight skewing of the antenna pattern usually goes unnoticed. Or, they may be significant: False SWR readings may cause the transmitter to shut down or destroy the output transistors; radiating coax near a TV feed line may cause strong local interference. Therefore, it is better to eliminate feed-line radiation whenever possible, and

a balun should be used at any transition between balanced and unbalanced systems. (The **Transmission Lines** chapter thoroughly describes baluns and their construction.) Even so, balanced or unbalanced systems without a balun often operate with no apparent problems. For temporary or emergency stations, do not let the lack of a balun deter you from operating.

### Practical Dipole Antennas

A classic dipole antenna is  $1/2\lambda$  long and fed at the center. The feed-point impedance is low at the resonant frequency,  $f_0$ , and odd harmonics thereof. The impedance is high near even harmonics. When fed with coax, a classic dipole provides a reasonably low SWR at  $f_0$  and its odd harmonics.

When fed with ladder line (see Fig 20.8A) and a Transmatch, the classic dipole should be usable near  $f_0$  and all harmonic frequencies. (With a wide-range Transmatch, it may work on all frequencies.) If there are problems (such as extremely high SWR or evidence of RF on objects at the operating position), change the feed-line length by adding or subtracting  $1/8\lambda$  at the problem frequency. A few such adjustments should yield a workable solution. Such a system is sometimes called a "center-fed Zepp." A true "Zepp" antenna is an end-fed dipole that is matched by  $1/4\lambda$  of open-wire feed line (see Fig 20.8B). The antenna was originally used on zeppelins, with the dipole trailing from the feeder, which hung from the airship cabin. It is intended for use on a single band, but should be usable near odd harmonics of  $f_0$ .

Most dipoles require a little pruning to reach the desired resonant frequency. Here's a technique to speed the adjustment.

How much to prune: When assembling the antenna, cut the wire 2 to 3% longer than the calculated length and record the length. When the antenna is complete, raise it to the working height and check the SWR at several frequencies. Multiply the frequency of the SWR minimum by the antenna length and divide the result by the desired  $f_0$ . The result is the finished length; trim both ends equally to reach that length and you're done.

Loose ends: Here's another trick, if you use nonconductive end support lines. When assembling the antenna, mount the end insulators in about 5% from the ends. Raise the antenna and let the ends hang free. Figure how much to prune and cut it from the hanging ends. If the pruned ends are very long, wrap them around the insulated line for support.

**Fig 20.7—Method of affixing feed line to the center of a dipole antenna. A plastic block is used as a center insulator. The coax is held in place by a clamp. A balun is often used to feed dipoles or other balanced antennas to ensure that the radiation pattern is not distorted. See text for explanation.**

**Fig 20.8—Center-fed multiband "Zepp" antenna (A) and an end-fed Zepp at (B).**

### Dipole Orientation

Dipole antennas need not be installed in a horizontal straight line. They are generally tolerant of bending, sloping or drooping as required by the antenna site. Remember, however, that dipole antennas are RF conductors. For safety's sake, mount all antennas away from conductors (especially power lines), combustibles and well beyond the reach of passersby.

A *sloping dipole* is shown in Fig 20.9. This antenna is often used to favor one direction (the "forward direction" in the figure). With a nonconducting support and poor earth, signals off the back are weaker than those off the front. With a nonconducting mast and good earth, the response is omnidirectional. There is no gain in any direction with a nonconducting mast.

A conductive support such as a tower acts as a parasitic element. (So does the coax shield, unless it is routed at 90° from

the antenna.) The parasitic effects vary with earth quality, support height and other conductors on the support (such as a

beam at the top). With such variables, performance is very difficult to predict. Losses increase as the antenna ends

approach the support or the ground. To prevent feed-line radiation, route the coax away from the feed-point at  $90^\circ$  from the antenna, and continue on that line as far as possible.

An *Inverted V* antenna appears in Fig 20.10. While "V" accurately describes the shape of this antenna, this antenna should not be confused with long-wire V antennas, which are highly directive. The radiation pattern and dipole impedance depend on the apex angle, and it is very important that the ends do not come too close to lossy ground.

Bent dipoles may be used where antenna space is at a premium. Fig 20.11 shows several possibilities; there are many more. Bending distorts the radiation pattern somewhat and may affect the impedance as well, but compromises are acceptable when the situation demands them. When an antenna bends back on itself (as in Fig 20.11B) some of the signal is canceled; avoid this if possible.

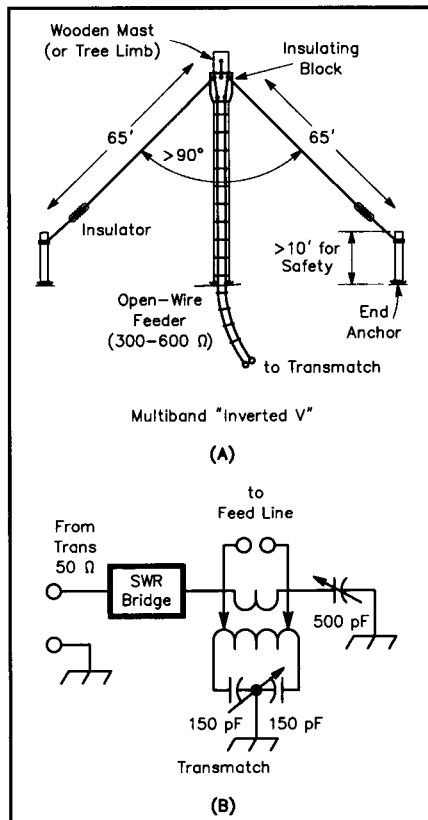

Remember that current produces the radiated signal, and current is maximum at the dipole center. Therefore, performance is best when the central area of the antenna is straight, high and clear of nearby objects. Be safe! Keep any bends, sags or hanging ends well clear of conductors (especially power lines) and combustibles, and beyond the reach of persons.

### Multiband Dipoles

There are several ways to construct coax-fed multiband dipole systems. These techniques apply to dipoles of all orientations. Each method requires a little more work than a single dipole, but the materials don't cost much.

**Fig 20.9**—Example of a sloping  $1/2\lambda$  dipole, or "full sloper." On the lower HF bands, maximum radiation over poor to average earth is off the sides and in the "forward direction" as indicated. If a nonconductive support is used. A metal support will alter this pattern by acting as a parasitic element. How it alters the pattern is a complex issue depending on the electrical height of the mast, what other antennas are located on the mast, and on the configuration of guy wires.

**Fig 20.10**—At A, details for an inverted V fed with open-wire line for multiband HF operation. A Transmatch is shown at B, suitable for matching the antenna to the transmitter over a wide frequency range. The included angle between the two legs should be greater than  $90^\circ$  for best performance.

**Fig 20.11**—When limited space is available for a dipole antenna, the ends can be bent downward as shown at A, or back on the radiator as shown at B. The inverted V at C can be erected when the available supporting structure is not high enough.

**Fig 20.12**—Multiband antenna using paralleled dipoles, all connected to a common 50 or 75- $\Omega$  coax line. The half-wave dimensions may be either for the centers of the various bands or selected for favorite frequencies in each band. The length of a half wave in feet is  $468/\text{frequency in MHz}$ , but because of interaction among the various elements, some pruning for resonance may be needed on each band. See text.

Parallel dipoles are a simple and convenient answer. See Fig 20.12. Center-fed dipoles present low-impedances near  $f_0$ , or its odd harmonics, and high impedances elsewhere. This lets us construct simple multiband systems that automatically select the appropriate antenna. Consider a 50- $\Omega$  resistor connected in parallel with a 5-k $\Omega$  resistor. A generator connected across the two resistors will see 49.5  $\Omega$ , and 99% of the current will flow through the 50- $\Omega$  resistor. When resonant and nonresonant antennas are parallel connected, the nonresonant antenna takes little power and has little effect on the total feed-point impedance. Thus, we can connect several antennas together at the feed-point, and power naturally flows to the resonant antenna.

There are some limits, however. Wires in close proximity tend to couple and produce mutual inductance. In parallel dipoles, this means that the resonant length of the shorter dipoles lengthens a few percent. Shorter antennas don't affect longer ones much, so adjust for resonance in order from longest to shortest. Mutual inductance also reduces the bandwidth of shorter dipoles, so a Transmatch may be needed to achieve an acceptable SWR across all bands covered. These effects can be reduced by spreading the ends of the dipoles.

Also, the power-distribution mechanism requires that only one of the parallel dipoles is near resonance on any amateur band. Separate dipoles for 80 and 30 m should not be parallel connected because the higher band is near an odd harmonic of the lower band ( $80/3 \approx 30$ ) and center-fed dipoles have low impedance near odd harmonics. (The 40 and 15-m bands have a similar relationship.) This means that you must either accept the lower performance of the low-band antenna operating on a harmonic or erect a separate antenna for those odd-harmonic bands. For example, four parallel-connected dipoles cut for 80, 40, 20 and 10 m (fed by a single Transmatch and coaxial cable) work reasonably on all HF bands from 30 through 10 m.

*Trap dipoles* provide multiband operation from a coax-fed single-wire dipole. Fig 20.13 shows a two-band trap antenna. A trap is a parallel-resonant circuit that effectively disconnects wire beyond the trap at the resonant frequency. Traps may be constructed from coiled sections of coax or from discrete LC components.

Choose capacitors (C1 in the figure) that are rated for high current and voltage. Mica transmitting capacitors are good. Ceramic transmitting capacitors may work, but their values may change with

Fig 20.13—Example of a trap dipole antenna. L1 and C1 can be tuned to the desired frequency by means of a dip meter before they are installed in the antenna.

### The Trusty Slingshot

Trees make excellent supports for wire antennas, but how do you get a rope over tall branches? Some hams use bows and arrows with good success, but many prefer a slingshot. Use a short section of leader (2 to 4 ft is adequate) between the weight and the line. The leader should be strong enough to withstand the shock of launching the weight, but must be rated at less tensile strength than the main line. Then, if the weight wraps around a limb or otherwise becomes stuck, pulling on the line will break the leader and free the main line. (Often, the weight breaks free and drops to the ground.) This arrangement works better than using one continuous piece of line and getting the whole mess hopelessly stuck in the tree.

Use a "Wrist Rocket" or equivalent, with 20 to 25-lb monofilament line (the main line) laid out neatly on the ground. Use an 8 to 12-lb monofilament line as the leader, with a 2 to 3-oz teardrop fishing weight. This combination is a low-cost method to shoot lines accurately over 100 to 125-ft fir trees. With a little patience, a 2 to 3-oz weight is sufficient to drop the line to ground level for attachment to support ropes, and so on.—K7FL

temperature. Use large wire for the inductors to reduce loss. Any reactance ( $X_L$  and  $X_C$ ) above 100  $\Omega$  (at  $f_0$ ) will work, but bandwidth increases with reactance (up to several thousand ohms).

Check trap resonance before installation. This can be done with a dip meter and a receiver. To construct a trap antenna, cut a dipole for the highest frequency and connect the pretuned traps to its ends. It is fairly complicated to calculate the additional wire needed for each band, so just add enough wire to make the antenna  $\frac{1}{2} \lambda$  and prune it as necessary. Because the inductance in each trap reduces the physical length needed for resonance, the finished antenna will be shorter than a simple  $\frac{1}{2} \lambda$  dipole.

### Shortened Dipoles

Inductive loading increases the electrical length of a conductor without increasing its physical length. Therefore, we can build physically short dipole antennas by placing inductors in the antenna. These are called "loaded antennas," and *The ARRL Antenna Book* shows how to design them. There are some trade-offs involved: Inductively loaded antennas are less efficient and have narrower bandwidths than full-size antennas. Generally they should not be shortened more than 50%.

### Building Dipole Antennas

The purpose of this section is to offer

information on the actual physical construction of wire antennas. Because the dipole, in one of its configurations, is probably the most common amateur wire antenna, it is used in the following examples. The techniques described here, however, enhance the reliability and safety of all wire antennas.

### Wire

Choosing the right type of wire for the project at hand is the key to a successful antenna—the kind that works well and stays up through a winter ice storm or a gusty spring wind storm. What gauge of wire to use is the first question to settle, and the answer depends on strength, ease of handling, cost, availability and visibility. Generally, antennas that are expected to support their own weight, plus the weight of the feed line should be made from #12 wire. Horizontal dipoles, Zepps, some long wires and the like fall into this category. Antennas supported in the center, such as inverted-V dipoles and delta loops, may be made from lighter material, such as #14 wire—the minimum size called for in the National Electrical Code.

The type of wire to be used is the next important decision. Table 30.33 details popular wire styles and sizes. The strongest wire suitable for antenna service is *copperclad steel*, also known as *copperweld*. The copper coating is necessary for RF service because steel is a rela-

tively poor conductor. Practically all of the RF current is confined to the copper coating because of skin effect. Copper-clad steel is outstanding for permanent installations, but it can be difficult to work with. Kinking, which severely weakens the wire, is a constant threat when handling any solid conductor. Solid-copper wire, either hard drawn or soft drawn, is another popular material. Easier to handle than copper-clad steel, solid copper is available in a wide range of sizes. It is generally more expensive however, because it is all copper. Soft drawn tends to

stretch under tension, so periodic pruning of the antenna may be necessary in some cases. Enamel-coated *magnet-wire* is a good choice for experimental antennas because it is easy to manage, and the coating protects the wire from the weather. Although it stretches under tension, the wire may be prestretched before final installation and adjustment. A local electric motor rebuilder might be a good source for magnet wire.

Hook-up wire, speaker wire or even ac lamp cord are suitable for temporary installations. Almost any copper wire may be used, as long as it is strong enough for the demands of the installation. Steel wire is a poor conductor at RF; avoid it.

It matters not (in the HF region at least) whether the wire chosen is insulated or bare. If insulated wire is used, a 3 to 5% shortening beyond the standard  $468/f$  length will be required to obtain resonance at the desired frequency, because of the increased distributed capacitance resulting from the dielectric constant of the plastic insulating material. The actual length for resonance must be determined experimentally by pruning and measuring because the dielectric constant of the insulating material varies from wire to wire. Wires that might come into contact with humans or animals should be insulated to reduce the chance of shock or burns.

### Insulators

Wire antennas must be insulated at the ends. Commercially available insulators are made from ceramic, glass or plastic. Insulators are available from many Amateur Radio dealers. Radio Shack and local hardware stores are other possible sources.

Acceptable homemade insulators may be fashioned from a variety of material including (but not limited to) acrylic sheet or rod, PVC tubing, wood, fiberglass rod or even stiff plastic from a discarded container. **Fig 20.14** shows some homemade insulators. Ceramic or glass insulators will usually outlast the wire, so they are highly recommended for a safe, reliable, permanent installation. Other materials may tear under stress or break down in the presence of sunlight. Many types of plastic do not weather well.

Many wire antennas require an insulator at the feedpoint. Although there are many ways to connect the feed line, there are a few things to keep in mind. If you feed your antenna with coaxial cable, you have two choices. You can install an SO-239 connector on the center insulator and use a PL-259 on the end of your coax, or you can separate the center conductor from the braid and connect the feed line directly to the antenna wire. Although it

**Fig 20.14—Some ideas for homemade antenna insulators.**

**Fig 20.15—Some homemade dipole center insulators. The one is the center includes a built-in SO-239 connector. Others are designed for direct connection to the feed line. (See the Transmission Lines chapter for details on baluns.)**

**Fig 20.16—A piece of cut Plexiglas can be used as a center insulator and to support a ladder-line feeder. The Plexiglas acts to reduce the flexing of the wires where they connect to the antenna.**

**Fig 20.17—Details of dipole antenna construction. The end insulator connection is shown at A, while B illustrates the completed antenna. This is a balanced antenna and is often fed with a balun.**

costs less to connect direct, the use of connectors offers several advantages.

Coaxial cable braid soaks up water like a sponge. If you do not adequately seal the antenna end of the feed line, water will find its way into the braid. Water in the feed line will lead to contamination, rendering the coax useless long before its normal lifetime is up. It is not uncommon for water to drip from the end of the coax inside the shack after a year or so of service if the antenna connection is not properly waterproofed. Use of a PL-259/SO-239 combination (or connector of your choice) makes the task of waterproofing connections much easier. Another advantage to using the PL-259/SO-239 combination is that feed line replacement is much easier, should that become necessary.

Whether you use coaxial cable, ladder line, or twin lead to feed your antenna, an often-overlooked consideration is the mechanical strength of the connection. Wire antennas and feed lines tend to move a lot in the breeze, and unless the feed line is attached securely, the connection will weaken with time. The resulting failure can range from a frustrating intermittent electrical connection to a complete separation of feed line and antenna. **Fig 20.15** illustrates several different ways of attaching the feed line to the antenna. An idea for supporting ladder line is shown in **Fig 20.16**.

### Putting It Together

**Fig 20.17** shows details of antenna construction. Although a dipole is used for the examples, the techniques illustrated here apply to any type of wire antenna. **Table 20.5** shows dipole lengths for the amateur HF bands.

How well you put the pieces together is second only to the ultimate strength of the materials used in determining how well your antenna will work over the long term. Even the smallest details, such as how you connect the wire to the insulators (**Fig 20.17A**), contribute significantly to antenna longevity. By using plenty of wire at the insulator and wrapping it tightly, you will decrease the possibility of the wire pulling loose in the wind. There is no need to solder the wire once it is wrapped. There is no electrical connection here, only mechanical. The high heat needed for soldering can anneal the wire, significantly weakening it at the solder point.

Similarly, the feed-line connection at the center insulator should be made to the antenna wires after they have been secured to the insulator (**Fig 20.17B**). This way, you will be assured of a good electrical connection between the antenna and feed line without compromising the mechanical strength. Do a good job of soldering the antenna and feed-line connections. Use a heavy iron or a torch, and be sure to

**Table 20.5**

### Dipole Dimensions for Amateur Bands

Freq MHz	Overall Length	Leg Length
28.4	16' 6"	8' 3"
21.1	22' 2"	11' 1"
18.1	25' 10"	12' 11"
14.1	33' 2"	16' 7"
10.1	46' 4"	23' 2"
7.1	65' 10"	32' 11"
3.6	130' 0"	65' 0"

clean the materials thoroughly before starting the job. Proper planning should allow you to solder indoors at a workbench, where the best possible joints may be made. Poorly soldered or unsoldered connections will become headaches as the wire oxidizes and the electrical integrity degrades with time. Besides degrading your antenna performance, poorly made joints can even be a cause of TVI because of rectification. Spray paint the connections with acrylic for waterproofing.

If made from the right materials, the dipole should give a builder years of maintenance-free service—unless of course a tree falls on it. As you build your antenna, keep in mind that if you get it right the first time, you won't have to do it again for a long time.

## A 135-FT MULTIBAND CENTER-FED DIPOLE

An 80-m dipole fed with ladder line is a versatile antenna. If you add a wide-range matching network, you have a low-cost antenna system that works well across the entire HF spectrum. Countless hams have used one of these in single-antenna stations and for Field Day operations.

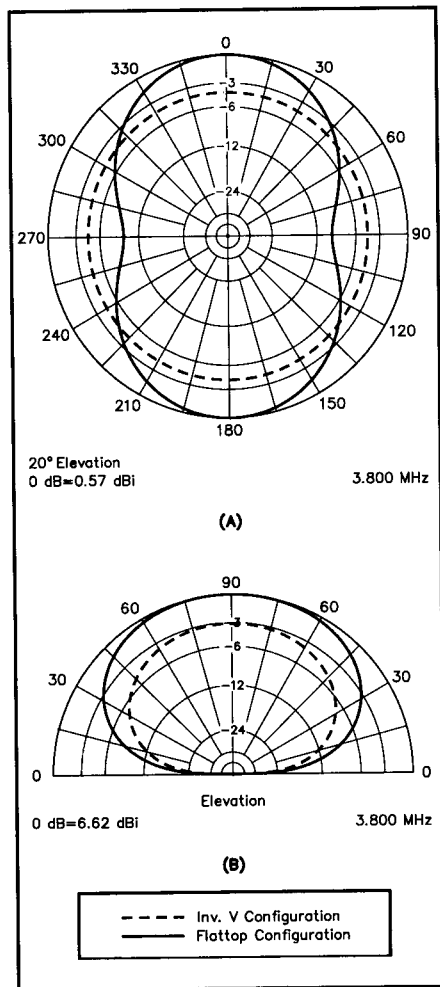

For best results place the antenna as high as you can, and keep the antenna and ladder line clear of metal and other conductive objects. Despite significant SWR on some bands, system losses are low. (See the **Transmission Lines** chapter.) You can make the dipole horizontal, or you can

install in as an inverted V. ARRL staff analyzed a 135-ft dipole at 50 ft above typical ground and compared that to an inverted V with the center at 50 ft, and the ends at 10 ft. The results show that on the 80-m band, it won't make much difference which configuration you choose. (See **Fig 20.18**.) The inverted V exhibits additional losses because of its proximity to ground.

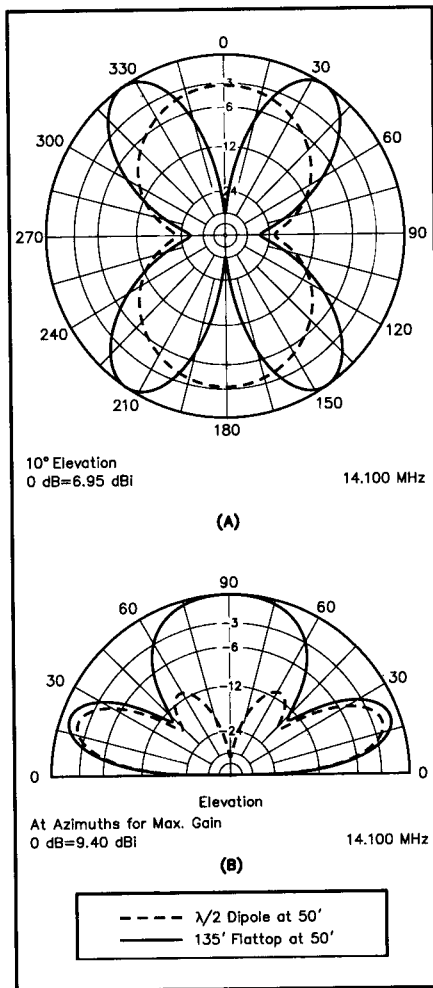

**Fig 20.19** shows a comparison between

a 20-m flat-top dipole and the 135-ft flat-top dipole when both are placed at 50 ft above ground. At a 10° elevation angle, the 135-ft dipole has a gain advantage. This advantage comes at the cost of two deep, but narrow, nulls that are broadside to the wire.

**Fig 20.20** compares the 135-ft dipole to the inverted-V configuration of the same antenna on 14.1 MHz. Notice that the inverted-V pattern is essentially omnidirectional

**Fig 20.18**—Patterns on 80 m for 135-ft, center-fed dipole erected as a horizontal dipole at 50 ft, and as an inverted V with the center at 50 ft and the ends at 10 ft. The azimuth pattern is shown at A, where conductor lies in 0° to 180° plane. The elevation pattern is shown at B, where conductor comes out of paper at right angle. At the fundamental frequency the patterns are not markedly different.

**Fig 20.19**—Patterns on 20 m comparing a standard  $\lambda/2$ - $\lambda$  dipole and a multiband 135-ft dipole. Both are mounted horizontally at 50 ft. The azimuth pattern is shown at A, where conductors lie in 0° to 180° plane. The elevation pattern is shown at B. The longer antenna has four azimuthal lobes, centered at 35°, 145°, 215°, and 325°. Each is about 2 dB stronger than the main lobes of the  $\lambda/2$ - $\lambda$  dipole. The elevation pattern of the 135-ft dipole is for one of the four maximum-gain azimuthal lobes, while the elevation pattern for the  $\lambda/2$ - $\lambda$  dipole is for the 0° azimuthal point.

**Fig 20.20**—Patterns on 20 m for two 135-ft dipoles. One is mounted horizontally as a flat-top and the other as an inverted V with 120° included angle between the two legs. The azimuth pattern is shown at A, and the elevation pattern is shown at B. The inverted V has about 6 dB less gain at the peak azimuths, but has a more uniform, almost omnidirectional, azimuthal pattern. In the elevation plane, the inverted V has a fat lobe overhead, making it a somewhat better antenna for local communication, but not quite so good for DX contacts at low elevation angles.

tional. That comes at the cost of gain, which is less than that for a horizontal flat-top dipole.

As expected, patterns become more complicated at 28.4 MHz. As you can see in Fig 20.21, the inverted V has the advantage of a pattern with slight nulls, but with reduced gain compared to the flat-top con-

figuration.

Installed horizontally, or as an inverted V, the 135-ft center-fed dipole is a simple antenna that works well from 3.5 to 30 MHz. Bandswitching is handled by a Transmatch that is located near your operating position.

## COMPUTER-AIDED DESIGN OF LOADED SHORT-DOUBLET ANTENNAS

By Richard Ellers, K8JLK, 426 Central Pkwy, SE, Warren, OH 44483-6213

◊ I've devised a BASIC program<sup>1</sup> you can use to design shortened doublet (dipole) antennas, using loading coils of known inductance. The program uses common BASIC commands and should run as-is on any IBM PC-compatible or Apple II personal computer. This program is an offshoot and adaptation of previously published charts, a formula and a BASIC program. The charts and formula, published in *QST*,<sup>2</sup> and the original BASIC program, published in *CQ*,<sup>3</sup> were devised to calculate the inductances required to resonate a short doublet, given the overall antenna length, the coil spacing and the element diameter.

The development of my program began when I decided to build a 2-element phased array of short doublets, using four surplus mobile coils I'd bought at a hamfest. Checking through my ham magazines, I found Dick (K5QY) Sander's ingenious BASIC version of Jerry Hall's (then K1PLP, now K1TD) comprehensive work on the design of off-center-loaded antennas. However, I was in the opposite position: *I had the inductance values in hand* and needed instead to figure *where to place the coils* in an antenna of a certain size.

Not being very adept at higher math, I didn't even attempt to rewrite Jerry's formula or K5QY's program. Instead, I revised K5QY's program by adding a computer routine known as a *binary search*. Although more often used to seek data in large files, my program uses a binary search as a form of computerized empirical determination (more commonly known as cut-and-try). The search is accurate—and rapid. In just seconds, the routine finds the coil spacing that matches the desired antenna to the existing inductance.

I wrote the program to find the coil spacing for a single antenna (and for a series of 10 antennas) between two specified lengths. Incidentally, because the program actually calculates the center-to-coil distance (as did K5QY's version), it can be used to design short vertical antennas, but you must enter *twice the desired overall length*. As with K5QY's program, mine handles antenna elements of wire or tubing, the diameters being entered in decimal fractions of an inch where necessary. To keep the program short and simple, I omitted K5QY's optional wire table. (You can find such a wire table in Chapter 24, **Component Data**, or use the following as a guide: 22-gauge wire has a diameter of 0.025 inch; 10-gauge wire's diameter is 0.101 inch.)

Program error traps catch (and explain) parameter combinations that don't match the given inductor. One trap catches dimensions that would normally put the program in an endless loop. I've tested my program for many configurations and frequencies using inductances first determined by K5QY's program. The results matched every time.

<sup>1</sup>The disk that accompanies this book contains ASCII QBASIC files for IBM-compatible computers in file ELLERS.EXE.

<sup>2</sup>J. Hall, "Off-Center-Loaded Antennas," *QST*, Sep 1974, pp 28-34 and 58.

<sup>3</sup>D. Sander, "A Computer Designed Loaded Dipole Antenna," *CQ*, Dec 1981, p 44.

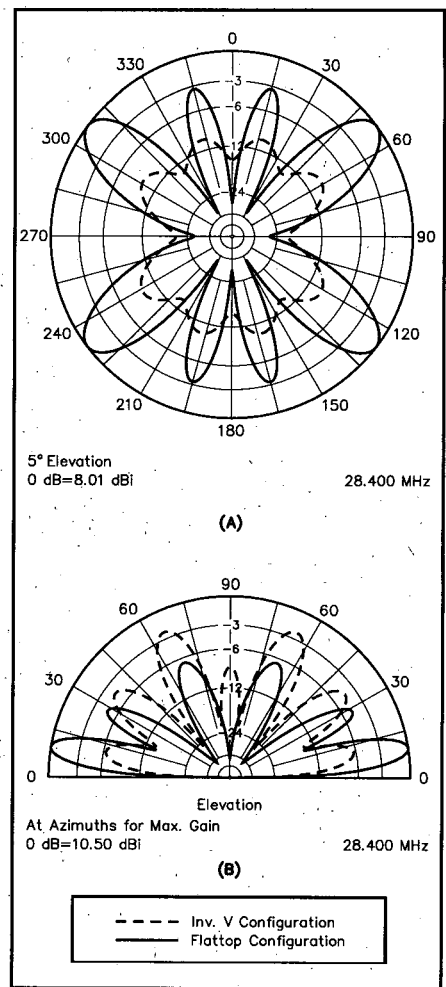

Fig 20.21—Patterns on 10 m for 135-ft dipole mounted horizontally and as an inverted V, as in Fig 20.20. The azimuth pattern is shown at A, and the elevation pattern is shown at B. Once again, the inverted-V configuration yields a more omnidirectional pattern, but at the expense of almost 8 dB less gain than the flat-top configuration at its strongest lobes.

## AN EXTENDED DOUBLE ZEPP FOR 12 M

This antenna was first described in December 1987 and December 1988 *QST*. The author is John J. Reh, K7KGP.

*Zepp*—short for Zeppelin—is a term applied to just about any resonant antenna end-fed by ladder line. Double, in this case, means a center-fed antenna. The extended version of this antenna, although an old-fashion design, provides 3-dB gain over a dipole—quite suitable for modern amateur needs. The extended double Zepp (EDZ) consists of two collinear  $0.64\lambda$  elements fed in phase. Fig 20.22 shows current distribution in an EDZ antenna,

Fig 20.22—The extended double Zepp (EDZ) antenna consists of two  $0.64\lambda$  elements fed in phase.

and Fig 20.23 shows its directivity pattern in free space.

Fig 20.24 shows the configuration of the 12-m version, cut for 24.950 MHz. Each element is 25 ft, 3 inches long, and consists of #14 stranded copper wire. The antenna elements are center fed by a short matching section made of a 5-ft, 5-inch

Fig 20.23—Horizontal directivity pattern for an extended double Zepp antenna in free space. Relative to a  $\frac{1}{2}\lambda$  dipole, it exhibits a gain of approximately 3 dB. The antenna elements lie along the  $90^\circ$  to  $270^\circ$  axis.

length of 450- $\Omega$  ladder line. Connection to a 50- $\Omega$  coaxial feed line is made by means of a 1:1 balun transformer.

### Matching Section

The ladder-line matching section is 52 electrical degrees long ( $0.145\lambda$ ). The matching section transforms the EDZ's input impedance to about 55  $\Omega$ , as measured with a noise bridge. The matching-section dimension given in Fig 20.24 assumes a velocity factor of 0.95 for the 450- $\Omega$  ladder line.

Trimming the matching section to size is the only adjustment necessary with the EDZ. Make the transformer a little long to begin with, and shorten it an inch or two at a time to bring the system into resonance. You can check resonance with a noise bridge or by monitoring the SWR.

### Building an EDZ for Other Bands

You can scale the antenna dimensions given in Fig 20.24 in order to use this design on other bands. The length of each leg, or side, of the antenna (in ft) can be derived by dividing 630 by the frequency in MHz. The matching section (in ft) is approximately 135 divided by the frequency in MHz. Table 20.6 gives dimensions for several amateur bands.

Fig 20.24—The extended double Zepp used at K7KGP, cut for 24.950 MHz. The 450- $\Omega$  matching section transforms the calculated input impedance ( $142 - j555 \Omega$ ) to 55  $\Omega$  (measured) for connection to 52- $\Omega$  coaxial cable by means of a 1:1 balun. The electrical length of the matching section is 52°; the linear dimension shown in the drawing assumes 450- $\Omega$  line with a velocity factor of 0.95.

Table 20.6

EDZ Dimensions for Amateur Bands

Freq MHz	Leg Length	Matching Section
28.4	22' 2"	4' 9"
21.1	29' 10"	6' 5"
18.1	34' 10"	7' 6"
14.1	44' 8"	9' 7"
10.1	62' 5"	13' 5"
7.1	88' 8"	19' 7"
3.6	175'	37' 7"

## A TRAP DIPOLE FOR 40, 80 AND 160 M

This antenna was designed for amateurs with limited space who also wanted to operate the low bands. It was first described in July 1992 *QST* by A. C. Buxton, W8NX, and features innovative coaxial-cable traps.

Fig 20.25 shows the antenna layout; it is resonant at 1.865, 3.825, and 7.225 MHz. The antenna is made of #14 stranded wire and two pairs of coaxial traps. Construction is conventional in most respects, except for the high inductance-to-capacitance (L/C) ratio that results from the unique trap construction.

The traps use two series-connected coil layers, wound in the same direction using RG-58 coaxial cable's center conductor, together with the insulation over the center conductor. The black outer jacket from the cable is stripped and discarded. The shield braid is also removed from the cable (pushing is easier than pulling the shield off). No doubt you will want to save the

braid for use in other projects. RG-58 with a stranded center conductor is best for this project. Fig 20.26 shows the traps. The 3.8-MHz trap is shown with the weather-proofing cover of electrical tape removed to show construction details.

### Precautions and Trap Specifications

With this trap-winding configuration, there are two thicknesses of coax dielectric material between adjacent turns, which doubles the breakdown voltage of the traps. The transformer action of the two windings gives a second doubling of the trap-voltage rating, bringing it to 5.6 kV.

The 7-MHz traps have 33  $\mu\text{H}$  of inductance and 15 pF of capacitance, and the 3.8-MHz traps have 74  $\mu\text{H}$  of inductance and 24 pF of capacitance. The trap Qs are over 170 at their design frequencies.

These traps are suitable for high-power operation. Do not use RG-8X or any other

foam-dielectric cable for making the traps. Breakdown voltage is less for foam dielectric, and the center conductor tends to migrate through the foam when there is a short turn radius.

Loading caused by the traps causes a reduced bandwidth for any trap dipole compared to a half-wave dipole. This antenna covers 65 kHz of 160 m, 75 kHz of 80 m, and the entire 40-m band with less 2:1 SWR.

### Construction

Although these traps are similar in many ways to other coaxial-cable traps, the shield winding of the common coax-cable trap has been replaced by a top winding that fits snugly into the grooves formed by the bottom layer. Capacitance is reduced to 7.1 pF per ft, compared to 28.5 pF per ft with conventional coax traps made from RG-58. Trap reactance can be up to four times greater than that provided by con-

Fig 20.25—The W8NX trap dipole resonates in the SSB portions of the 40, 80 and 160-m bands. The antenna is 124 ft long.

(A)

(B)

Fig 20.26—The W8NX coaxial-cable traps use two layered windings in series to provide an unusually high inductance-to-capacitance ratio, higher Q, and twice the breakdown voltage of single-layer traps. At A is shown an inside view of a W8NX two-layer trap, showing how the windings enter and exit the form. Two holes at each end of the PVC form pass the windings in and out of the form. At B, an outside view of a partially assembled W8NX trap. The bottom winding starts at hole "1" and reenters the form just below the "EXIT" hole. The wire then comes back through the inside of the form to hole "2," where it comes back out to make the second winding in the same direction, on top of the first. It reenters the form at the "EXIT" hole. The black electrical tape holds the bottom winding in place from spreading as you wind the top layer over it. Other holes drilled in the ends of the form provide convenient points for the antenna wires to connect mechanically to the traps.

ventional coax-cable traps.

The coil forms are cut from PVC pipe. The 7-MHz trap form is made from 2-inch-ID pipe with an outer diameter of 2.375 inches. The 3.8-MHz trap form is made from 3-inch pipe with an outer diameter of 3.5 inches. The 7-MHz trap uses a 12.3-turn bottom winding and an 11.4-turn top winding. The 3.8-MHz trap uses a 14.3-turn bottom winding and a 13.4-turn top winding. All turns are close wound. The 40-m trap frequency is 7.17 MHz and the 80-m trap frequency is 3.85 MHz.

Use a #30 (0.128-inch) diameter drill for the feed-through holes in the PVC coil forms. The start and end holes of the 7-MHz traps are spaced 1.44 inches center to center, measured parallel to the trap center line. The holes in the 3.8-MHz traps are 1.66 inches apart. Wind the traps with a single length of coax center conductor. The lengths are 17.55 ft for the 7-MHz traps and 28.45 ft for the 3.8-MHz traps. These lengths include the trap pigtails and a few inches for fine tuning.

Use electrical tape to keep the turns of

the inner-layer winding closely spaced during the winding process. This counteracts the tendency of the tension in the outer-layer winding to spread the bottom-layer turns. Stick the tape strips directly to the coil form before winding and then tightly loop them over and around the bottom layer before winding the outer layer. Use six or more tape strips for each trap. Other smaller holes may be drilled in the ends of the traps to provide a place for the antenna wires to make secure mechanical connections to the traps.

## 80-M BROADBAND DIPOLE WITH COAXIAL RESONATOR MATCH

This material has been condensed from an article by Frank Witt, AI1H, that appeared in April 1989 *QST*. A full technical description appears in *The ARRL Antenna Compendium, Volume 2*.

Fig 20.27 shows the detailed dimensions of the 3.5-MHz coaxial resonator match broadband dipole. Notice that the coax is an electrical quarter wavelength, has a short at one end, an open at the other end, a strategically placed crossover, and is fed at a tee junction. (The crossover is made by connecting the shield of one coax segment to the center conductor of the adjacent segment and by connecting the remaining center conductor and shield in a similar way.) At AI1H, the antenna is constructed as an inverted-V dipole with a  $110^\circ$  included angle and an apex at 60-ft. The measured SWR vs frequency is shown in Fig 20.28. Also in Fig 20.28 is the SWR characteristic for an uncompensated inverted-V dipole made from the same materials and positioned exactly as was the broadband version.

The antenna is made from RG-8 coaxial cable and #14 AWG wire, and is fed with 50- $\Omega$  coax. The coax should be cut so that the stub lengths of Fig 20.27 are within  $\frac{1}{2}$  inch of the specified values. PVC plastic pipe couplings and SO-239 UHF chassis connectors can be used to make the T and crossover connections, as shown in Fig 20.29 at A and B. Alternatively, a standard UHF T connector and coupler can be used for the T, and the crossover may be a soldered connection (Fig 20.29C). Witt used RG-8 because of its ready availability, physical strength, power handling capability and moderate loss.

Cut the wire ends of the dipole about three ft longer than the lengths given in Fig 20.27. If there is a tilt in the

Fig 20.27—Coaxial-resonator-match broadband dipole for 3.5 MHz. The coax segment lengths total  $\frac{1}{4} \lambda$ . The overall length is the same as that of a conventional inverted-V dipole.

Fig 20.28—The measured SWR performance of the antenna of Fig 20.27, curve A. Also shown for comparison is the SWR of the same dipole without compensation, curve B.

**Fig 20.29—T and crossover construction.** At A, a 2-inch PVC pipe coupling can be used for the T, and at B, a 1-inch coupling for the crossover. These sizes are the nominal inside diameters of the PVC pipe which is normally used with the couplings. The T could be made from standard UHF hardware (an M-358 T and a PL-258 coupler). An alternative construction for the crossover is shown at C, where a direct solder connection is made.

**Fig 20.30—Dipole matching methods.** At A, the T match; at B, the gamma match; at C, the coaxial resonator match.

**Fig 20.31—Evolution of the coaxial-resonator-match broadband dipole.** At A, the resonant transformer is used to match the feed line to the off-center-fed dipole. The match and dipole are made collinear at B. At C, the balanced transmission-line resonator/transformer of A and B is replaced by a coaxial version. Because the shield of the coax can serve as a part of the dipole radiator, the wire adjacent to the coax match may be eliminated, D.

SWR-frequency curve when the antenna is first built, it may be “flattened” to look like the shape given in Fig 20.28 by increasing or decreasing the wire length. Each end should be lengthened or shortened by the same amount.

**A word of caution:** If the coaxial cable chosen is not RG-8 or equivalent, the dimensions will need to be modified. The following cable types have about the same characteristic impedance, loss and velocity factor as RG-8 and could be substituted: RG-8A, RG-10, RG-10A, RG-213 and RG-215. If the Q of the dipole is particularly high or the radiation resistance is unusually low because of different ground characteristics, antenna height, surrounding objects and so on, then different segment lengths will be required. In fact, if the dipole Q is too high, broadbanding is possible, but an SWR under 2:1 over the whole band cannot be achieved.

What is the performance of this broadband antenna relative to that of a conventional inverted-V dipole? Apart from the slight loss (about 1 dB at band edges, less elsewhere) because of the nonideal matching network, the broadband version will behave essentially the same as a dipole cut for the frequency of interest. That is, the radiation patterns for the two cases will be virtually the same. In reality, the dipole itself is not “broadband,” but the coaxial resonator match provides a broadband match between the transmission line and the dipole antenna. This match is a remarkably simple way to broaden the SWR response of a dipole.

### The Coaxial Resonator Match

The coaxial resonator match performs the same function as the T match and the gamma match; that is, matching a transmission line to a resonant dipole. These familiar matching devices as well as the coaxial resonator match are shown in Fig 20.30. The coaxial resonator match has some similarity to the gamma match in that it allows connection of the shield of the coaxial feed line to the center of the dipole, and it feeds the dipole off center. The coaxial resonator match has a further advantage: It can be used to broadband the antenna system while it is providing an impedance match.

The coaxial resonator match is a resonant transformer made from a quarter-wave long piece of coaxial cable. It is based on a technique used at VHF and UHF to realize a low-loss impedance transformation.

### The Coaxial Resonator Match Broadband Dipole

Fig 20.31 shows the evolution of the

broadband dipole. Now it becomes clear why coaxial cable is used for the quarter-wave resonator/transformer; interaction between the dipole and the matching network is minimized. The effective dipole feedpoint is located at the crossover. In effect, the match is physically located “inside” the dipole. Currents flowing on the inside of the shield of the coax are associated with the resonator; currents flowing on the outside of the shield of the coax are the usual dipole currents. Skin effect provides a degree of isolation and allows the coax to perform its dual function. The wire extensions at each end make up the remainder of the dipole, making the overall length equal to one half-wave.

A useful feature of an antenna using the

coaxial resonator match is that the entire antenna is at the same dc potential as the feed line, thereby avoiding charge buildup on the antenna. Hence, noise and the potential of lightning damage are reduced.

### A Model for DXers

The design of Fig 20.27 may be modified to yield a “3.5-MHz DX Special.” In this case the band extends from 3.5 MHz to 3.85 MHz. Over that band the SWR is better than 1.6:1 and the matching network loss is less than 0.75 dB. See Fig 20.32 for measured performance of a 3.5-MHz DX Special built and used by Ed Parsons, K1TR. Design dimensions for the DX Special are given in Fig 20.33.

Fig 20.32—Measured SWR performance of the 3.5-MHz DX Special, curve A. Note the substantial broadbanding relative to a conventional uncompensated dipole, curve B.

Fig 20.33—Dimensions for the 3.5-MHz DX Special, an antenna optimized for the phone and CW DX portions of the 3.5-MHz band.

A 40-M AND 15-M DUAL-BAND DIPOLE

Two popular ham bands, especially for Novice and Technician class operators, are those at 7 and 21 MHz. As mentioned earlier, dipoles have harmonic resonances at odd multiples of their fundamental resonances. Because 21 MHz is the third harmonic of 7 MHz, 7-MHz dipoles are harmonically resonant in the popular ham band at 21 MHz. This is attractive because it allows you to install a 40-m dipole, feed it with coax, and use it without an antenna tuner on both 40 and 15 m.

But there's a catch: The third harmonic of the Novice 40-m allocation (7100-7150 kHz) begins at 21,300 kHz; yet the Novice segment of 15 m is 21,100-21,200 kHz. As a result of this and other effects, a 40-m dipole does not provide a low SWR in the 40 and 15-m Novice segments without a tuner.

An easy fix for this, as shown in Fig 20.34, is to capacitively load the

antenna about a quarter wavelength (at 21.1 MHz) away from the feedpoint in both wires. Known as *capacitance hats*, the simple loading wires shown lower the antenna's resonant frequency on 15 m without substantially affecting resonance on 40 m.

To put this scheme to use, first measure, cut and adjust the dipole to resonance at the desired 40-m frequency. Then, cut two 2-ft-long pieces of stiff wire (such as #12 or #14 house wire) and solder the ends of each one together to form two loops. Twist the loops in the middle to form figure-8s, and strip and solder the wires where they cross. Install these capacitance hats on the dipole by stripping the antenna wire (if necessary) and soldering the hats to the dipole about a third of the way out from the feedpoint (placement isn't critical) on each wire. To resonate the antenna on 15 m, adjust the loop shapes (*not while*

*you're transmitting!*) until the SWR is acceptable in the desired segment of the 15-m band.

Fig 20.34—Figure-8-shaped capacitance hats made and placed as described in the text, can make your 40-m dipole resonate anywhere you like in the 15-m band.

A RESONANT FEED-LINE DIPOLE

This antenna, first described by James Taylor, W2OZH in August 1991 *QST*, uses a section of the feed line as part of the antenna. Taylor's design takes advantage of the fact that separate currents can flow on the inside and outside of the shield of a coaxial cable. Current flows from the feedpoint back along the outside of the coax's shield. At 1/4 λ from the feedpoint, an RF choke effectively stops current flow, and thus the dipole is formed.

The antenna, also known as an RFD, is

shown in Fig 20.35. Dipole dimensions can be taken from Table 20.5. Length of coax and number of turns for the choke are given in Table 20.7.

The RFD has the advantage of being end fed. That means no feed line supported by the antenna. This makes it easy to erect, and makes the RFD particularly handy for portable operation. Like any dipole, the RFD should be installed as high, and in the clear, as possible.

Table 20.7  
Choke Dimensions for RFD Antenna

Freq	RG-213, RG-8	RG-58
3.5	22 ft, 8 turns	20 ft, 6-8 turns
7	22 ft, 10 turns	15 ft, 6 turns
10	12 ft, 10 turns	10 ft, 7 turns
14	10 ft, 4 turns	8 ft, 8 turns
21	8 ft, 6-8 turns	6 ft, 8 turns
28	6 ft, 6-8 turns	4 ft, 6-8 turns

Wind the indicated length of coaxial feed line into a coil (like a coil of rope) and secure with electrical tape. Lengths are not highly critical.

Fig 20.35—The RFD (resonant feed-line dipole) antenna for 80 m. Be sure to weatherproof the feedpoint.

# Long-Wire Antennas

An antenna will be resonant so long as an integral number of standing waves of current and voltage can exist along its length; in other words, so long as its length is some integral multiple of a half wavelength. When an antenna is more than one wavelength long it usually is called a long-wire antenna, or a harmonic antenna.

**Fig 20.36—Standing-wave current and voltage distribution along an antenna when it is operated at various harmonics of its fundamental resonant frequency.**

**Fig 20.37—Curve A shows the variation in radiation resistance with antenna length when the antenna is fed at a current maximum. Curve B shows power in the lobes of maximum radiation for long-wire antennas as a ratio to the maximum radiation for a half-wave antenna.**

## Current and Voltage Distribution

**Fig 20.36** shows the current and voltage distribution along a wire operating at its fundamental frequency (where its length is equal to a half wavelength) and at its second, third and fourth harmonics. For example, if the fundamental frequency of the antenna is 7 MHz, the current and voltage distribution will be as shown at A. The same antenna excited at 14 MHz would have current and voltage distribution as shown at B. At 21 MHz, the third harmonic of 7 MHz, the current and voltage distribution would be as in C; and at 28 MHz, the fourth harmonic, as in D. The number of the harmonic is the number of half waves contained in the antenna at the particular operating frequency.

The polarity of current or voltage in each standing wave is opposite to that in the adjacent standing waves. This is shown in the figure by drawing the current and voltage curves successively above and below the antenna (taken as a zero reference line), to indicate that the polarity reverses when the current or voltage goes through zero. Currents flowing in the same direction are in phase; in opposite directions, out of phase.

It is evident that one antenna may be used for harmonically related frequencies, such as the various amateur bands. The long-wire or harmonic antenna is the basis of multiband operation with one antenna.

## Physical Length

The length of a long-wire antenna is not

an exact multiple of that of a half-wave antenna because the end effects operate only on the end sections of the antenna; in other parts of the wire these effects are absent, and the wire length is approximately that of an equivalent portion of the wave in space. The formula for the length of a long-wire antenna, therefore is

$$\text{Length (ft)} = \frac{492 (N - 0.05)}{f(\text{MHz})} \quad (5)$$

where N is the number of half waves on the antenna.

Example: An antenna 4-half-waves long at 14.2 MHz would be

$$\frac{492 (4 - 0.05)}{14.2} = \frac{492 (3.95)}{14.2} = 136.9 \text{ ft, or } 136 \text{ ft } 10 \text{ inches.}$$

It is apparent that an antenna cut as a half-wave for a given frequency will be slightly off resonance at exactly twice that frequency (the second harmonic), because of the decreased influence of the end effects when the antenna is more than one-half wavelength long. The effect is not important, except for a possible unbalance in the feeder system and consequent radiation from the feed line. If the antenna is fed in the exact center, no unbalance will occur at any frequency, but end-fed systems will show an unbalance on all but one frequency in each harmonic range.

## Impedance and Power Gain

The radiation resistance as measured at a current loop becomes higher as the antenna length is increased. Also, a long-wire antenna radiates more power in its most favorable direction than does a half-wave antenna in its most favorable direction. This power gain is obtained at the expense of radiation in other directions. **Fig 20.37** shows how the radiation resistance and the power in the lobe of maximum radiation vary with the antenna length.

## Directional Characteristics

As the wire is made longer in terms of the number of half wavelengths, the directional effects change. Instead of the doughnut pattern of the half-wave antenna, the directional characteristic splits up into lobes that make various angles with the wire. In general, as the length of the wire is increased the direction in which maximum radiation occurs tends to approach the line of the antenna itself. Directional characteristics for antennas  $1\lambda$ ,  $1.25\lambda$ , and  $2\lambda$  are given in **Fig 20.38**, **Fig 20.39** and **Fig 20.40** for three vertical angles of radiation. Note that, as the wire

**Fig 20.38—Horizontal patterns of radiation from a full-wave antenna. The solid line shows the pattern for a vertical angle of 15°; broken lines show deviation from the 15° pattern at 9° and 30°. All three patterns are drawn to the same relative scale; actual amplitudes will depend on the height of the antenna.**

length increases, the radiation along the line of the antenna becomes more pronounced. (The antenna is aligned from  $90^\circ$  to  $270^\circ$  in the plots.) Still longer antennas can be considered to have practically end-on directional characteristics even at the lower radiation angles.

When a long-wire antenna is fed at one end or at the current loop closest to that end, the radiation is most pronounced from the long section. This "unidirectional" pattern can be accentuated by terminating the far end in a load resistance to ground. The load resistor will dissipate energy that would ordinarily be reflected back toward the feedpoint. Depending on the pattern symmetry of the unterminated antenna, this resistor may have to handle up to half the power delivered to the feedpoint. The exact resistance must be determined empirically, but the voltage-to-current ratio at a current node is a good starting value. A quarter-wavelength wire beyond the resistor can serve as a pseudo ground for the system.

### Methods of Feeding

In a long-wire antenna, the currents in adjacent half-wave sections will be out of phase, as shown in Fig 20.36. The feeder system must not upset this phase relation-

**Fig 20.39—Horizontal patterns from an antenna three half-waves long. The solid line shows the pattern for a vertical angle of  $15^\circ$ ; broken lines show deviation from the  $15^\circ$  pattern at  $9^\circ$  and  $30^\circ$ . Minor lobes coincide for all three angles.**

ship. This is satisfied by feeding the antenna at either end or at any current loop. A two-wire feeder cannot be inserted at a current node, however, because this invariably brings the currents in two adjacent half-wave sections in phase. A long-

**Fig 20.40—Horizontal patterns from an antenna  $2\lambda$  long. The solid line shows the pattern for a vertical angle of  $15^\circ$ ; broken lines show deviation from the  $15^\circ$  pattern at  $9^\circ$  and  $30^\circ$ . Minor lobes nearly coincide for all three angles.**

wire antenna is usually made a half wavelength at the lowest frequency and fed at the end. Further information on these antennas can be found in *The ARRL Antenna Book*.

# Vertical Antennas

One of the more popular amateur antennas is the *vertical*. Although amateurs often use the term “vertical” somewhat loosely, it usually refers to a single radiating element placed vertically over the ground. A vertical is usually  $\frac{1}{4}\lambda$  long electrically and constructed out of wire or tubing. Many amateurs live on city lots with zoning restrictions preventing them from putting up tall towers with large Yagi arrays. Amateurs are also creative and ingenious—a vertical disguised to look like a flagpole can be both patriotic and a good radiator of RF!

Vertical antennas are omnidirectional radiators. This can be beneficial or detrimental, depending on the exact situation. On transmission there are no nulls in any direction, unlike most horizontal antennas. However, QRM on receive can’t be nulled out from the directions that are not of interest, unless multiple verticals are used in an array.

When compared to horizontal antennas, verticals also suffer more acutely from two main types of losses—*ground return losses* for currents in the near field, and *far-field ground losses*. Ground losses in the near field can be minimized by using many ground radials. This is covered in detail in the following section.

Far-field losses are highly dependent on the conductivity and dielectric constant of the earth around the antenna, extending out as far as  $100\lambda$  from the base of the antenna. There is very little that someone can do to change the character of the ground that far away—other than moving to a small island surrounded by saltwater! Far-field losses greatly affect low-angle

radiation, causing the radiation patterns of practical vertical antennas to fall far short of theoretical patterns over “perfect ground,” often seen in classical texts. **Fig 20.41** shows the elevation pattern response for two different 40-m quarter-wave verticals. One is placed over a theoretical infinitely large, infinitely conducting ground. The second is placed over an extensive radial system over average soil, having a conductivity of 5 mS/m and a dielectric constant of 13. This sort of soil is typical of heavy clay found in pastoral regions of the US mid-Atlantic states. At a  $10^\circ$  elevation angle, the real antenna losses are almost 6 dB compared to the theoretical one; at  $20^\circ$  the difference is about 3 dB. See *The ARRL Antenna Book* chapter on the effects of the earth for further details.

While real verticals over real ground are not a magic method to achieve low-angle radiation, cost versus performance and ease of installation are incentives that inspire many antenna builders. For use on the lower frequency amateur bands—notably 160 and 80 m—it is not always practical to erect a full-size vertical. At 1.8 MHz, a full-sized quarter-wave vertical is 130 ft high. In such instances it is often necessary to accept a shorter radiating element and use some form of *loading*.

**Fig 20.42** provides curves for the physical height of verticals in wavelength versus radiation resistance and reactance. Although the plots are based on perfectly conducting ground, they show general trends for installations where many radials have been laid out to make a ground screen. As the radiator is made shorter, the

radiation resistance decreases—with 6  $\Omega$  being typical for a  $0.1\lambda$  high antenna. The lower the radiation resistance, the more the antenna efficiency depends on ground conductivity and the effectiveness of the ground screen. Also, the bandwidth decreases markedly as the length is reduced toward the left of the scale in **Fig 20.42**. It can be difficult to develop suitable matching networks when radiation resistance is very low.

## Ground Systems

The importance of an effective ground system for vertical antennas cannot be emphasized too strongly. However, it is not always possible to install a radial network that approaches the ideal. The AM broadcast industry uses 120 buried radials as a standard radial ground system for their antennas. This is rarely practical for most amateurs, and a compromise ground is certainly better than no ground at all. The amateur should experiment with whatever is physically possible when working with vertical antennas. Even modest radial systems can produce contacts, even if they don’t consistently crack big pileups!

Although the matter of less-than-optimum ground systems could be debated almost endlessly, some practical rules of thumb are in order for those wishing to erect vertical antennas. Generally a large number of shorter radials offers a better ground system than a few longer ones. For example, 8 radials of  $\frac{1}{8}\lambda$  are preferred over 4 radials of  $\frac{1}{4}\lambda$ . If the physical height of the vertical is an  $\frac{1}{8}\lambda$ , the radial wires should be of the same length and dispersed uniformly from the base.

The conductor size of the radials is not especially significant. Wire gauges from #4 to #20 have been used successfully by amateurs. Copper wire is preferred, but where soil is low in acid (alkali), aluminum wire can be used. The wires may be bare or insulated, and they can be laid on the earth’s surface or buried a few inches below ground. Insulated wires will have greater longevity by virtue of reduced corrosion and dissolution from soil chemicals. The amateur should bury as much ground wire as time and budget permit. Some operators have literally miles of wire buried radially beneath their vertical antennas.

When property dimensions do not allow a classic installation of equally spaced radial wires, they can be placed on the ground as space permits. They may run away from the antenna in only one or two compass directions. They may be bent to fit on your property.

**Fig 20.41—Elevation patterns for two quarter-wave vertical antennas over different ground. One vertical is placed over “perfect” ground, and the other is placed over average ground. The far-field response at low elevation angles is greatly affected by the quality of the ground—as far as  $100\lambda$  away from the vertical antenna.**

**Fig 20.42—Radiation resistance (solid curve) and reactance (dotted curve) of vertical antennas as a function of physical height.**

A single ground rod, or group of them bonded together, is seldom as effective as a collection of random-length radial wires. In some instances a group of short radial wires can be used in combination with ground rods driven into the soil near the base of the antenna. Bear in mind, though, that RF currents at MF and HF seldom penetrate the earth more than several inches. If a metal fence skirts the property it can be used as part of the ground system. Rolls of galvanized "chicken wire" fencing fanned out from the base of the vertical make good ground systems, especially when used in conjunction with longer wire radials. Six 30-ft long by 3-ft wide rolls of chicken wire make a good ground screen for a 160-m vertical, backed up with 6 or more 130-ft long radials. A good rule is to use anything that will serve as a ground when developing a radial ground system.

All radial wires should be connected together at the base of the vertical antenna. The electrical bond needs to be of low resistance. Best results will be obtained when the wires (and chicken-wire screen, if used) are soldered together at the junction point. When a grounded vertical is used, the ground wires should be affixed securely to the base of the driven element. A lawn edging tool is excellent for cutting slits in grass sod or in soil when laying radial wires.

Ground return losses are lower when vertical antennas and their radials are elevated above ground, a point that is well-known by those using *ground plane* antennas on their roofs. Even on 160 or 80 m, effective vertical antenna systems can be made with as few as four quarter-wave long radials elevated 10 to 20 ft off the ground.

### Full-Size Vertical Antennas

When it is practical to erect a full-size  $\frac{1}{4}\lambda$  vertical antenna, the forms shown in Fig 20.43 are worthy of consideration. The example at A is the well-known *vertical ground plane*. The ground system consists of four above-ground radial wires. The length of the radials and the driven element is derived from the standard equation

$$L(\text{ft}) = \frac{234}{f(\text{MHz})} \quad (6)$$

With four equidistant radial wires drooped at approximately  $45^\circ$  (Fig 20.43A), the feed-point impedance is roughly  $50\ \Omega$ . When the radials are at right angles to the radiator (Fig 20.43B) the impedance approaches  $36\ \Omega$ . Besides minimizing ground return losses, another major advantage in this type of vertical antenna over a ground-mounted type is

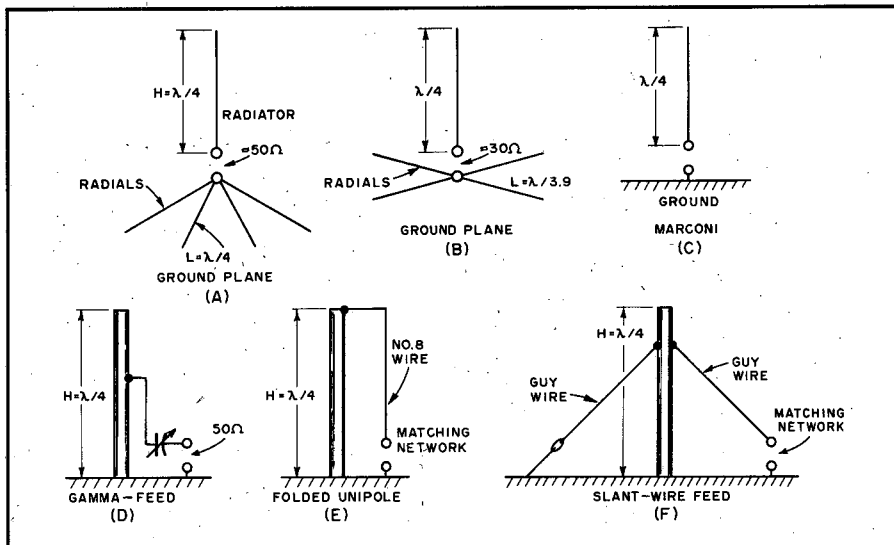

Fig 20.43—Various types of vertical antennas.

that the system can be elevated well above nearby conductive objects (power lines, trees, buildings and so on). When drooping radials are used, they can also serve as guy wires for the mast that supports the antenna. The coax shield braid is connected to the radials, and the center conductor to the driven element.

The *Marconi* vertical antenna shown in Fig 20.43C is the classic form taken by a ground-mounted vertical. It can be grounded at the base and shunt fed, or it can be isolated from ground, as shown, and series fed. As always, this vertical antenna depends on an effective ground system for efficient performance. If a perfect ground were located below the antenna, the feed impedance would be near  $36\ \Omega$ . In a practical case, owing to imperfect ground, the impedance is more apt to be in the vicinity of  $50$  to  $75\ \Omega$ .

A gamma feed system for a grounded  $\frac{1}{4}\lambda$  vertical is presented in Fig 20.43D. Some rules of thumb for arriving at workable gamma-arm and capacitor dimensions are to make the rod length  $0.04$  to  $0.05\lambda$ , its diameter  $\frac{1}{3}$  to  $\frac{1}{2}$  that of the driven element and the center-to-center spacing between the gamma arm and the driven element roughly  $0.007\lambda$ . The capacitance of C1 at a  $50\text{-}\Omega$  matched condition will be about  $7\text{ pF}$  per meter of wavelength. The absolute value of C1 will depend on whether the vertical is resonant and on the precise value of the radiation resistance. For best results, make the radiator approximately  $3\%$  shorter than the resonant length.

Amateur antenna towers lend themselves to use as shunt-fed verticals, even though an HF-band beam antenna is usu-

ally mounted on the tower. The overall system should be close to resonance at the desired operating frequency if a gamma feed is used. The HF-band beam will contribute somewhat to *top loading* of the tower. The natural resonance of such a system can be checked by dropping a #12 or #14 wire from the top of the tower (making it common to the tower top) to form a folded unipole (Fig 20.43E). A four- or five-turn link can be inserted between the lower end of the drop wire and the ground system. A dip meter is then inserted in the link to determine the resonant frequency. If the tower is equipped with guy wires, they should be broken up with strain insulators to prevent unwanted loading of the vertical. In such cases where the tower and beam antennas are not able to provide  $\frac{1}{4}\lambda$  resonance, portions of the top guy wires can be used as top-loading capacitance. Experiment with the guy-wire lengths (using the dip-meter technique) while determining the proper dimensions.

A folded unipole is depicted at E of Fig 20.43. This system has the advantage of increased feed-point impedance. Furthermore, a Transmatch can be connected between the bottom of the drop wire and the ground system to permit operation on more than one band. For example, if the tower is resonant on  $80\text{ m}$ , it can be used as shown on  $160$  and  $40\text{ m}$  with reasonable results, even though it is not electrically long enough on  $160$ . The drop wire need not be a specific distance from the tower, but you might try spacings between  $12$  and  $30$  inches.

The method of feed shown at Fig 20.43F is commonly referred to as "slant-wire feed." The guy wires and the tower com-

**Fig 20.44—Vertical antennas that are less than one-quarter wavelength in height.**

bine to provide quarter-wave resonance. A matching network is placed between the lower end of one guy wire and ground and adjusted for an SWR of 1:1. It does not matter at which level on the tower the guy wires are connected, assuming that the Transmatch is capable of effecting a match to 50 Ω.

### Physically Short Verticals

A group of short vertical radiators is presented in Fig 20.44. Illustrations A and B are for top and center loading. A capacitance hat is shown in each example. The hat should be as large as practical to increase the radiation resistance of the antenna and improve the bandwidth. The wire in the loading coil is chosen for the largest gauge consistent with ease of winding and coil-form size. The larger wire diameters will reduce the resistive ( $I^2R$ ) losses in the system. The coil-form material should have a medium or high dielectric constant. Phenolic or fiberglass tubing is entirely adequate.

A base-loaded vertical is shown at C of Fig 20.44. The primary limitation is that the high current portion of the vertical exists in the coil rather than the driven element. With center loading, the portion of the antenna below the coil carries high current, and in the top-loaded version the entire vertical element carries high current. Since the high-current part of the antenna is responsible for most of the radiating, base loading is the least effective of the three methods. The radiation resistance of the coil-loaded antennas shown is usually less than 16 Ω.

A method for using guy wires to top load

a short vertical is illustrated in Fig 20.44D. This system works well with gamma feed. The loading wires are trimmed to provide an electrical quarter wavelength for the overall system. This method of loading will result in a higher radiation resistance and greater bandwidth than the systems shown at A through C. If an HF-band or VHF array is at the top the tower, it will simply contribute to the top loading.

A three-wire unipole is shown at E. Two #8 drop wires are connected to the top of the tower and brought to ground level. The wires can be spaced any convenient distance from the tower—normally 12 to 30 inches from one side. C1 is adjusted for best SWR. This type of vertical has a fairly narrow bandwidth, but because C1 can be motor driven and controlled from the operating position, frequency changes can be accomplished easily. This technique will not be suitable for matching to 50-Ω line unless the tower is less than an electrical quarter wavelength high.

A different method for top loading is shown at F. Barry Boothe, W9UCW, described this method in December 1974 *QST*. An extension is used at the top of the tower to effect an electrical quarter-wavelength vertical. L1 is a loading coil with sufficient inductance to provide antenna resonance. This type of antenna lends itself nicely to operation on 160 m.

A method for constructing the top-loading shown in Fig 20.44F is illustrated in Fig 20.45. Pipe section D is mated with the mast above the HF-band beam antenna. A loading coil is wound on solid Plexiglas rod or phenolic rod (item C), then clamped inside the collet (B). An aluminum slug (part A) is clamped inside item B. The top part of A is bored and tapped for a 3/8 × 24 stud. This permits a standard 8-ft stainless-steel mobile whip to be threaded into item A above the loading coil. The capacitance hat (Fig 20.45B) can be made from a 1/4-inch-thick brass or aluminum plate. It may be round or square. Lengths of 1/8-inch brazing rod can be threaded and screwed into the edge of the aluminum plate. The plate contains a row of holes along its perimeter, each having been tapped for a 6-32 thread. The capacitance hat is affixed to item A by means of the 8-ft whip antenna. The whip will increase the effective height of the vertical antenna.

### Cables and Control Wires on Towers

Most vertical antennas of the type shown in Fig 20.43 consist of towers, usually with HF or VHF beam antennas at the top. The rotator control wires and the coaxial feeders to the top of the tower will not affect antenna performance adversely. In fact, they become a part of the compos-

**Fig 20.45—At A are the details for the tubing section of the loading assembly. Illustration B shows the top hat and its spokes. The longer the spokes, the better.**

ite antenna. To prevent unwanted RF currents from following the wires into the shack, simply dress them close to the tower legs and bring them to ground level. This decouples the wires at RF. The wires should then be routed along the earth surface (or buried underground) to the operating position. It is not necessary to use bypass capacitors or RF chokes in the rotator control leads if this is done, even when maximum legal power is employed.

### Trap Verticals

The 2-band trap vertical antenna of Fig 20.46 operates in much the same manner as a trap dipole or trap Yagi. The notable difference is that the vertical is one half of a dipole. The radial system (in-ground or above-ground) functions as a ground plane for the antenna, and represents the missing half of the dipole. Once again, the more effective the ground system, the better will be the antenna performance.

Trap verticals usually are adjusted as  $1/4\lambda$  radiators. The portion of the antenna below the trap is adjusted as a  $1/4\lambda$  radiator at the higher proposed operating frequency. That is, a 20/15-m trap vertical would be a resonant quarter wavelength at 15 m from the feedpoint to the bottom of the trap. The trap and that portion of the antenna above the trap (plus the 15-m section below the trap) constitute the complete antenna during 20-m operation. But because the trap is in the circuit, the overall physical length of the vertical antenna will be slightly less than that of a single-band, full-size 20-m vertical.

### Traps

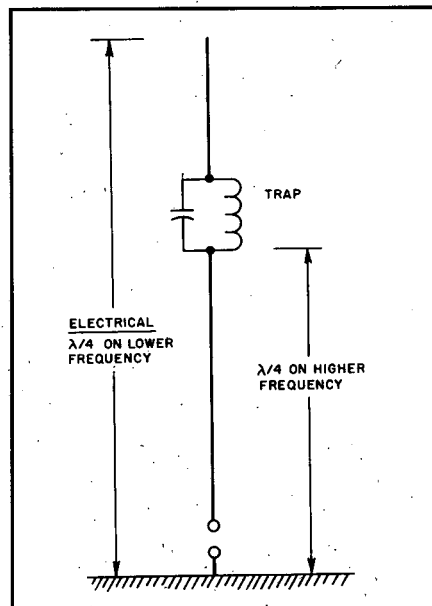

The trap functions as the name implies: It traps the 15-m energy and confines it to the part of the antenna below the trap.

During 20-m operation it allows the RF energy to reach all of the antenna. The trap in this example is tuned as a parallel resonant circuit to 21 MHz. At this frequency it divorces the top section of the vertical from the lower section because it presents a high impedance (barrier) at 21 MHz. Generally, the trap inductor and capacitor have a reactance of 100 to 300  $\Omega$ . Within that range it is not critical.

The trap is built and adjusted separately from the antenna. It should be resonated at the center of the portion of the band to be operated. Thus, if one's favorite part of the 15-m band is between 21.0 and 21.1 MHz, the trap should be tuned to 21.05 MHz.

Resonance is checked by using a dip meter and detecting the dipper signal in a calibrated receiver. Once the trap is adjusted it can be installed in the antenna, and no further adjustment will be required. It is easy, however, to be misled after the system is assembled: Attempts to check the trap with a dip meter will suggest that the trap has moved much lower in frequency (approximately 5 MHz lower in a 20/15-m vertical). This is because the trap is part of the overall antenna, and the resultant resonance is that of the total antenna. Measure the trap separate from the rest of the antenna.

Multiband operation is quite practical by using the appropriate number of traps and tubing sections. The construction and adjustment procedure is the same, regardless of the number of bands covered. The highest frequency trap is always closest to the feed end of the antenna, and the next to lowest frequency trap is always the farthest from the feedpoint. As the operating frequency is progressively lowered, more traps and more tubing sections become a functional part of the antenna.

**Fig 20.46—A two-band trap vertical antenna. The trap should be resonated by itself as a parallel resonant circuit at the center of the operating range for the higher frequency band. The reactance of either the inductor or the capacitor range from 100 to 300  $\Omega$ . At the lower frequency the trap will act as a loading inductor, adding electrical length to the total antenna.**

Traps should be weatherproofed to prevent moisture from detuning them. Several coatings of high dielectric compound, such as Polystyrene Q Dope, are effective. Alternatively, a protective sleeve of heat-shrink tubing can be applied to the coil after completion. The coil form for the trap should be of high dielectric quality and be rugged enough to sustain stress during periods of wind.

## TIPS ON INSTALLING AND CONNECTING TO GROUND RODS

♦ Driving a ground rod 8 feet into the ground with a sledgehammer batters the rod end into an ugly flare. Some types of ground clamps can't open far enough to slip over the enlarged rod. Of course, you can file, grind or saw off the flared end, but doing all of these things at ground level can be difficult.

Alternatively, you could slip the clamp over the rod before driving it into the ground; or use a clamp that opens far enough to pass over the flare. In the case of  $1/2$ -inch ground rods, however, clamps wide enough to pass the flare may not tighten adequately.

After considering these problems, I attached my shack ground wire to a  $1/2$ -inch ground rod as follows. I drilled a tap-size hole, about  $3/4$  inch deep, into the rod top. I tapped this hole for a  $1/4$ -inch, standard thread. Driving in

a hex-head bolt permitted firm attachment of the wire to the rod end.

Although I did this by drilling only one hole, drilling a pilot hole—say, about  $1/8$  inch in diameter—before driving in the rod would assist. Doing so would allow you to put the rod in a vise for stability and accurate drilling. Your sledgehammer may obliterate this hole, but you should be able to relocate it by probing with a center punch.

In any such drilling and thread cutting, use a sharp drill and lubricate it and your tap often while cutting. One more tip: If you have a welder friend, consider having him or her weld a  $1/4$ -inch bolt to the ground-rod top—after you've driven it in—to provide a stud for connections.—A. W. Edwards, K5CN, Corpus Christi, Texas

## DUAL-BAND VERTICALS FOR 17/40 OR 12/30 M

Thanks to the harmonic relationships between the HF ham bands, many antennas can be made to do "double duty." The simple verticals described here cover two bands at once. Here's how to turn a 30-m  $\frac{1}{4}$ - $\lambda$  vertical into a 0.625- $\lambda$  vertical for the 12-m band, and a 40-m  $\frac{1}{4}$ - $\lambda$  vertical into a 0.625- $\lambda$  vertical for the 17-m band. These verticals were designed and constructed

by John J. Reh, K7KGP. The write-up first appeared in April 1989 *QST*.

### Construction Details

For the 30 and 12-m vertical, an old aluminum multiband vertical was cut to a length of 25 ft, 3 inches. This corresponds to a design frequency of 24.95 MHz. The length-to-diameter ratio is approximately 460. The input impedance of a vertical that is substantially longer than a  $\frac{1}{4}$ - $\lambda$  (in this case 0.625  $\lambda$ ) is particularly sensitive to the  $\lambda/D$  ratio of the radiating element. If this antenna is duplicated with materials having a significantly different  $\lambda/D$  ratio, the results may be different.

After installing a good ground system, the input impedance was measured and found to have a resistance of about 50  $\Omega$ , and a capacitance of about -155  $\Omega$  (at 24.95 MHz). At 10.125 MHz, the input impedance was just under 50  $\Omega$ , and purely resistive. To tune out the reactance at 24.95 MHz, a series inductor is installed (see Fig 20.47) and tapped to resonance at the design frequency. The easiest way to find resonance is by measuring the antenna SWR. Use a good-quality coil for the series inductor. The recommended coil has a diameter of 2  $\frac{1}{2}$  inches, and has 6 turns per inch (B&W stock no. 3029). Resonance on 12 m was established with 3  $\frac{1}{4}$  turns. The SWR on 12 m is 1.1:1, and on 30 m, 1:1. To change bands from 12 to 30 m, move the coil tap to the end of the coil closest to the vertical element. Alternatively, a single-pole switch or remotely operated relay can be installed at the base of the vertical for bandswitching.

lowest possible losses in the immediate area for both types of verticals. In addition to a ground radial system, 6 $\times$ 6-ft aluminum ground screen is used at the base of the antenna. The screen makes a good tie point for the radials and conducts ground currents efficiently. Seventeen wire radials, each about 33 ft long, are spaced evenly around the antenna. More radials would probably work better. Each radial is bolted to the screen using corrosion-resistant #10-24 hardware. (Do not attempt to connect copper directly to aluminum. The electrical connection between the two metals will quickly deteriorate.) The radials can be made of bare or insulated wire. Make sure the ground screen is bolted to the ground side of the antenna with heavy-gauge wire. Current flow is fairly heavy at this point.

Table 20.8 gives specifications for the dual-band vertical. If your existing 40-m vertical is a few inches longer than 32 ft, 3 inches, try using it anyway—a few inches isn't too critical to performance on 17 m.

### Automatic Bandswitching

In October 1989 *QST*, James Johnson, W8EUI, presented this scheme for automatic bandswitching of the 40/17-m vertical. Johnson shortened his 40-m vertical approximately 12 inches and found an inductance that gave him 40 and 17-m band operation with an SWR of less than 1.4:1 across each band. He used an inductor made from B&W air-wound coil stock (no. 3033). This coil is 3 inches in diameter, and has 3  $\frac{1}{8}$  turns of #12 wire wound at 6 turns per inch, providing an inductance of about 2.8  $\mu$ H. Johnson experimentally determined the correct tap position.

For the 30/12-m version, start with the vertical radiator 9 inches shorter than the value given in the table. In both cases, radiator height and inductance should be adjusted for optimum match on the two bands covered.

**Fig 20.47—Dual-band vertical.** Use a switch or relay to remove the loading coil from the circuit for lower frequency operation. Adjust the coil tap for best SWR on the higher-frequency band. The radial system should be as extensive as possible. See *The ARRL Antenna Book* for more information on ground systems for vertical antennas.

**Table 20.8**

### Specifications for Dual-Band Verticals

Bands	Height	Required Matching Inductance ( $\mu$ H)
12 m & 30 m	23' 5"	0.99
17 m & 40 m	32' 3"	1.36

### The Ground System

Maximum RF current density—and therefore maximum ground losses—for  $\frac{1}{4}$ - $\lambda$  verticals occurs in the immediate area of the base of the antenna. Maximum return current ground loss for a 0.625- $\lambda$  vertical occurs about  $\frac{1}{2}$   $\lambda$  away from the base of the antenna. It's important to have the

## FERRITE SHIELD-CURRENT CHOKES CURE STRAY RF ON VERTICAL-ANTENNA TRANSMISSION LINES

♦ A vertical antenna can induce current on the shield of its coax feeder. The antenna induces current on the shield in the same manner that it induces current in the ground-system radials.

Since the shield is connected to station ground, RF current flowing on the feeder shield also flows on the outer surfaces of the equipment when the transmitter operates. This current can induce undesirable voltages in interconnecting cables, causing erratic operation of computer keyboards and power supplies. RF feedback also can occur

through the transmitter microphone circuit.

These problems occurred when I operated my kilowatt power amplifier and Kenwood TS-940S transceiver. (RF feedback in the TS-940 microphone preamplifier has been recognized by others and can be solved with bypass capacitors and RF chokes.) A better solution—one that will address all station problems caused by coax-shield RF currents—is to prevent the RF from getting into the station from the coax shield. Gary Peterson, K0CX, suggested that I do this by putting a ferrite-bead shield-current choke in my

## A TREE-MOUNTED HF GROUNDPLANE ANTENNA

A tree-mounted, vertically polarized antenna may sound silly. But is it, really? Perhaps engineering references do not recommend it, but such an antenna does not cost much, is inconspicuous, and it works. This idea was described by Chuck Hutchinson, K8CH, in *QST* for September 1984.

The antenna itself is simple, as shown in Fig 20.48. A piece of RG-58 cable runs to the feedpoint of the antenna, and is attached to a porcelain insulator. Two radial wires are soldered to the coax-line braid at this point. Another piece of wire forms the radiator. The top of the radiator section is suspended from a tree limb or other con-

venient support, and in turn supports the rest of the antenna.

The dimensions for the antenna are given in Fig 20.49. (You can use the values given for leg lengths in Table 20.5.) All three wires of the antenna are  $\frac{1}{4}\lambda$  long. This generally limits the usefulness of the antenna for portable operation to 7 MHz and higher bands, as temporary supports higher than 35 or 40 ft are difficult to come by. Satisfactory operation can

be accomplished on 3.5 MHz with an inverted-L configuration of the radiator, if you can overcome the accompanying difficulty of erecting the antenna at the operating site. The tree-mounted vertical idea can also be used for fixed station installations to make an "invisible" antenna. Shallow trenches can be slit for burying the coax feeder and the radial wires. The radiator itself is difficult to see unless you are standing right next to the tree.

**Fig 20.48—The feedpoint of the tree-mounted groundplane antenna. The opposite ends of the two radial wires may be connected to stakes or other convenient anchor points. Make sure that the radials are high enough so that people cannot come in contact with them.**

**Fig 20.49—Dimensions and construction of the tree-mounted groundplane antenna.**

antenna feed line where it enters my station.

A good source of the required components is The Wireman, Inc (see Address List in **References**). The required components are a package of 50 type FB73-2401 ferrite beads (Wireman part #912B), 15 inches of RG-303 coax, and two coax connectors (UHF connectors [PL-259s; the Wireman's #702] with inserts [UG-175s; the Wireman's #704] for installation on RG-58 coax, or N connectors intended for installation on RG-58 [UG-536B/Us, available as the Wireman's #737]. Although the Wireman sells these parts bundled as part of a W2DU Balun kit [#833], the coax in the kit is too short to accommodate the connectors, so I recommend ordering the parts individually instead of buying them as The Wireman's W2DU Balun kit.

To assemble the choke, install one connector on the cable. Because the UG-536B/U connector is made for RG-58 (which has a larger diameter than RG-303), you must heat-shrink a piece of 1-inch-long,  $\frac{3}{16}$ -inch-diameter plastic tubing on the end of the coax before you install the connector. This will make the connector fit the cable tightly.

Next, put a  $\frac{1}{2}$ -inch-long piece of heat-shrink tubing on the cable about 1 inch from the connector to hold the beads in place. Then place the 50 beads on the cable. Put on another  $\frac{1}{2}$ -inch piece of tubing to anchor the other end of the beads, and then shrink a piece of  $\frac{3}{8}$ -inch-diameter tubing over the beads. Install the other connector on the cable. Install the choke on the transmission line where it leaves your station.

This should largely do away with problems related to stray RF traveling into your station on your feed line's coax shield. An idea for clubs: Build one or more chokes that members can borrow to test this fix's effectiveness before building their own chokes.

If your station is not in the immediate vicinity of your antenna and you have problems with stray RF with a dipole or inverted V, the problem may be due to lack of a balun or use of an ineffective balun. If this is the case, install the choke at the antenna feedpoint as discussed in W2DU's book *Reflections* rather than using the choke at the station end of your feed line.—Bruce R. Palmer, KØWM, Edmond, Oklahoma

# Inverted L and Sloper antennas

This section covers variations on the vertical antenna. Fig 20.50A shows a flat-top T vertical. Dimension H should be as tall as possible for best results. The horizontal section, L, is adjusted to a length that provides resonance. Maximum radiation is polarized vertically despite the horizontal top-loading wire. A variation of the T antenna is depicted at B of Fig 20.50. This antenna is commonly referred to as an *inverted L*. Vertical member H should be as long as possible. L is added to provide an electrical quarter wavelength overall.

## The Half-Sloper Antenna

Many hams have had excellent results with *half-sloper* antennas, while others have not had such luck. Work by ARRL Technical Advisor John S. Belrose, VE2CV, has brought some insight to the situation through computer modeling with *ELNEC* and antenna-range tests. The following is taken from VE2CV's Technical Correspondence in Feb 1991 *QST*, pp 39 and 40. Essentially, the half sloper is a top-fed vertical antenna worked against a ground plane (such as a grounded Yagi antenna) at the top of the tower. The tower acts as a reflector.

For half slopers, the input impedance, the resonant length of the sloping wire and the antenna pattern all depend on the tower height, the angle (between the sloper and tower) the type of Yagi and the Yagi orientation. Here are several configurations extracted from VE2CV's work:

*At 160 m*—use a 40-m beam on top of a 95-ft tower with a 55° sloper apex angle. The radiation pattern varies little with Yagi type. The pattern is slightly cardioid with about 8 dB front-to-back ratio at a 25° takeoff angle (see Fig 20.50D and E). Input impedance is about 50 Ω.

*At 80 m*—use a 20-m beam on top of a 50-ft tower with a 55° sloper apex angle. The radiation pattern and input impedance are similar to those of the 160-m half sloper.

*At 40 m*—use a 20-m beam on top of a 50-ft tower with a 55° sloper apex angle. The radiation pattern and impedance depend strongly on the azimuth orientation of the Yagi. Impedance varies from 76 to 127 Ω depending on Yagi direction.

**Fig 20.50—Some variations in vertical antennas. D is the vertical radiation pattern in the plane of a half sloper, with the sloper to the right. E is the azimuthal pattern of the half sloper (90° azimuth is the direction of the sloping wire). Both patterns apply to 160- and 80-m antennas described in the text.**

## 1.8-MHz INVERTED L

The antenna shown in Fig 20.51 is simple and easy to construct. It is a good antenna for the beginner or the experienced 1.8 MHz DXer. Because the overall electrical length is greater than  $\frac{1}{4} \lambda$ , the feed-point resistance is on the order of  $50 \Omega$ , with an inductive reactance. That reactance is canceled by a series capacitor, which for power levels up to the legal limit can be a air-variable capacitor with a voltage rating of 1500 V. Adjust antenna length and variable capacitor for lowest SWR.

A yardarm or a length of line attached to a tower can be used to support the vertical section of the antenna. (Keep the inverted L as far from the tower as is practical.) For best results the vertical section should be as long as possible. A good ground system is necessary for good results.

Fig 20.51—The 1.8-MHz inverted L. Overall wire length is 165 to 175 ft. The variable capacitor has a maximum capacitance of 500 to 800 pF.

## THE AE6C DUAL-BAND INVERTED-L ANTENNA

In July 1991 *QST*, Dennis Monticelli, AE6C, described a dual-band inverted L. A drawing of his installation is shown in Fig 20.52. Dimensions and values are given in Table 20.9. For ease of explanation, only the 80/40-m version is described here. On 80 m the antenna is  $0.375 \lambda$  long, which raises the antenna's radiation resistance and feed-point impedance, and thus decreases the effect of ground losses. (The feed-point exhibits inductive reactance—which is canceled with series capacitance.) For 40 m the antenna is  $0.75 \lambda$  long, and is therefore resonant on that band. The

pattern on 40 m, depending on how you install the antenna, resembles a combination of a vertical and a low dipole.

If you use a modest radial system with this antenna, the feed-point impedance is roughly  $100 \Omega$  on both bands. Fig 20.53 and Fig 20.54 show details of the matching system and the 1:2 (50 to  $100 \Omega$ ) broadband transformer. The matching capacitor, C1, is not used on the higher frequency band, and so it is shorted out to operate there.

To tune the antenna, start with the dimensions given in Table 20.9. With the

Fig 20.52—Drawing of the Dual-Band Inverted-L antenna installed at AE6C.

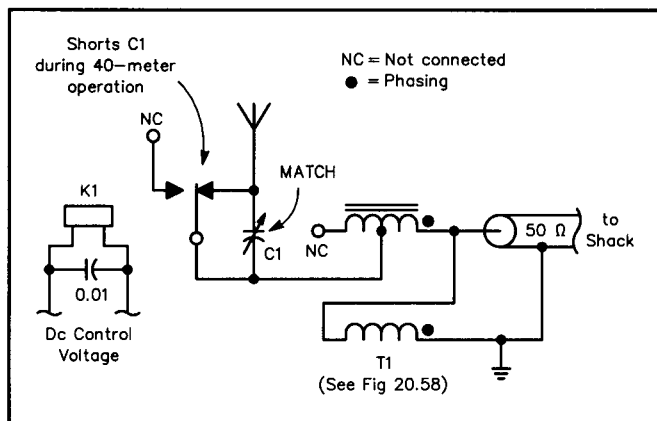

Fig 20.55—At A, 40-m SWR curve. At B, measured SWR curves for 80 m. Curves representing two different series capacitor values are shown.

**Fig 20.53**—The resonating, impedance-matching, and band-switching circuitry required at the base of the inverted L. Fig 20.54 shows details of T1.

**Fig 20.54**—Winding details for constructing broadband bifilar transformer T1, which is wound on T-200-2 core. The primary is 16 turns of #14 enameled wire, and the secondary is 10 turns of #14 enameled wire tapped at about the eighth turn from the feed-line end.

**Table 20.9**

**Recommended Wire Lengths and Capacitor Values\***

Bands	Vertical Length (ft)	Horizontal Length (ft)	Total Length (ft)	Series Capacitor
80/40	32	64	96	≈ 100 pF
160/80	64	128	192	≈ 200 pF

\* The total length is important, but the portions allocated to the vertical and horizontal members aren't critical.

series capacitor shorted, trim the wire length for best SWR at your 40-m frequency of interest. Unshort the capacitor and adjust it for best SWR at your frequency of interest on 80 m. You can further adjust SWR by changing transformer taps. (This will affect both bands.) As

shown in **Fig 20.55**, a single capacitance value yields a 2:1 SWR bandwidth of approximately 225 kHz on 80 m. Different capacitance values can be used to cover other parts of the 80-m band.

You can make you own fixed-value,

high-voltage, high-current capacitor from a piece of coax. For example, RG-8 (solid dielectric) exhibits 29.5 pF per ft and can withstand 4 kV at several amperes. Connect it by attaching one end of the inner conductor to the antenna and the braid (at the same end) to the feed system; leave the other end open. Start with about 4 ft of RG-8 and trim the coax for minimum SWR. (Make your cuts when you're not transmitting!) Other solid-dielectric cables are also suitable for this application. The **Transmission Lines** chapter gives capacitance per unit length in its table of coaxial-cable characteristics. The ends of the coaxial capacitors must be sealed to prevent water ingress.

**Cork Your SO-239 Connectors!**

◊ Those little red plastic caps (CAPPLUGS) that are used to protect unused coax (SO-239) connectors from moisture, dirt and damage are expensive if you are lucky enough to find them. An alternative is to use plastic caps from inexpensive champagne bottles (Fig A). These caps fit perfectly.—Roy Berkowitz, K3NFU, Monroeton, Pennsylvania

**Fig A**—Champagne corks may be recycled into protective caps for SO-239 connectors.

## THE KI6O 160-M SLOPER

In April 1986 *QST*, Deane J. Yungling, KI6O, described a linear-loaded sloper for 1.8 MHz. This sloper, shown in Fig 20.56, has a 2:1 SWR bandwidth of approximately 70 kHz. This antenna is a derivative of the  $\frac{1}{4}\lambda$  half-sloper antenna. This loading technique allows you to use a shorter tower or support than that required for a full size  $\frac{1}{4}\lambda$  1.8-MHz sloper.

In later correspondence, Yungling reported a feed-point impedance on the order of 100  $\Omega$ . He added a  $\frac{1}{4}\lambda$  matching section of 75- $\Omega$  coaxial cable. (For RG-59 or RG-11 solid-dielectric cable this is 88 ft.) The 75- $\Omega$  line is attached directly to the antenna in place of the 50- $\Omega$  line, and if long enough, runs to the operating position. If additional feeder length is required, it should be made of 50- $\Omega$  line attached to the 75- $\Omega$  line by means of a barrel connector. Yungling reported an improved match and improved SWR bandwidth using this feed method.

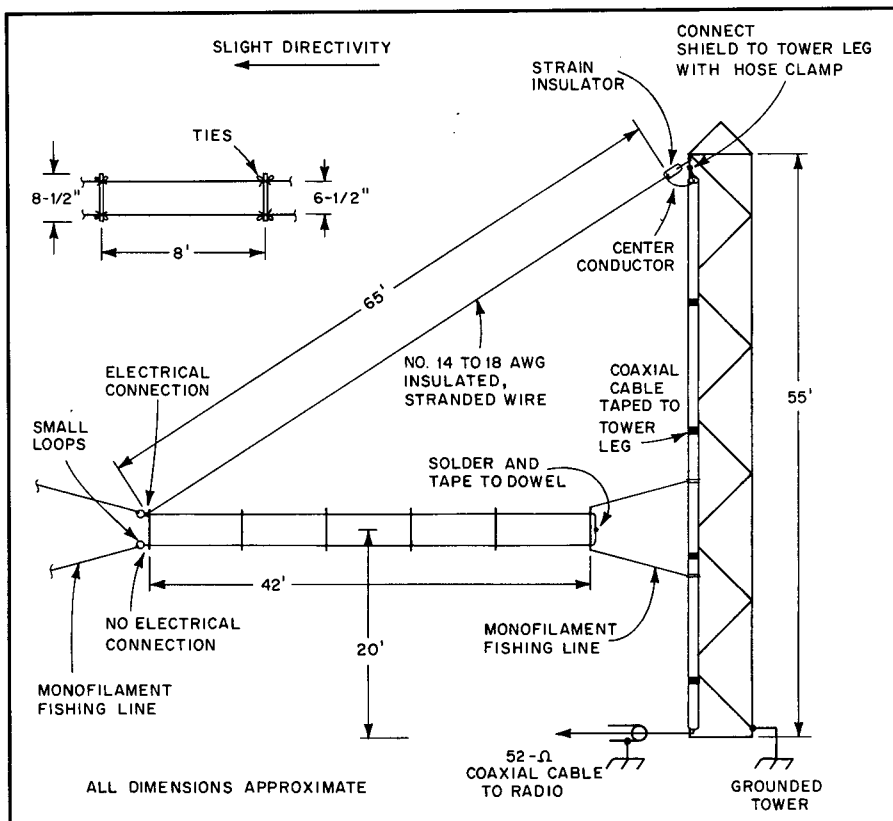

Fig 20.56—Construction details for the KI6O 1.8-MHz linear-loaded sloper.

## NORTH SHADOW

By Irvin L. McNally, K6WX, 26119 Fairlane Dr, Sun City, CA 92586

♦ Determining which way is north is essential for setting up a satellite dish or beam antenna. Articles I've read have shown different ways of making this determination. One method covers the use of a magnetic compass and a knowledge of the local magnetic variation (the difference between true north and magnetic north). However, an accurate value of the local magnetic variation is not always available. And with small hand-held compasses, it's difficult to read the exact bearing because the scale isn't graduated in degrees.

Another method is to observe the north star, Polaris, and sight from the observer to a vertical plumb-bob line to the star. The latter step isn't easy to do in the dark. Furthermore, unless a *Nautical Almanac* is available to determine the exact time of Polaris' meridian transit, there will be a maximum error of about 1°.

Homeowners can try another source of information: the surveyor's plot plan may have noted the magnetic or true bearing relative to the property line.

Mariners use the noon sight to determine their position at sea. With a sextant and chronometer, the altitude and time of the sun's meridian crossing is determined. Combining this data with the declination of the sun, equation of time,<sup>2</sup> sextant correction, refraction and dip, the position can readily be calculated.

I figured that this method could be used in a reverse

calculation to find north. Knowing your exact longitude and the equation of time, the local time of the sun's meridian crossing can be determined. This is the time when the shadow of a vertical pole or tower points true north.

Because the equation of time varies from day to day, its value must be taken from the *Nautical Almanac* or an appropriate table. This difference is shown in the *Nautical Almanac* for each day of the year. World globes used to have an analema printed on a barren area of the Pacific Ocean. The analema is a figure-eight pattern that represents the year-long cycle of the sun's declination and the equation of time. Most globe users fail to grasp its significance.

I've written an IBM BASIC computer program<sup>1</sup> that determines the local time of the north shadow for any day of the year. The required information is: local longitude, month number, day number and local time zone number. A *Nautical Almanac* isn't needed because the equation of time, taken from Mixer's *Primer of Navigation*,<sup>2</sup> is in the program. The maximum error using this table is about 20 seconds, with a possible error of 2 seconds or less, four times a year.

### Notes

<sup>1</sup>The program *NSHADOW.BAS* is on the accompanying diskette.

<sup>2</sup>G. Mixer, *Primer of Navigation* (New York: Van Nostrand Reinhold Co., 5th ed.), 1967, Chapter 21, Table 10, p 539. ISBN: 0-442-05443-2.

## THE KØEØU BROADBAND SLOPER

Brian L. Wermager, KØEOU, described a broadband sloper antenna in April 1986 *QST*. This antenna covers the entire 3.5 to

4-MHz band and is good for working DX. The feed arrangement is shown in **Fig 20.57**. A second wire is connected directly

**Fig 20.57—Feed-point arrangement of the KØEOU broadband sloper. The coaxial cable shield is connected to the tower, with both wires of the two-wire element connected to the center conductor. The wires are spread approximately 8 ft at the ends and are each approximately 52 ft long.**

**Fig 20.59—SWR measurements for the antenna at K0EQU. The highest SWR measurement between 3.5 and 4.0 MHz is 1.2, but this is doubtless an indication of appreciable earth losses rather than broadband antenna performance.**

**Fig 20.58—The Brian Wermager antenna as constructed at K0EQU. The tower is 70 ft high. The feedpoint is shown in Fig 20.57, and is 15 ft above ground level on the tower. The sloper element is 74 ft long, is connected to the tower at the top end, and slopes to a point 11 ft above ground level at the end. Dimensions for the Kelly Davis version constructed at KD7XY are shown in parentheses.**

# Yagi and Quad Directive Antennas

Most antennas described earlier in this chapter have unity gain compared to a dipole, or just slightly more. For the purpose of obtaining gain and directivity it is convenient to use a Yagi-Uda or quad beam antenna. The former is commonly called a *Yagi*, and the latter is referred to as a *quad*.

Most operators prefer to erect these antennas for horizontal polarization, but they can be used as vertically polarized arrays merely by rotating the elements by 90°. In effect, the beam antenna is turned on its side for vertical polarity. The number of elements used will depend on the gain desired and the limits of the supporting structure. Many amateurs obtain satisfactory results with only two elements in a beam antenna, while others have four or five elements operating on a single amateur band.

Regardless of the number of elements used, the height-above-ground considerations discussed earlier for dipole antennas remain valid with respect to the angle of radiation. This is demonstrated in **Fig 20.60** at A and B where a comparison of radiation characteristics is given for a 3-element Yagi at one-half and one wavelength above average ground. It can be seen that the higher antenna (**Fig 20.60B**) has a main lobe that is more favorable for DX work (roughly 15°) than the lobe of the lower antenna in **Fig 20.60A** (approximately 30°). The pattern at B shows that some useful high-angle radiation exists also, and the higher lobe is suitable for short-skip contacts when propagation conditions dictate the need.

The azimuth pattern for the same antenna is provided in **Fig 20.61**. Most of the power is concentrated in the *main lobe* at 0° azimuth. The lobe directly behind the main lobe at 180° is often called the *backlobe*. Note that there are small *sidelobes* at approximately 110° and 260° in azimuth. The peak power difference, in decibels, between the “nose” of the main lobe at 0° and the strongest rearward lobe is called the *front-to-rear ratio (F/R)*. In this case the worst-case rearward lobe is at 180°, and the F/R is 12 dB. It is infrequent that two 3-element Yagis with different element spacings and tuning will yield the same lobe patterns. The pattern of **Fig 20.61** is shown only for illustrative purposes.

## Parasitic Excitation

In most of these arrangements the additional elements receive power by induction or radiation from the driven element and reradiate it in the proper phase relationship to give the desired effect. These

elements are called *parasitic elements*, as contrasted to *driven elements*, which receive power directly from the transmitter through the transmission line.

The parasitic element is called a *director* when it reinforces radiation on a line pointing to it from the driven element, and a *reflector* when the reverse is the case. Whether the parasitic element is a director or reflector depends on the parasitic element tuning, which is usually adjusted by changing its length.

## Gain, Front-to-Rear Ratio and SWR

The gain of an antenna with parasitic elements varies with the spacing and tuning of the elements. Element tuning is a function of length, diameter and taper schedule if the element is constructed with telescoping tubing. For any given spacing, there is a tuning condition that will give maximum gain at this spacing. However, the maximum front-to-rear ratio seldom, if ever, occurs at the same condition that gives maximum forward gain. The impedance of the driven element in a parasitic array, and thus the SWR, also varies with the tuning and spacing.

It is important to remember that all these parameters change as the operating frequency is varied. For example, if you operate both the CW and phone portions of the 20-m band with a Yagi or quad antenna, you probably will want an antenna that “spreads out” the performance over most of the band. Such designs typically must sacrifice a little gain in order to achieve good F/R and SWR performance across the band. The longer the boom of a Yagi or a quad, and the more elements that are placed on that boom, the better will be the overall performance over a given amateur band. For the lower HF bands, the size of the antenna quickly becomes impractical for truly “optimal” designs, and compromise is necessary.

## Two-Element Beams

A 2-element beam is useful where space or other considerations prevent the use of a three element, or larger, beam. The general practice is to tune the parasitic element as a reflector and space it about 0.15  $\lambda$  from the driven element, although some successful antennas have been built with 0.1- $\lambda$  spacing and director tuning. Gain vs element spacing for a two-element antenna is given in **Fig 20.62** for the special case where the parasitic element is resonant. It is indicative of the performance to be expected under maximum-gain tuning

conditions. Changing the tuning of the driven element in a Yagi or quad will not materially affect the gain or F/R. Thus, only the spacing and the tuning of the single parasitic element have any effect on the performance of a 2-element Yagi or quad. Most 2-element Yagi designs achieve a compromise F/R of about 10 dB, together with acceptable SWR and gain across a frequency band with a percentage bandwidth less than about 4%. A 2-element quad can achieve better F/R, gain and SWR across a band, at the expense of greater mechanical complexity compared to a Yagi.

**Fig 20.60—Elevation-plane response of a 3-element Yagi placed  $\frac{1}{2} \lambda$  above perfect ground at (A) and the same antenna spaced  $1 \lambda$  above ground at (B).**

**Fig 20.61—Azimuth-plane pattern of a typical three-element Yagi in free space. The Yagi's boom is along the 0° to 180° axis.**

### Three-Element Beams

A theoretical investigation of the 3-element case (director, driven element and

**Fig 20.62—Gain vs element spacing for a 2-element Yagi, having one driven and one parasitic element.** The reference point, 0 dB, is the field strength from a half-wave antenna alone. The greatest gain is in the direction A at spacings of less than  $0.14\lambda$ , and in direction B at greater spacings. The front-to-rear ratio is the difference in decibels between curves A and B. Variation in radiation resistance of the driven element is also shown. These curves are for the special case of a self-resonant parasitic element, but are representative of how a 2-element Yagi works. At most spacings the gain as a reflector can be increased by slight lengthening of the parasitic element; the gain as a director can be increased by shortening. This also improves the front-to-rear ratio.

reflector) has indicated a maximum gain of about 9.7 dBi. A number of experimental investigations have shown that the spacing between the driven element and reflector for maximum gain is in the region of  $0.15$  to  $0.25\lambda$ . With  $0.2\lambda$  reflector spacing, **Fig 20.63** shows that the gain variation with director spacing is not especially critical. Also, the overall length of the array (boom length in the case of a rotatable antenna) can be anywhere between  $0.35$  and  $0.45\lambda$  with no appreciable difference in the maximum gain obtainable.

If maximum gain is desired, wide spacing of both elements is beneficial because adjustment of tuning or element length is less critical and the input resistance of the driven element is generally higher than with close spacing. A higher input resistance improves the efficiency of the antenna and makes a greater bandwidth pos-

**Fig 20.63—General relationship of gain of 3-element Yagi versus director spacing, the reflector being fixed at  $0.2\lambda$ . This antenna is tuned for maximum forward gain.**

sible. However, a total antenna length, director to reflector, of more than  $0.3\lambda$  at frequencies of the order of 14 MHz introduces difficulty from a construction standpoint. Lengths of  $0.25$  to  $0.3\lambda$  are therefore used frequently for this band, even though they are less than optimum from the viewpoint of maximum gain.

In general, Yagi antenna gain drops off less rapidly when the reflector length is increased beyond the optimum value than it does for a corresponding decrease below the optimum value. The opposite is true of a director. It is therefore advisable to err, if necessary, on the long side for a reflector and on the short side for a director. This also tends to make the antenna performance less dependent on the exact frequency at which it is operated: An increase above the design frequency has the same effect as increasing the length of both parasitic elements, while a decrease in frequency has the same effect as shortening both elements. By making the director slightly short and the reflector slightly long, there will be a greater spread between the upper and lower frequencies at which the gain starts to show a rapid decrease.

We recommend “plumbers delight” construction, where all elements are mounted directly on, and grounded to, the boom. This puts the entire array at dc ground potential, affording better lightning protection. A gamma- or T-match section can be used for matching the feed line to the array.

### Computer-Optimized Yagis

Yagi designers are now able to take advantage of powerful personal computers and software to optimize their designs for the parameters of gain, F/R and SWR across frequency bands. ARRL Senior Assistant Technical Editor Dean Straw, N6BV, has designed a family of Yagis for HF bands. These can be found in **Tables 20.10** through **Table 20.14**, for the 10, 12, 15, 17 and 20-m amateur bands.

For 12 through 20 m, each design has been optimized for better than 20 dB F/R, and an SWR of less than 2:1 across the entire amateur frequency band. For the 10-m band, the designs were optimized for the lower 800 kHz of the band, from 28.0 to 28.8 MHz. Each Yagi element is made of telescoping 6061-T6 aluminum tubing, with 0.058 inch thick walls. This type of element can be telescoped easily, using techniques shown in **Fig 20.64**. Measuring each element to an accuracy of  $1/8$  inch results in performance remarkably consistent with the computations, without any need for “tweaking” or fine-tuning when the Yagi is on the tower.

**Table 20.10**

**Fig 20.66—Illustrations of gamma and T matching systems.** At A, the gamma rod is adjusted along with C until the lowest SWR is obtained. A T match is shown at B. It is the same as two gamma-match rods. The rods and C1 and C2 are adjusted alternately for a best SWR. A coaxial 4:1 balun transformer is shown at C. A toroidal balun can be used in place of the coax model shown. The toroidal version has a broader frequency range than the coaxial one. The T match is adjusted for 200  $\Omega$  and the balun steps this balanced value down to 50  $\Omega$ , unbalanced. Or the T match can be set for 300  $\Omega$ , and the balun used to step this down to 75  $\Omega$  unbalanced. Dimensions for the gamma and T match rods will depend on the tubing size used, and the spacing of the parasitic elements of the beam. Capacitors C, C1 and C2 can be 140 pF for 14-MHz beams. Somewhat less capacitance will be needed at 21 and 28 MHz.

**Fig 20.64—Some methods of connecting telescoping tubing sections to build beam elements.** See text for a discussion of each method.

**Fig 20.65—The boom-to-element plate at A uses muffler-clamp-type U-bolts and saddles to secure the round tubing to the flat plate. The boom-to-mast plate at B is similar to the boom-to-element plate. The main difference is the size of materials used.**

Each element is mounted above the boom with a heavy rectangular aluminum plate, by means of galvanized U-bolts with saddles, as shown in **Fig 20.65**. This

method of element mounting is rugged and stable, and because the element is mounted away from the boom, the amount of element detuning due to the presence of the boom is minimal. The element dimensions given in each table already take into account any element detuning due to the boom-to-element mounting plate. The element-to-boom mounting plate for all the 10-m Yagis is a 0.250-inch thick flat aluminum plate, 4 inches wide by 4 inches long. For the 12 and 15-m Yagis, a 0.375-inch thick flat aluminum plate, 5 inches wide by 6 inches long is used, and for the 17 and 20-m Yagis, a 0.375-inch thick flat aluminum plate, 6 inches wide by 8 inches long is used. Where the plate is rectangular, the long dimension is in line with the element.

Each design table shows the dimensions for *one-half* of each element, mounted on one side of the boom. The other half of each element is the same, mounted on the other side of the boom. Use a tubing sleeve inside the center portion of the element so

that the element is not crushed by the mounting U-bolts. Each telescoping section is inserted 3 inches into the next size of tubing. For example, in the 310-08.YAG design (3 elements on an 8-ft boom), the reflector tip, made out of  $\frac{1}{2}$ -inch OD tubing, sticks out 66.75 inches from the  $\frac{5}{8}$ -inch OD tubing. For each 10-m element, the overall length of each  $\frac{5}{8}$ -inch OD piece of tubing is 21 inches, before insertion into the  $\frac{3}{4}$ -inch piece.

Since the  $\frac{3}{4}$ -inch OD tubing is 24 inches long on each side of the boom, the center portion of each element is actually 48 inches of uncut  $\frac{3}{4}$ -inch OD tubing.

The boom for all these antennas should be constructed with at least 2-inch-OD tubing, with 0.065-inch wall thickness. Because each boom has 3 inches extra space at each end, the reflector is actually placed 3 inches from one end of the boom. For the 310-08.YAG, the driven element is placed 36 inches ahead of the reflector, and the director is placed 54 inches ahead of the driven element.

Each antenna is designed with a driven element length appropriate for a gamma or T matching network, as shown in Fig 20.66. The variable gamma or T capacitors can be housed in small plastic cups for weatherproofing; receiving-type variable capacitors with close plate spacing can be used at powers up to a few hundred watts. Maximum capacitance required is usually 140 pF at 14 MHz and proportionally less at the higher frequencies.

The driven-element's length may require slight readjustment for best match, particularly if a different matching network is used. *Do not change either the lengths or the telescoping tubing schedule of the parasitic elements*—they have been optimized for best performance and will not be affected by tuning of the driven element.

### Tuning Adjustments

Preliminary matching adjustments can be done on the ground. The beam should be set up so the reflector element rests on the earth, with the beam pointing upward. The matching system is then adjusted for best SWR. When the antenna is raised to its operating height, only slight touch-up of the matching network may be required.

### Construction of Yagis

Most beams and verticals are made from sections of aluminum tubing. Compromise beams have been fashioned from less-expensive materials such as electrical conduit (steel) or bamboo poles wrapped with conductive tape or aluminum foil. The steel conduit is heavy, is a poor conductor and is subject to rust. Similarly, bamboo with conducting material attached to it will deteriorate rapidly in the weather. The dimensions shown for the Yagis in the preceding section are designed for specific telescoping aluminum elements, but the elements may be scaled to different sizes by using the information about tapering and scaling in Chapter 2 of *The ARRL Antenna Book*, although with a likelihood of deterioration in performance over the whole frequency band.

For reference, Table 20.15 details the standard sizes of aluminum tubing, available in many metropolitan areas. Dealers may be found in the Yellow Pages under "Aluminum." Tubing usually comes in 12-ft lengths, although 20-ft lengths are available in some sizes. Your aluminum dealer will probably also sell aluminum plate in various thicknesses needed for boom-to-mast and boom-to-element connections.

Aluminum is rated according to its hardness. The most common material used in antenna construction is grade 6061-T6. This material is relatively strong and has good workability. In addition, it will bend without taking a "set," an advantage in antenna applications where the pieces are constantly flexing in the wind. The softer grades (5051, 3003 and so on) will bend much more easily, while harder grades (7075 and so on) are more brittle.

Wall thickness is of primary concern when selecting tubing. It is of utmost importance that the tubing fits snugly where the element sections join. Sloppy joints will make a mechanically unstable antenna. The "magic" wall thickness is 0.058 inch. For example (from Table 20.15), 1-inch outside diameter (OD) tubing with a 0.058-inch wall has an inside diameter (ID) of 0.884 inch. The next smaller size of tubing,  $\frac{7}{8}$  inch, has an OD of 0.875 inch. The 0.009-inch difference provides just the right amount of clearance for a snug fit.

Fig 20.64 shows several methods of fastening antenna element sections together. The slot and hose clamp method shown in Fig 20.64A is probably the best for joints where adjustments are needed. Generally, one adjustable joint per element half is sufficient to tune the antenna—usually the tips at each end of an element are made adjustable. Stainless steel hose clamps (beware—some "stainless steel" models do not have a stainless screw and will rust) are recommended for longest antenna life.

Fig 20.64B, C and D show possible fastening methods for joints that are not adjustable. At B, machine screws and nuts hold the elements in place. At C, sheet metal screws are used. At D, rivets secure the tubing. If the antenna is to be assembled permanently, rivets are the best choice. Once in place, they are permanent. They will never work free, regardless of vibration or wind. If aluminum rivets with aluminum mandrels are employed, they will never rust. Also, being aluminum, there is no danger of corrosion from interaction between dissimilar metals. If the antenna is to be disassembled and moved periodically, either B or C will work. If machine screws are used, however, take precautions to keep the nuts

**Fig 20.67—A long boom needs both vertical and horizontal support. The crossbar mounted above the boom can support a double truss, which will help keep the antenna in position.**

from vibrating free. Use of lock washers, lock nuts and flexible adhesive such as silicone bathtub sealant will keep the hardware in place.

Use of a conductive grease at the element joints is essential for long life. Left untreated, the aluminum surfaces will oxidize in the weather, resulting in a poor connection. Some trade names for this conductive grease are Penetrox, Noalox and Dow Corning Molykote 41. Many electrical supply houses carry these products.

### Boom Material

The boom size for a rotatable Yagi or quad should be selected to provide stability to the entire system. The best diameter for the boom depends on several factors, but mostly the element weight, number of elements and overall length. Two-inch-diameter booms should not be made any longer than 24 ft unless additional support is given to reduce both vertical and horizontal bending forces. Suitable reinforcement for a long 2-inch boom can consist of a truss or a truss and lateral support, as shown in Fig 20.67.

A boom length of 24 ft is about the point where a 3-inch diameter begins to be very worthwhile. This dimension provides a considerable amount of improvement in overall mechanical stability as well as increased clamping surface area for element hardware. The latter is extremely important to prevent rotation of elements around the boom if heavy icing is commonplace. Pinning an element to the boom with a large bolt helps in this regard. On smaller diameter booms, however, the elements sometimes work loose and tend to elongate the pinning holes in both the element and the boom. After some time the elements shift their positions slightly (sometimes from day to day) and give a ragged appearance to the system, even though this may not harm the electrical performance.

A 3-inch-diameter boom with a wall thickness of 0.065 inch is very satisfac-

tory for antennas up to about a 5-element, 20-m array that is spaced on a 40-ft boom. A truss is recommended for any boom longer than 24 ft. One possible source for large boom material is irrigation tubing sold at farm supply houses.

## Putting It Together

Once you assemble the boom and elements, the next step is to fasten the elements to the boom securely and then fasten the boom to the mast or supporting structure. Be sure to leave plenty of material on either side of the U-bolt holes on the element-to-boom mounting plates. The U-bolts selected should be a snug fit for the tubing. If possible, buy muffler-clamp U-bolts that come with saddles.

The boom-to-mast plate shown in Fig 20.65B is similar to the boom-to-element plate. The size of the plate and number of U-bolts used will depend on the size of the antenna. Generally, antennas for the bands up through 20 m require only two U-bolts each for the mast and boom. Longer antennas for 15 and 20 m (35-ft booms and up) and most 40-m beams should have four U-bolts each for the boom and mast because of the torque that the long booms and elements exert as the antennas move in the wind. When tightening the U-bolts, be careful not to crush the tubing. Once the wall begins to collapse, the connection begins to weaken. Many aluminum suppliers sell 1/4-inch or 3/8-inch plates just right for this application. Often

they will shear pieces to the correct size on request. As with tubing, the relatively hard 6061-T6 grade is a good choice for mounting plates.

The antenna should be put together with good-quality hardware. Stainless steel is best for long life. Rust will attack plated steel hardware after a short while, making nuts difficult, if not impossible, to remove. If stainless muffler clamps are not available, the next best thing is to have them plated. If you can't get them plated, then at least paint them with a good zinc-chromate primer and a finish coat or two. Good-quality hardware is more expensive initially, but if you do it right the first time, you won't have to take the antenna down after a few years and replace the hardware.

Also, when repairing or modifying an installation, nothing is more frustrating than fighting rusty hardware at the top of a tower.

## Quad Antennas

One of the more effective DX arrays is called a *quad* antenna. It consists of two or more loops of wire, each supported by a bamboo or fiberglass cross-arm assembly. The loops are a quarter wavelength per side (full wavelength overall). One loop is driven and the other serves as a parasitic element—usually a reflector. A variation of the quad is called the *delta loop*. The electrical properties of both antennas are

the same. Both antennas are shown in Fig 20.68. They differ mainly in their physical properties, one being of plumber's delight construction, while the other uses insulating support members. One or more directors can be added to either antenna if additional gain and directivity are desired, though most operators use the 2-element arrangement.

It is possible to interlace quads or "deltas" for two or more bands, but if this is done the formulas given in Fig 20.68 may have to be changed slightly to compensate for the proximity effect of the second antenna. For quads the length of the full-wave loop can be computed from

$$\text{Full-wave loop} = \frac{1005}{f(\text{MHz})} \quad (7)$$

If multiple arrays are used, each antenna should be tuned separately for maximum forward gain, or best front-to-rear ratio, as noted on a field-strength meter. The reflector stub on the quad should be adjusted for this condition. The gamma match should be adjusted for best SWR. The resonance of the antenna can be found by checking the frequency at which the lowest SWR occurs. The element length (driven element) can be adjusted for resonance in the most-used portion of the band by lengthening or shortening it.

**Fig 20.68—Information on building a quad or a delta-loop antenna. The antennas are electrically similar, but the delta-loop uses plumber's delight construction. The  $\lambda/4$  length of 75-Ω coax acts as a Q-section transformer from approximate 100-Ω feedpoint impedance of quad to 50-Ω feed line coax.**

## FEEDING A QUAD WITH OPEN-WIRE LINE

After purchasing a GEM quad antenna, I determined that the best place for the antenna on my property was 375 feet from my operating position. Even low-loss coax could easily result in a 3-dB loss at 28 MHz.

At the encouragement of Jay Kolinsky, NE2Q, I looked at using open-wire transmission line. Using readily available 450-Ω line, the losses would be low and the line cost went down to only 10 cents per foot. As we learned later, there were even bigger benefits.

### Feeding the Antenna

I've talked to a lot of people using quads, and I couldn't find anyone who had fed their quad with open-wire line. A call to the antenna manufacturer produced some suggestions, but not firm guidance on how to do the job.

The antenna was set up for four bands: 20, 17, 15 and 10 m. Jay and I decided to take the easy way out and tie all of its driven elements together, spacing their terminals with a  $1\frac{1}{2}$ -inch porcelain insulator, and feed the all four driven elements with the open-wire line as shown in Figure 2. We ignored the driven elements' sum feed-point impedance, since using open-wire line meant using an antenna tuner between the transmitter and the line, anyway. We did not attempt to tune the antenna's driven elements, deciding instead to carefully adjust the quad's front-to-back ratio on each band and let the tuner take care of the rest.

### Unexpected Results

Careful front-to-back ratio adjustments yielded results better than those claimed by the antenna

**Figure 2—Curtis, NT5E, simplified his quad feed by connecting its elements' feed points together and feeding all three simultaneously with open-wire line.**

manufacturer. NT5E went on the air with a new antenna, and the performance proved well worth the work. Using the tuner, I was able to operate anywhere in the bands with a 1:1 SWR. The only drawback was that I still needed antennas for 7, 10 and 24 MHz—or did I?

A quick check proved that the system would load up at 10 and 24 MHz. More careful adjustments were required for tuning up at 7 MHz. We roughly measured its radiation pattern as similar to that of a half-wave loop. My antenna had grown—at least in terms of frequency coverage! Further rough measurements at 7 MHz showed that there was a slight front-to-back ratio, possibly because of the reflectors present for 14, 18, 21 and 28 MHz.—Curtis Robb, NT5E, Boerne, Texas

## A FIVE-BAND, TWO-ELEMENT HF QUAD

Two quad designs are described in this article, both nearly identical. One was constructed by KC6T from scratch, and the other was built by Al Doig, W6NBH, using modified commercial triband quad hardware. The principles of construction and adjustment are the same for both models, and the performance results are also essentially identical. One of the main advantages of this design is the ease of (relatively) independent performance adjustments for each of the five bands. These quads were described by William A. Stein, KC6T, in *QST* for April 1992. Both models use 8-ft-long, 2-inch diameter booms, and conventional X-shaped spreaders (with two sides of each quad loop parallel to the ground).

### *The Five-Band Quad as a System*

Unless you are extraordinarily lucky, you should remember one general rule: Any quad must be adjusted for maximum performance after assembly. Simple quad designs can be tuned by pruning and re-stringing the elements to control front-to-rear ratio and SWR at the desired operat-

ing frequency. Since each element of this quad contains five concentric loops, this adjustment method could lead to a nervous breakdown!

**Fig 20.69** shows that the reflectors and driven elements are each independently adjustable. After assembly, adjustment is simple, and although gamma-match components on the driven element and capacitors on the reflectors add to the antenna's parts count, physical construction is not difficult. The reflector elements are purposely cut slightly long (except for the 10-m reflector), and electrically shortened by means of a tuning capacitor. The driven-element gamma matches set the lowest SWR at the desired operating frequency.

As with most multiband directive antennas, the designer can optimize any two of the following three attributes at the expense of the third: forward gain, front-to-rear ratio and bandwidth (where the SWR is less than 2:1). These three characteristics are related, and changing one changes the other two. The basic idea behind this quad design is to permit (without resorting to trimming loop lengths, spac-

ing or other gross mechanical adjustments):

- The forward gain, bandwidth and front-to-rear ratio may be set by a simple adjustment after assembly. The adjustments can be made on a band-by-band basis, with little or no effect on previously made adjustments on the other bands.
- Setting the minimum SWR in any portion of each band, with no interaction with previously made front-to-back or SWR adjustments.

The first of the two antennas described, the KC6T model, uses aluminum spreaders with PVC insulators at the element attachment points. (The author elected not to use fiberglass spreaders because of their high cost.) The second antenna, the W6NBH model, provides dimensions and adjustment values for the same antenna, but using standard triband-quad fiberglass spreaders and hardware. If you have a triband quad, you can easily adapt it to this design. When W6NBH built his antenna, he had to shorten the 20-m reflector because the KC6T model uses a larger 20-m reflector than W6NBH's fiberglass spreaders would allow. Performance is essentially identical for both models.

### *Mechanical Considerations*

Even the best electrical design has no value if its mechanical construction is lacking. Here are some of the things that contribute to mechanical strength: The gamma-match capacitor KC6T used was a small, air-variable, chassis-mount capacitor mounted in a plastic box (see **Fig 20.70**). A male UHF connector was mounted to the box, along with a screw terminal for connection to the gamma rod.

**Fig 20.69—Mechanical layout of the five-band quad. The boom is 8 ft long; see Table 20.16 for all other dimensions.**

**Fig 20.70—Photo of one of the feed-point gamma-match capacitors.**

The terminal lug and wire are for later connection to the driven element. The box came from a local hobby shop, and the box lid was replaced with a piece of 1/32-inch ABS plastic, glued in place after the capacitor, connector and wiring had been installed. The capacitor can be adjusted with a screwdriver through an access hole. Small vent (drain) holes were drilled near corresponding corners of each end.

Enclose the gamma-match capacitor in such a manner that you can tape unwanted openings closed so that moisture can't be directly blown in during wind and rain-storms. Also, smaller boxes and sturdy mounts to the driven element ensure that you won't pick up gamma capacitor assemblies along with the leaves after a wind storm.

Plastic gamma-rod insulators/standoffs were made from 1/32-inch ABS, cut 1/2-inch wide with a hole at each end. Use a knife to cut from the hole to the side of each insulator so that one end can be slipped over the driven element and the other over the gamma rod. Use about four such insulators for each gamma rod, and mount the first insulator as close to the capacitor box as possible. Apply five-minute epoxy to the element and gamma rod at the insulator hole to keep the insulators from sliding. If you intend to experiment with gamma-rod length, perform this gluing operation after you have made the final gamma-rod adjustments.

#### Element Insulators

As shown in Fig 20.69, the quad uses insulators in the reflectors for each band to break the loop electrically, and to allow reflector adjustments. Similar insulators were used to break up each driven element so that element impedance measurements could be made with a noise bridge. After the impedance measurements, the driven-element loops are closed again. The insulators are made from 1/4 x 2 x 3/4-inch phenolic stock. The holes are 1/2-inch apart. Two terminal lugs (shorted together at the center hole) are used in each driven element. They offer a convenient way to open the loops by removing one screw. Fig 20.71 shows these insulators and the gamma-match construction schematically. Table 20.16 lists the component values, element lengths and gamma-match dimensions.

#### Element-to-Spreader Attachment

Probably the most common problem with quad antennas is wire breakage at the element-to-spreader attachment points. There are a number of functional attachment methods; Fig 20.72 shows one of them. The attachment method with both

**Fig 20.71—Gamma-match construction details (A) and reflector-tuning capacitor (C<sub>R</sub>) attachment schematic (B). The gamma matches consist of matching wires (one per band) with series capacitors (C<sub>G</sub>). See Table 20.16 for lengths and component specifications.**

**Table 20.16**

#### Element Lengths and Gamma-Match Specifications of the KC6T and W6NBH Five-Band Quads

##### KC6T Model

Band (MHz)	Driven Element	Length (in.)	Gamma Match		Reflector Length (in.)	C <sub>R</sub> (pF)
			Spacing	C <sub>G</sub> (pF)		
14	851.2	33	2	125	902.4	68
18	665.6	24	2	110	705.6	47
21	568	24	1.5	90	604.8	43
24.9	483.2	29.75	1	56	514.4	33
28	421.6	26.5	1	52	448.8	(jumper)

##### W6NBH Model

Band (MHz)	Driven Element	Length (in.)	Gamma Match		Reflector Length (in.)	C <sub>R</sub> (pF)
			Spacing	C <sub>G</sub> (pF)		
14	851.2	31	2	117	890.4	120
18	665.6	21	2	114	705.6	56
21	568	26	1.5	69	604.8	58
24.9	483.2	15	1	75.5	514.4	54
28	421.6	18	1	41	448.8	(jumper)

KC6T and W6NBH spreaders is the same, even though the spreader constructions differ. The KC6T model uses #14 AWG, 7-strand copper wire; W6NBH used #18, 7-strand wire. At the point of element attachment (see Fig 20.73), drill a hole through both walls of the spreader using a #44 (0.086-inch) drill. Feed a 24-inch-long piece of antenna wire through the hole and center it for use as an attachment wire.

After fabricating the spider/spreader assembly, lay the completed assembly on a flat surface and cut the element to be installed to the correct length, starting with the 10-m element. Attach the element ends to the insulators to form a closed loop before attaching the elements to the spreaders. Center the insulator between the spreaders on what will become the bottom side of the quad loop, then carefully measure and mark the element-mounting-points with fingernail polish (or a similar substance). Do not depend on the at-rest position of the spreaders to guarantee that the mounting

**Fig 20.72—Attaching quad wires to the spreaders must minimize stress on the wires for best reliability. This method (described in the text) cuts the chances of wind-induced wire breakage by distributing stress.**

**Fig 20.73—Spreader-drilling diagram and dimensions for the five-band quad.** These dimensions apply to both spreader designs described in the text, except that most commercial spreaders are only a bit over 13 ft (156 inches) long. This requires compensation for the W6NBH model's shorter 20-m reflector as described in the text.

points will all be correct.

Holding the mark at the centerline of the spreader, tightly loop the attachment wire around the element and then gradually space out the attachment-wire turns as shown. The attachment wire need not be soldered to the element. The graduated turn spacing minimizes the likelihood that the element wire will flex in the same place with each gust of wind, thus reducing fatigue-induced wire breakage.

#### *Feeding the Driven Elements*

Each driven element is fed separately, but feeding five separate feed lines down the tower and into the shack would be costly and mechanically difficult. The ends of each of these coax lines also require support other than the tension (or lack of thereof) provided by the driven element at the feed-point. It is best to use a remote coax switch on the boom approximately 1 ft from the driven-element spider-assembly attachment point.

At installation, the cables connecting the gamma-match capacitors and the coax switch help support the driven elements and gamma capacitors. The support can be improved by taping the cables together in several places. A single coaxial feed line (and a control cable from the remote coax switch, if yours requires one) is the only required cabling from the antenna to the shack.

#### *The KC6T Model's Composite Spreaders*

If you live in an area with little or no wind, spreaders made from wood or PVC are practical but, if you live where winds can reach 60 to 80 mi/h, strong, lightweight spreaders are a must. Spreaders constructed with electrical conductors (in this case, aluminum tubing) can cause a myriad of problems with unwanted resonances, and the problem gets worse as the number of bands increases.

To avoid these problems, this version uses composite spreaders made from machined PVC insulators at the element-attachment points. Aluminum tubing is inserted into (or over) the insulators 2 inches on each end. This spreader is designed to withstand 80 mi/h winds. The overall insulator length is designed to provide a 3-inch center insulator clear of the aluminum tubing. The aluminum tubing used for the 10-m section (inside dimension "A" in Fig 20.73) is 1 $\frac{1}{8}$ -inch diameter  $\times$  0.058-inch wall. The next three sections are  $\frac{3}{4}$ -inch diameter  $\times$  0.035-inch wall, and the outer length is made from  $\frac{1}{2}$  inch diameter  $\times$  0.035-inch wall. The dimensions shown in Fig 20.73 are *attachment point* dimensions only.

Attach the insulators to the aluminum using #6 sheet metal screws. Mechanical strength is provided by Devcon no. S 220 Plastic Welder Glue (or equivalent) applied liberally as the aluminum and plastic parts are joined. Paint the PVC insulators before mounting the elements to them. Paint protects the PVC from the harmful effects of solar radiation. As you can see from Fig 20.73, an additional spreader insulator located about halfway up the 10-m section (inside dimension "A") removes one of the structure's electrical resonances not eliminated by the attachment-point insulators. Because it mounts at a relatively high-stress point in the spreader, this insulator is fabricated from a length of heavy-wall fiberglass tubing.

Composite spreaders work as well as fiberglass spreaders, but require access to a well-equipped shop, including a lathe. The main objective of presenting the composite spreader is to show that fiberglass spreaders aren't a basic requirement—there are many other ways to construct usable spreaders. If you can lay your hands on a used multiband quad, even one that's damaged, you can probably obtain enough spreaders to reduce construction costs considerably.

#### *Gamma Rod*

The gamma rod is made from a length of #12 solid copper wire (W6NBH used #18, 7-strand wire). Dimensions and spacings are shown in Table 20.16. If you intend to experiment with gamma-rod lengths and capacitor settings, cut the gamma-rod lengths about 12 inches longer than the length listed in the table. Fabricate a sliding short by soldering two small alligator clips back-to-back such that they can be clipped to the rod and the antenna element and easily moved along the driven element. Note that gamma-rod spacing varies from one band to another. When you find a suitable shorting-clip position, mark the gamma rod, remove the clip, bend the gamma rod at the mark and solder the end to the element.

#### *The W6NBH Model*

As previously mentioned, this model uses standard 13-ft fiberglass spreaders, which aren't quite long enough to support the larger 20-m reflector specified for the KC6T model. The 20-m W6NBH reflector loop is cut to the dimensions shown in Table 20.16, 12 inches shorter than that for the KC6T model. To tune the shorter reflector, a 6-inch-long stub of antenna wire (spaced 2 inches) hangs from the reflector insulator, and the reflector tuning capacitor mounts on another insulator at the end of this stub.

### *Gamma-Match and Reflector-Tuning Capacitor*

Use an air-variable capacitor of your choice for each gamma match. Approximately 300 V can appear across this capacitor (at 1500 W), so choose plate spacing appropriately. If you want to adjust the capacitor for best match and then replace it with a fixed capacitance, remember that several amperes of RF will flow through the capacitance. If you choose disc-ceramic capacitors, use a parallel combination of at least four 1-kV units of equal value. Any temperature coefficient is acceptable. NP0 units are not required. Use similar components to tune the reflector elements.

### *Adjustments*

Well, here you are with about 605 ft of wire. Your antenna will weigh about 45 pounds (the W6NBH version is slightly lighter) and have about 9 square ft of wind area. If you chose to, you can use the dimensions and capacitance values given, and performance should be excellent. If you adjust the antenna for minimum SWR at the band centers, it should cover all of the lower four bands and 28 to 29 MHz with SWRs under 2:1; front-to-rear ratios are given in **Table 20.17**.

Instead of building the quad to the dimensions listed and hoping for the best, you can adjust your antenna to account for most of the electrical environment variables of your installation. The adjustments are conceptually simple: First adjust the reflector's electrical length for maximum

front-to-rear ratio (if you desire good gain, but are willing to settle for a narrower than maximum SWR bandwidth), or accept some compromise in front-to-rear ratio that results in the widest SWR bandwidth. You can make this adjustment by placing an air-variable capacitor (about 100-pF maximum) across the open reflector loop ends, one band at a time, and adjusting the capacitor for the desired front-to-rear ratio. The means of doing this will be discussed later.

During these reflector adjustments, the driven-element gamma-match capacitors may be set to any value and the gamma rods may be any convenient length (but the sliding-short alligator clips should be installed somewhere near the lengths specified in Table 20.16). After completing the front-to-rear adjustments, the gamma capacitors and rods are adjusted for minimum SWR at the desired frequency.

### *Adjustment Specifics*

Adjust each band by feeding it separately. You can make a calibrated variable capacitor (with a hand-drawn scale and wire pointer). Calibrate the capacitor using your receiver, a known-value inductor and a dip meter (plus a little calculation).

To adjust front-to-rear ratio, simply clip the (calibrated) air-variable capacitor across the open ends of the desired reflector loop. Connect the antenna to a portable receiver with an S meter. Point the back of the quad at a signal source, and slowly adjust the capacitor for a dip in the S-meter reading.

**Table 20.17**

**Measured Front-to-Rear Ratios**

Band	KC6T Model	W6NBH Model
14	25 dB	16 dB
18	15 dB	10 dB
21	25 dB	>20 dB
24.9	20 dB	>20 dB
28	20 dB	>20 dB

After completing the front-to-rear adjustments, replace the variable capacitor with an appropriate fixed capacitor sealed against the weather. Then move to the driven-element adjustments. Connect the coax through the SWR bridge to the 10-m gamma-match capacitor box. Use an SWR bridge that requires only a watt or two (not more than 10 W) for full-scale deflection in the calibrate position on 10 m. Using the minimum necessary power, measure the SWR. Go back to receive and adjust the capacitor until (after a number of transmit/receive cycles) you find the minimum SWR. If it is too high, lengthen or shorten the gamma rod by means of the sliding alligator-clip short and make the measurements again.

Stand away from the antenna when making transmitter-on measurements. The adjustments have minimal effect on the previously made front-to-rear settings, and may be made in any band order. After making all the adjustments and sealing the gamma capacitors, reconnect the coax harness to the remote coax switch.

## Loops

The quad is not the only loop antenna used by radio amateurs. Horizontal full-wave loops, much like the quad driven element, are performers that are worth

considering. Multiband operation is a natural, and you only need one feed line.

Physically small loops can also be used

for transmitting. They're compact, but the price is a narrow bandwidth and somewhat reduced efficiency.

## THE LOOP SKYWIRE

Here's a multiband HF antenna that's easy to build, costs nearly nothing and works great—yet relatively few amateurs use it. The antenna is the full-size horizontal loop—or, as this one's called—the *Loop Skywire*. The Loop Skywire eliminates the need for multiple antennas to cover the HF bands, is made only of wire and coaxial cable (or open-wire line) and often needs no

Transmatch. It's efficient and omnidirectional over real earth, can be used on all harmonics of the fundamental frequency, and fits on almost every amateur's lot. The Loop Skywire has been called "the best easy-to-build, multiband antenna around," and to those who now use it, it's "the best kept secret in the amateur circle."

It is curious that many references to

this antenna are brief pronouncements that it operates best as a high-angle radiator and is good for only short-distance contacts. This is not the case. Those who use the Loop Skywire know that DX is easy to work. This antenna was originally featured in November 1985 *QST* and was presented by Dave Fischer, W0MHS.

## The Design

The Loop Skywire is shown in Fig 20.74. It is simply a full-wavelength loop antenna erected horizontal to the

earth. Maximize enclosed area within the wire loop, and mount the antenna up as high as possible above ground. The antenna has one wavelength of wire in its perimeter at the design, or fundamental,

frequency. If you choose to calculate  $L_{\text{total}}$  in ft, use the following equation:

$$L_{\text{total}} = 1005/f \quad (9)$$

where  $f$  equals the frequency in MHz. (This is the standard formula for determining the length of full-wavelength loops.)

Given any length of wire, a circle encloses the maximum possible area. Since it takes an infinite number of supports to support a circular loop, a square loop (with four supports) is more practical. Further reducing the area enclosed by the wire loop (fewer supports) brings the antenna closer to the properties of the folded dipole; both harmonic-impedance and feed-line voltage problems can result. Loop geometries other than a square are thus possible, but remember the two fundamental requirements for the Loop Skywire—its horizontal position and maximum enclosed area.

## Construction

The antenna's construction is simple. Although the loop can be made for any band or frequency of operation, the following two Loop Skywires are star performers. Both antennas work on the 10-MHz band also.

**3.5-MHz Loop Skywire:** (3.5–28 MHz), total loop perimeter: 272 ft. Square side length: 68 ft.

**7-MHz Loop Skywire:** (7–28 MHz), total loop perimeter: 142 ft. Square side length: 35.5 ft.

The actual total length can vary by a few ft, as the length is not at all critical. Do not worry about tuning and pruning the loop to resonance. No signal difference will be detected on the air.

Insulated, stranded copper wire—#12 to #18—is usually used for the loop.

Fig 20.75 shows the placement of the insulators at the loop corners. Either lock or tie the insulator in place with a loop wire tie, as shown in Fig 20.75A, or leave the insulator free to “float” or slide along the wire, Fig 20.75B. Most loop users float at least two insulators. This allows pulling the slack out of the loop once it is in the air, and eliminates the need to have all the supports exactly placed for proper tension in each leg. It's best to float two opposite corners.

The feedpoint can be positioned anywhere along the loop. Most users feed the Skywire at a corner, however. Fig 20.76 shows a method of doing this. It is advantageous to keep the feed-point mechanically away from a corner support. Feeding a foot or so from one corner allows the feed line to exit more freely.

Generally, a minimum of four supports is required. If trees are used for supports, then at least two of the ropes or guys used to support the insulators should be coun-

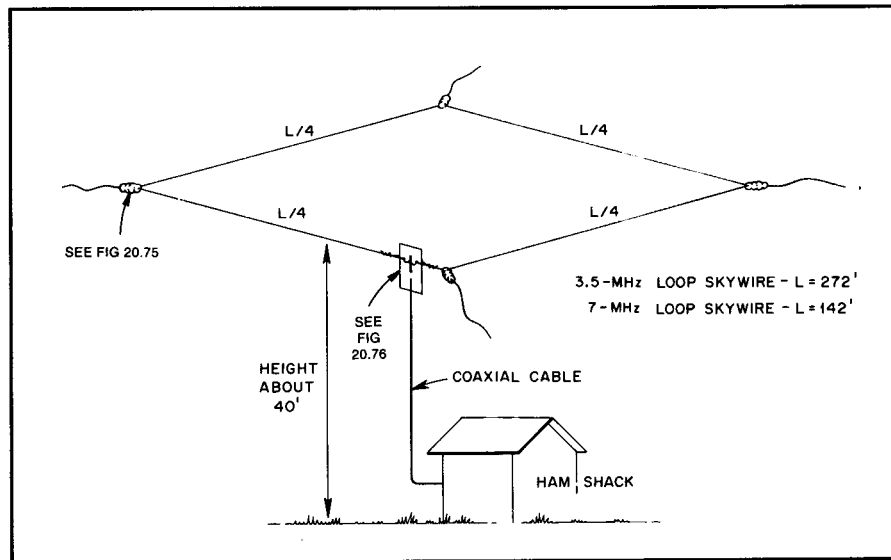

Fig 20.74—A complete view of the Loop Skywire. The square loop is erected horizontal to the earth.

Fig 20.75—Two methods of installing the insulators at the corners of the loop.

Fig 20.76—Most users feed the Loop Skywire at the corner. Dimensions shown are approximate.

terweighted and allowed to move freely. The feed-line corner is almost always tied down, however. Several loops have been constructed with bungee cords tied to three of the four insulators. This eliminates the need for counter weighting.

Recommended height for the antenna is 40 ft or more. Higher is better. However, successful local and DX operation has been reported in several cases with the loop as low as 25 ft.

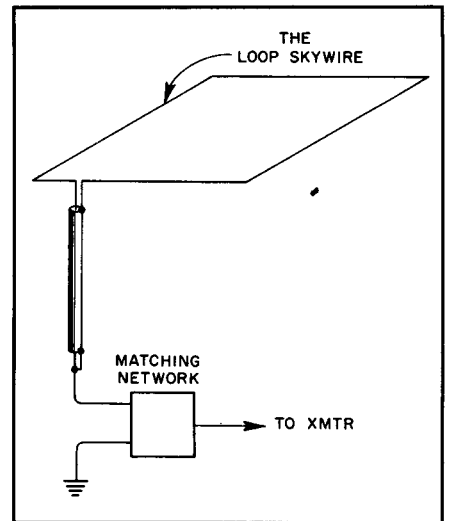

The SWR will depend on operating frequency and the type of feed line used. Coaxial cable is sufficient. Open-wire line works well, too. Many users feed the loop with RG-58. The SWR from either of these loops is rarely over 3:1. If you are concerned about the SWR, use a Transmatch.

When constructing the loop, connect (solder) the coaxial feed line ends directly to the loop wire ends. Baluns or choke

coils at the feedpoint are unnecessary. The highest SWR usually occurs at the second harmonic of the design frequency. The Loop Skywire is somewhat more broadband than corresponding dipoles, and is also more efficient. Do not expect SWR curves that are "dummy load" flat.

#### *Using the Loop Skywire as a Vertical*

Another interesting feature of this loop is its ability to be used as an all-band vertical antenna with top-hat loading. This is accomplished by keeping the feed-line run from the shack as vertical as possible and clear of metallic objects. Both feed-line conductors are then tied together (by means of a shorted SO-239 jack, for example), and the antenna is fed against a good ground system. This method allows excellent performance of the 40-m loop on 80 m, and the 80-m loop on 160 m.

**Fig 20.77—The feed arrangement for operating the loop as a vertical antenna.**

### **A Simple Gain Antenna for 28 MHz**

With the large number of operators and wide availability of inexpensive, single-band radios, the 10-m band could well become the hangout for local ragchewers that it was before the advent of 2-m FM, even at a low point in the solar cycle.

This simple antenna provides gain over a dipole or inverted V. It is a resonant loop with a particular shape. It provides 2.1 dB gain over a dipole at low radiation angles when mounted well above ground. The antenna is simple to feed—no matching network is necessary. When fed with 50- $\Omega$  coax, the SWR is close to 1:1 at the design frequency, and is less than 2:1 from 28.0-28.8 MHz for an antenna resonant at 28.4 MHz.

The antenna is made from #12 AWG wire (see Fig A) and is fed at the center of the bottom wire. Coil the coax into a few turns near the feedpoint to provide a simple balun. A coil diameter of about a foot will work fine. You can support the antenna on a mast with spreaders made of bamboo, fiberglass, wood, PVC or other nonconducting material. You can also use aluminum tubing both for support and conductors, but you'll have to readjust the antenna dimensions for resonance.

This rectangular loop has two advantages over a resonant square loop. First, a square loop has just 1.1 dB gain over a dipole. This is a power increase of only 29%. Second, the input impedance of a square loop is about 125  $\Omega$ . You must use a matching network to feed a square loop with 50- $\Omega$  coax. The rectangular loop achieves gain by compressing its radiation pattern in the elevation plane. The azimuth plane pattern is slightly wider than that of a dipole (it's about the same as that of an inverted V). A broad pattern is an advantage for a general-purpose, fixed antenna. The rectangular loop provides a bidirectional gain over a broad azimuth region.

Mount the loop as high as possible. To provide 1.7 dB gain at low angles over an inverted V, the top wire must be at least 30 ft high. The loop will work at lower heights, but its gain advantage disappears. For example, at 20 ft the loop provides the same gain at low angles as an inverted V.

**Fig A—Construction details of the 10-m rectangular loop antenna.**

## A SMALL LOOP FOR 160 M

**Fig 20.78—Relative comparisons of small loop elevation-plane radiation patterns to those of dipoles and verticals. At A, a vertical; B, a dipole; C, loop over radials; D, loop over short radials; E, loop over ground (no radials). In B, the inner pattern is that in the plane perpendicular to the antenna axis. In C through E, the inner patterns are those in the plane perpendicular to the antenna axis.**

**Fig 20.79—Electrically small loop antenna azimuth-plane radiation patterns at several wave angles.**

For amateurs with limited space, a small loop antenna is ideal for 160 m. Because small loops have high Q, they exhibit very narrow bandwidth, suppress harmonics and give a significant receiving noise reduction compared to dipoles. This project by Charles J. Mozzochi, W1LYQ, appeared in the June 1993 issue of *QST*. More information on theory and design considerations can be found in *The ARRL Antenna Book*.

Mozzochi found that for distances of 700 to 1000 miles, his loop performed the same as a full-size inverted-V antenna (62 ft high at the midpoint and fed with open-wire transmission line). Contacts with Europe report signals from the loop essentially the same as that from the inverted V. However, some report signals from the loop slightly stronger than from the inverted V. Both antennas are oriented to favor Europe. Also, the inverted V is more than 90% efficient, whereas the loop's efficiency is close to 50% ( $\approx 3$  dB)

### Radiation Pattern

**Fig 20.78** compares the vertical radiation patterns of the loop with those of a vertical and a dipole. The inner-pattern axis is perpendicular to that of the outer patterns. Note that the loop performs better at low angles, making it a good DX antenna. **Fig 20.79** compares horizontal patterns at four elevation angles.

### Physical Description

**Fig 20.80** shows the antenna schematically and **Fig 20.81** shows the base section of the antenna. The outer loop is made in the form of a hexagon with eight 10-ft sections of 1-inch copper pipe joined with 45° couplers. The inner loop is a circle, 15 ft, 6 inches in circumference, made from  $\frac{5}{8}$ -inch copper pipe. Choose values

**Fig 20.80—Schematic of the loop antenna.**

and ratings for C1, C2 and C3 as discussed later.

The antenna is mounted vertically, approximately a foot off the ground, although it would be wise to mount it higher or install a protective wooden fence around the antenna to keep away people or pets. Very high voltages occur on small transmitting loops! Mozzochi installed 12 radials,  $\frac{1}{4}\lambda$  long, under the loop. These radials are joined under the loop, but are not electrically connected to it. The radials act as a reflective screen to help reduce ground loss. The use of radials is not absolutely necessary, but they can help reduce losses.

### Construction

Because the outer loop's radiation resistance is on the order of  $0.1\ \Omega$ , every effort must be made to minimize losses. Antenna efficiency increases with the diameter of the pipe used in both loops. One-inch copper pipe is used as a compromise in the outer loop; larger pipe would provide better efficiency, but would weigh considerably more. Mozzochi supports the outer loop with nylon rope strung between two trees. Smaller nylon ropes guy the lower section between trees and a fence. The inner loop is hung from the top of the outer loop with nylon rope, and nylon rope is used to guy and position the inner loop.

Solder all of the loop joints with rosin-core tin/lead or tin/lead/silver solder. Do not use acid-core solder.

### Capacitors

C1 is a 200-pF vacuum-variable unit. A split-stator capacitor would work in place of a vacuum variable; however, under no circumstances should a conventional variable capacitor be used at C1 because the loss in the wiper contacts is significant compared to the outer loop's radiation resistance. C2 is composed of ten 100-pF "doorknob" capacitors connected in parallel via copper straps, and C3 is a single 740-pF doorknob.

The outer loop radiates and the inner loop functions as a low loss matching and coupling device. This antenna puts very high voltages across C1 and C2 and passes unusually high currents through them. The formulas in Table 20.18 give approximate currents and voltages for C1, C2 and C3, where P is the applied power, in watts.

The formulas in Table 20.18 are based on a steady-state analysis, under the as-

**Fig 20.81—Feed-point detail of the W1LYQ loop. C1, a vacuum variable, is secured to the top of a wooden box. C2 is made of ten "doorknob" capacitors in parallel, and C3 is one large doorknob. The loops are tied off to nearby objects for support.**

sumption that the radiation resistance and the loss resistance in the outer loop are each  $0.1\ \Omega$ . These resistances can differ significantly from this value depending on how the loop is constructed and located. Furthermore, substantial transient currents and voltages can occur under certain situations. It is wise to incorporate a safety factor of two to three after calculating the capacitor voltages and currents from these equations.

### Tuning and Matching

To adjust the antenna to resonance at 1.85 MHz, follow this procedure:

- 1) Place the inner loop in either lower corner area of the outer loop, but *not touching it*, in a plane parallel to the outer loop and approximately 20 inches from the outer loop.

- 2) Set the transmitter to 1.85 MHz.

- 3) Adjust C1 for minimum SWR.

By making minor adjustments in the loop position and C1's setting, you should easily get the SWR down to 1:1. Once a 1:1 SWR is achieved at 1.85 MHz, you need only adjust C1 for other frequencies between 1.8 and 2 MHz. The achievable SWR will be 1:1 from 1.8 to 1.85 MHz, and beginning at 1.85 MHz the SWR will climb slowly but steadily to 2:1 at 2 MHz. Changing frequency by more than 2 to 3 kHz requires readjusting C1 for minimum SWR. Keep in mind that a change of 1 pF in C1 makes a change of 3 to 5 kHz in

**Table 20.18**

### Calculating Capacitor Ratings

$$V_{C1} = 1800 \sqrt{P}$$

$$V_{C2} = 18 \sqrt{P}$$

$$V_{C3} = 17 \sqrt{P}$$

$$I_{C1} = 2.2 \sqrt{P}$$

$$I_{C2} = 0.21 \sqrt{P}$$

$$I_{C3} = 0.15 \sqrt{P}$$

Example: if  $P = 100$  watts, then  $V_{C1} = 18,000$ ;  $V_{C2} = 180$ ;  $V_{C3} = 170$ ;  $I_{C1} = 22$  A;  $I_{C2} = 2.1$  A; and  $I_{C3} = 1.5$  A.

the antenna's resonant frequency. Be sure that you use a motor drive with sufficient gear reduction.

For optimum performance, C1 should be mounted at the top of the loop. Also, it is possible to eliminate C2 and C3 by a suitable choice of the size and position of the inner loop. Consider this if you're planning to use high power with the loop.

### Warning

Operating a loop antenna indoors or close to dwellings can raise the risk of interference to consumer devices and ham gear. Also, it's prudent to minimize RF exposure to people who may be near the antenna by using the minimum necessary transmitter power to carry on the desired communications. Whenever possible, mount your antennas as far as possible from people and dwellings.

# HF Mobile Antennas

The antenna is perhaps the most important item in a successful mobile installation. Mobile antennas, whether designed for single or multiband use, should be securely mounted to the automobile, as far from the engine compartment as possible (for reducing noise pickup) and carefully matched to the coaxial feed line connecting them to the transmitter and receiver. All antenna connections should be tight and weatherproof. Mobile loading coils should be protected from dirt, rain and snow if they are to maintain their Q and resonant frequency. A higher-Q loading coil will result in better efficiency, at the expense of a narrower operating bandwidth.

Although bumper-mounted mobile antennas are favored by some, it is better to place the antenna mount on the rear deck of the vehicle, near the rear window. This locates the antenna high and in the clear, assuring less detuning of the system when the antenna moves to and from the car body.

The choice of base- or center-loading a mobile antenna has been a matter of controversy for many years. In theory, the center-loaded whip presents a slightly higher base impedance than does the base-loaded antenna. However, with proper impedance-matching techniques employed there is little or no discernible difference in performance between the two methods. A base-loading coil requires fewer turns of wire than one for center loading, and this is an electrical advantage because of

reduced coil losses. A base-loaded antenna is more stable during wind loading and sway. If a homemade antenna system is contemplated, either system will provide good results, but the base-loaded antenna may be preferred for its mechanical advantages (see Table 20.19).

## Loading Coils

There are many commercially built antenna systems available for mobile operation, and some manufacturers sell the coils as separate units. Air-wound coils of large wire diameter are excellent for use as loading inductors. Large Miniductor coils can be installed on a solid phenolic rod and used as loading coils. Miniductors, because of their turns spacing, are easy to adjust when resonating the mobile antenna and provide excellent Q. Phenolic-impregnated paper or fabric tubing of large diameter is suitable for making homemade loading coils. It should be coated with liquid fiberglass, inside and out, to make it weatherproof. Brass insert plugs can be installed in each end, their centers drilled and tapped for a standard  $\frac{3}{8} \times 24$  thread to accommodate the mobile antenna sections. After the coil winding is pruned to resonance (Table 20.20) it should be coated with a high quality, low-loss compound to hold the turns securely in place and to protect the coil from the weather. Liquid polystyrene is excellent for this. Hobby stores commonly stock this material for use as a protective film for wall plaques and other artwork. Details for

making a home-built loading coil are given in Fig 20.82.

## Impedance Matching

Fig 20.83 illustrates the shunt-fed method of obtaining a match between the antenna and the coaxial feed line. For operation on 75 m with a center-loaded whip, L2 will have approximately 18 turns of #14 wire, spaced one wire thickness between turns, and wound on a 1-inch-diameter form. Initially, the tap will be approximately five turns above the ground end of L2. Coil L2 can be inside the car body, at the base of the antenna, or it can be located at the base of the whip, outside the car body. The latter method is preferred.

Since L2 helps determine the resonance of the overall antenna, L1 should be tuned to resonance in the desired part of the band with L2 in the circuit. The adjustable top section of the whip can be telescoped until a maximum reading is noted on the field-strength meter. The tap is then adjusted on L2 for the lowest reflected-power reading on the SWR bridge. Repeat these two adjustments until no further increase in field strength can be obtained; this point should coincide with the lowest SWR. The number of turns needed for L2 will have to be determined experimentally for 40 and 20-m operation. There will be proportionately fewer turns required.

## Matching with an L Network

Any resonant mobile antenna that has a feed-point impedance less than the characteristic impedance of the transmission line can be matched to the line by means of a simple L network, as shown in Fig 20.84. The network is composed of  $C_M$  and  $L_M$ .

**Table 20.19**  
**Approximate Values for 8-Foot Mobile Whip**

### Base Loading

f(kHz)	Loading L( $\mu$ H)	RC(Q50) $\Omega$	RC(Q300) $\Omega$	RR $\Omega$	Feed R* $\Omega$	Matching L( $\mu$ H)
1800	345	77	13	0.1	23	3
3800	77	37	6.1	0.35	16	1.2
7200	20	18	3	1.35	15	0.6
14,200	4.5	7.7	1.3	5.7	12	0.28
21,250	1.25	3.4	0.5	14.8	16	0.28
29,000	—	—	—	—	36	0.23

### Center Loading

f(kHz)	Loading L( $\mu$ H)	RC(Q50) $\Omega$	RC(Q300) $\Omega$	RR $\Omega$	Feed R* $\Omega$	Matching L( $\mu$ H)
1800	700	158	23	0.2	34	3.7
3800	150	72	12	0.8	22	1.4
7200	40	36	6	3.0	19	0.7
14,200	8.6	15	2.5	11.0	19	0.35
21,250	2.5	6.6	1.1	27.0	29	0.29

RC = Loading-coil resistance; RR = radiation resistance.

\*Assuming loading coil Q = 300, and including estimated ground-loss resistance.

Suggested coil dimensions for the required loading inductance are shown in a following table.

**Table 20.20**  
**Suggested Loading-Coil Dimensions**

Required L ( $\mu$ H)	No. Turns	Wire Size	Diam Inches	Length Inches
700	190	22	3	10
345	135	18	3	10
150	100	16	2 $\frac{1}{2}$	10
77	75	14	2 $\frac{1}{2}$	10
77	29	12	5	4 $\frac{1}{4}$
40	28	16	2 $\frac{1}{2}$	2
40	34	12	2 $\frac{1}{2}$	4 $\frac{1}{4}$
20	17	16	2 $\frac{1}{2}$	1 $\frac{1}{4}$
20	22	12	2 $\frac{1}{2}$	2 $\frac{3}{4}$
8.6	16	14	2	2
8.6	15	12	2 $\frac{1}{2}$	3
4.5	10	14	2	1 $\frac{1}{4}$
4.5	12	12	2 $\frac{1}{2}$	4
2.5	8	12	2	2
2.5	8	6	2 $\frac{3}{8}$	4 $\frac{1}{2}$
1.25	6	12	1 $\frac{3}{4}$	2
1.25	6	6	2 $\frac{3}{8}$	4 $\frac{1}{2}$

**Fig 20.82**—Details for making a home-built mobile loading coil. A breakdown view of the assembly is given at A. Brass end plugs are snug-fit into the ends of the phenolic tubing, and each is held in place by four #6-32 brass screws. Center holes in the plugs are drilled and tapped for  $\frac{3}{8} \times 24$  thread. The tubing can be any diameter from 1 to 4 inches. Larger diameters are recommended. Illustration B shows the completed coil. Resonance can be obtained by installing the coil, applying transmitter power, then pruning the turns until the lowest SWR is obtained. Pruning the coil for maximum field-strength-meter indication will also serve as a resonance indication.

The required values of  $C_M$  and  $L_M$  may be determined from

$$C_M = \frac{\sqrt{R_A(Z_0 - R_A)}}{2\pi f \text{ (kHz)}} \times 10^9 \text{ pF} \quad (9)$$

and

$$L_M = \frac{\sqrt{R_A(Z_0 - R_A)}}{2\pi f \text{ (kHz)}} \times 10^3 \text{ } \mu\text{H} \quad (10)$$

where

$R_A$  = the antenna feed-point resistance  
 $Z_0$  = the characteristic impedance of the transmission line.

**Fig 20.83**—A mobile antenna using shunt-feed matching. Overall antenna resonance is determined by the combination of  $L_1$  and  $L_2$ . Antenna resonance is set by pruning the turns of  $L_1$ , or adjusting the top section of the whip, while observing the field-strength meter or SWR indicator. Then, adjust the tap on  $L_2$  for minimum SWR.

As an example, if the feed-point resistance is 20  $\Omega$  and the line is 50- $\Omega$  coaxial cable, then at 4000 kHz,

$$\begin{aligned} C_M &= \frac{\sqrt{20(50 - 20)}}{(6.28)(4000)(20)(50)} \times 10^9 \\ &= \frac{\sqrt{600}}{(6.28)(4)(2)(5)} \times 10^4 \\ &= \frac{24.5}{251.2} \times 10^4 = 975 \text{ pF} \end{aligned}$$

$$\begin{aligned} L_M &= \frac{\sqrt{20(50 - 20)}}{(6.28)(4000)} \times 10^3 \\ &= \frac{\sqrt{600}}{25.12} = \frac{24.5}{25.12} = 9.97 \text{ } \mu\text{H} \end{aligned}$$

The chart of **Fig 20.85** shows the capacitive reactance of  $C_M$  and the inductive reactance of  $L_M$  necessary to match various antenna impedances to 50- $\Omega$  coaxial cable. The chart assumes the antenna element has been resonated. In practice,  $L_M$

**Fig 20.84**—A whip antenna may also be matched to coax line by means of an L network. The inductive reactance of the L network can be combined in the loading coil, as indicated at the right.

**Fig 20.85**—Curves showing inductive and capacitive reactances required to match a 50- $\Omega$  coax line to a variety of antenna resistances.

need not be a separate inductor. Its effect can be duplicated by adding an equivalent amount of inductance to the loading coil, regardless of whether the loading coil is at the base or at the center of the antenna.

## Adjustment

In adjusting this system, at least part of  $C_M$  should be variable, the balance being made up of combinations of fixed mica capacitors in parallel as needed. A small, one-turn loop should be connected between  $C_M$  and the chassis of the car, and the loading coil should then be adjusted for resonance at the desired frequency as indicated by a dip meter coupled to the loop at the base. Then the transmission line should be connected, and a check made with an SWR indicator connected at the transmitter end of the line.

With the line disconnected from the antenna again,  $C_M$  should be readjusted and the antenna returned to resonance by readjustment of the loading coil. The line should be connected again, and another check made with the SWR bridge. If the SWR is less than it was on the first trial,  $C_M$  should be readjusted in the same direction until the point of minimum SWR is found.

Fig 20.85 shows that the inductive reactance varies only slightly over the range of antenna resistances likely to be encountered in mobile work. Therefore, most of the necessary adjustment is in the capacitor. The one-turn loop at the base should be removed at the conclusion of the adjustment and slight compensation made at the loading coil to maintain resonance.

For manufactured loading coils that have no means for either adjusting or tapping into the inductance, here is a simple L-network matching method that requires no series inductor, and needs only a measurement of SWR to determine the value of the shunt matching capacitor  $C_M$ . By extending the whip slightly beyond its

natural resonant length, the series inductance required for the L network appears in the feed-point impedance. At the correct length, the resulting parallel reactance component,  $X_L$ , causes the parallel resistance component,  $R_A$  to equal the feed line characteristic impedance,  $Z_0$  ohms. The match is accomplished by canceling the parallel inductive reactance component,  $X_L$ , with shunt capacitor  $C_M$ , of equal but opposite reactance.

To perform the matching operation, first resonate the antenna at the desired frequency by adjusting the whip length for minimum SWR without the capacitor. The approximate value of  $X_L$  with the whip lengthened to make  $R_A$  equal to  $Z_0$ , may now be found from

$$X_L = Z_0 \times \frac{\sqrt{\text{SWR}}}{\text{SWR} - 1} \quad (11)$$

where SWR is that obtained at resonance. The reactance,  $X_C$ , of the shunt matching capacitor  $C_M$  is the negative of  $X_L$ . The capacitance of  $C_M$  may be determined for the desired frequency,  $f$ , in MHz from

$$C_M = 1 \times 10^6 / 2\pi f X_C \text{ pF} \quad (12)$$

Form a capacitor,  $C_M$ , from a combination of fixed-mica capacitors in parallel, as needed, and connect the combination across the antenna input terminals as shown in Fig 20.84. Finally, increase the whip length in small increments until the minimum SWR is reached—it should be very low.

If a lower SWR is desired, a trimmer capacitor may be added to  $C_M$ , and by alternate adjustment of trimmer and whip length, a perfect 1:1 match can be obtained. Once  $C_M$  has been established for a given band, the antenna can then be matched at other frequencies in the band by simply adjusting the whip length for minimum SWR. If an inductive rather than a capacitive shunt element is preferred, replace the capacitor with an inductor having the same absolute value of reactance, and shorten the whip instead of lengthening it from the natural resonant length.

## Top-Loading Capacitance

Because the coil resistance varies with the inductance of the loading coil, the resistance can be reduced, beneficially, by reducing the number of turns on the coil. This can be done by adding capacitance to that portion of the mobile antenna that is *above* the loading coil (Fig 20.86). To achieve resonance, the inductance of the coil is reduced proportionally. Capacitive hats can consist of a single stiff wire, two wires or more, or a disc made up from several wires like the spokes of a wheel. A solid metal disc can also be used. The

larger the capacitive hat, in terms of surface area, the greater the capacitance. The greater the capacitance, the smaller the amount of inductance needed in the loading coil for a given resonant frequency.

There are two schools of thought concerning the attributes of center-loading and base-loading. It has not been definitively established that one system is superior to the other, especially in the lower part of the HF spectrum. For this reason both base and center-loading schemes are popular. Capacitive-hat loading is applicable to either system. Since more inductance is required for center-loaded whips to make them resonant at a given frequency, capacitive hats should be particularly useful in improving their efficiency.

The capacitance that is increased by the hat is the total antenna-to-ground and vehicle capacitance, which provides the path for the antenna currents to return to the generator or transmitter. To obtain optimum effectiveness, the hat should be placed at the top of the whip, which may require special mechanical considerations to keep the whip upright with wind loading. If the hat is large enough to be effective, only a negligible increase in capacitance will result from extending the whip above the hat.

It is important to realize that with center-loaded whips, the hat actually becomes more detrimental than helpful if placed directly above the loading coil. This incorrect placement causes an undesirable increase in hat-to-coil capacitance, which adds to the distributed capacitance of the coil, lowering the Q and increasing the coil resistance—just the opposite of the hat's intended purpose. Although often seen in this position, it is usually because of the mistaken notion that increased radiation results from the lower resonant SWR obtained by this incorrect placement. Such a placement does reduce feed-line load mismatch and SWR at resonance, but for the wrong reason. The total antenna-circuit load resistance is increased, bringing it closer to the 50- $\Omega$  impedance of the feed line. However, since this increase in load resistance is from the increased coil resistance, and not from an increase in radiation resistance, reducing the SWR in this manner increases the loss instead of the radiation.

It is also for this reason that loading coils of the highest Q should be favored over the coils of lower Q. The rule to follow then, is that, since the coil with the highest Q has the lowest loss resistance, the coil that yields the highest SWR at resonance (without any matching circuitry) will produce the greatest radiation.

**Fig 20.86—A capacitive hat can be used to improve the performance of base- or center-loaded whips. A solid metal disc can be used in place of the skeletal disc shown here.**

# VHF/UHF Antennas

## INTRODUCTION

Improving an antenna system is one of the most productive moves open to the VHF enthusiast. It can increase transmitting range, improve reception, reduce interference problems and bring other practical benefits. The work itself is by no means the least attractive part of the job. Even with high-gain antennas, experimentation is greatly simplified at VHF and UHF because an array is a workable size, and much can be learned about the nature and adjustment of antennas. No large investment in test equipment is necessary.

Whether we buy or build our antennas, we soon find that there is no one "best" design for all purposes. Selecting the antenna best suited to our needs involves much more than scanning gain figures and prices in a manufacturer's catalog. The first step should be to establish priorities.

## Gain

As has been discussed previously, shaping the pattern of an antenna to concentrate radiated energy, or received signal pickup, in some directions at the expense of others is the only possible way to develop gain. Radiation patterns can be controlled in various ways. One is to use two or more driven elements, fed in phase. Such arrays provide gain without markedly sharpening the frequency response, compared to that of a single element. More gain per element, but with some sacrifice in frequency coverage, is obtained by placing parasitic elements into a Yagi array.

## Radiation Pattern

Antenna radiation can be made omnidirectional, bidirectional, practically unidirectional, or anything between these conditions. A VHF net operator may find an omnidirectional system almost a necessity but it may be a poor choice otherwise. Noise pickup and other interference problems tend to be greater with omnidirectional antennas. Maximum gain and low radiation angle are usually prime interests of the weak-signal DX aspirant. A clean pattern, with lowest possible pickup and radiation off the sides and back, may be important in high-activity areas, where the noise level is high, or when challenging modes like EME (Earth-Moon-Earth) are employed.

## Height Gain

In general, the higher a VHF antenna is installed, the better will be the results.

If raising the antenna clears its view over nearby obstructions, it may make dramatic improvements in coverage. Within reason, greater height is almost always worth its cost, but height gain must be balanced against increased transmission-line loss. Line losses can be considerable at VHF, and they increase with frequency. The best available line may be none too good, if the run is long in terms of wavelength. Consider line losses in any antenna planning.

## Physical Size

A given antenna design for 432 MHz, say a 5-element Yagi on a 1- $\lambda$  boom, will have the same gain as one for 144 MHz, but being only one-third the size it will intercept only one-ninth as much energy in receiving. Thus, to be equal in communication effectiveness, the 432-MHz array should be at least equal in physical size to the 144-MHz one, requiring roughly three times the number of elements. With all the extra difficulties involved in going higher in frequency, it is well to be on the big side in building an antenna for the UHF bands.

## DESIGN FACTORS

Having sorted out objectives in a general way, we face decisions on specifics, such as polarization, type of transmission line, matching methods and mechanical design.

## Polarization

Whether to position the antenna elements vertically or horizontally has been a question since early VHF pioneering. Tests show little evidence on which to set up a uniform polarization policy. On long paths there is no consistent advantage, either way. Shorter paths tend to yield higher signal levels with horizontal in some kinds of terrain. Man-made noise, especially ignition interference, tends to be lower with horizontal. Verticals, however, are markedly simpler to use in omnidirectional systems and in mobile work.

Early VHF communication was largely vertical, but horizontal gained favor when directional arrays became widely used. The major trend to FM and repeaters, particularly in the 144-MHz band, has tipped the balance in favor of verticals in mobile work and for repeaters. Horizontal predominates in other communication on 50 MHz and higher frequencies. It is well to check in advance in any new area in which you expect to operate, however, as some localities may use vertical polariza-

tion. A circuit loss of 20 dB or more can be expected with cross-polarization.

## Transmission Lines

There are two main categories of transmission lines used at HF through UHF: balanced and unbalanced. Balanced lines include *open-wire lines* separated by insulating spreaders, and *twin-lead*, in which the wires are embedded in solid or foamed insulation. Unbalanced lines are represented by the family of coaxial cables, commonly called *coax*. Line losses in either types of line result from ohmic resistance, radiation from the line and deficiencies in the insulation.

Large conductors, closely spaced in terms of wavelength, and using a minimum of insulation, make the best balanced lines. Characteristic impedances are between 300 to 500  $\Omega$ . Balanced lines work best in straight runs, but if bends are unavoidable, the angles should be as gentle as possible. Care should also be taken to prevent one wire from coming closer to metal objects than the other.

Properly built open-wire line can operate with very low loss in VHF and even UHF installations. A total line loss under 2 dB per hundred ft at 432 MHz is readily obtained. A line made of #12 wire, spaced  $\frac{3}{4}$  inch or less with Teflon spreaders, and running essentially straight from antenna to station, can be better than anything but the most expensive "Hardline" coax, at a fraction of the cost. This assumes the use of high-quality baluns to match into and out of the balanced line, with a short length of low-loss coax for the rotating section from the top of the tower to the antenna. A similar 144-MHz setup could have a line loss under 1 dB.

Small coax such as RG-58 or RG-59 should never be used in VHF work if the run is more than a few feet. Half-inch lines (RG-8 or RG-11) work fairly well at 50 MHz, and are acceptable for 144-MHz runs of 50 ft or less. If these lines have foam rather than solid insulation they are about 30% better. Aluminum-jacket "Hardline" coaxial cables with large inner conductors and foam insulation are well worth their cost. Hardline can sometimes even be obtained for free from local Cable TV operators as "end runs"—pieces at the end of a roll. The most common CATV variety is  $\frac{1}{2}$ -inch OD 75- $\Omega$  Hardline. Waterproof commercial connectors for Hardline are fairly expensive, but enterprising amateurs have "home-brewed" low-cost connectors. If they are properly waterproofed, connectors and Hardline can last almost indefinitely. Of course, a

disadvantage implied by their name is that Hardline must not be bent too sharply, because it will kink. See *The ARRL Antenna Book* for details on Hardline connectors.

Effects of weather on transmission lines should not be ignored. A well-constructed open-wire line works well in nearly any weather, and it stands up well. TV type twin-lead is almost useless in heavy rain, wet snow or icing. The best grades of coax are impervious to weather. They can be run underground, fastened to metal towers without insulation, or bent into almost any convenient position, with no adverse effects on performance. However, beware of "bargain" coax. Lost transmitter power can be made up to some extent by increasing power, but once lost, a weak signal can

never be recovered in the receiver.

## Impedance Matching

Theory and practice in impedance matching are given in detail in the **Transmission Lines** chapter, and in theory, at least, is the same for frequencies above 50 MHz. Practice may be similar, but physical size can be a major modifying factor in choice of methods.

### Delta Match

Probably the first impedance match was made when the ends of an open line were fanned out and tapped onto a half-wave antenna at the point of most efficient power transfer, as in **Fig 20.87A**. Both the side length and the points of connection

either side of the center of the element must be adjusted for minimum reflected power in the line, but the impedances need not be known. The delta makes no provision for tuning out reactance, so the length of the dipole is pruned for best SWR.

Once thought to be inferior for VHF applications because of its tendency to radiate if adjusted improperly, the delta has come back to favor now that we have good methods for measuring the effects of matching. It is very handy for phasing multiple-bay arrays with low-loss open lines, and its dimensions in this use are not particularly critical.

### Gamma and T Matches

The gamma match is shown in **Fig 20.87C**, and the T match is shown in **Fig 20.87D**. These matches are covered in more detail in the chapter on **Transmission Lines**. There being no RF voltage at the center of a half-wave dipole, the outer conductor of the coax is connected to the element at this point, which may also be the junction with a metallic or wooden boom. The inner conductor, carrying the RF current, is tapped out on the element at the matching point. Inductance of the arm is canceled by means of C1. Both the point of contact with the element and the setting of the capacitor are adjusted for zero reflected power, with a bridge connected in the coaxial line.

The capacitor can be made variable temporarily, then replaced with a suitable fixed unit when the required capacitance value is found, or C1 can be mounted in a waterproof box. Maximum capacitance should be about 100 pF for 50 MHz and 35 to 50 pF for 144 MHz. The capacitor and arm can be combined with the arm connecting to the driven element by means of a sliding clamp, and the inner end of the arm sliding inside a sleeve connected to the inner conductor of the coax. It can be constructed from concentric pieces of tubing, insulated by plastic sleeving or shrink tubing. RF voltage across the capacitor is low, once the match is adjusted properly, so with a good dielectric, insulation presents no great problem, if the initial adjustment is made with low power. A clean, permanent, high-conductivity bond between arm and element is important, as the RF current is high at this point.

Because it is inherently somewhat unbalanced, the gamma match can sometimes introduce pattern distortion, particularly on long-boom, highly directive Yagi arrays. The T-match, essentially two gamma matches in series creating a balanced feed system, has become popular for this reason. A coaxial balun like that shown in **Fig 20.87B** is used from the bal-

**Fig 20.87—Matching methods commonly used in VHF antennas.** In the delta match, A and B, the line is fanned out to tap on the dipole at the point of best impedance match. The gamma match, C, is for direct connection of coax. C1 tunes out inductance in the arm. Folded dipole of uniform conductor size, D, steps up antenna impedance by a factor of four. Using a larger conductor in the unbroken portion of the folded dipole, E, gives higher orders of impedance transformation.

anced T-match to the unbalanced coaxial line going to the transmitter. See K1FO's Yagi designs later in this chapter for details.

### Folded Dipole

The impedance of a half-wave antenna broken at its center is  $72\ \Omega$ . If a single conductor of uniform size is folded to make a half-wave dipole, as shown in Fig 20.87D, the impedance is stepped up four times. Such a folded dipole can thus be fed directly with  $300\text{-}\Omega$  line with no appreciable mismatch. Coaxial line of 70 to  $75\ \Omega$  impedance may also be used if a 4:1 balun is added. Higher impedance step-up can be obtained if the unbroken portion is made larger in cross-section than the fed portion, as in Fig 20.87E.

### Baluns

Conversion from balanced loads to unbalanced lines, or vice versa, can be performed with electrical circuits, or their equivalents made of coaxial line. A balun made from flexible coax is shown in Fig 20.88A. The looped portion is an electrical half-wave. The physical length depends on the propagation factor of the line used, so it is well to check its resonant frequency, as shown at B. The two ends are shorted, and the loop at one end is coupled to a dip-meter coil. This type of balun gives an impedance step-up of 4:1, 50 to  $200\ \Omega$ , or 75 to  $300\ \Omega$  typically.

Coaxial baluns giving a 1:1 impedance transfer are shown in Fig 20.89. The coaxial sleeve, open at the top and connected to the outer conductor of the line at the lower end (A) is the preferred type. A conductor of approximately the same size as the line is used with the outer conductor to form a quarter-wave stub, in B. Another piece of coax, using only the outer conductor, will serve this purpose. Both baluns are intended to present an infinite impedance to any RF current that might otherwise tend to flow on the outer conductor of the coax.

### Stacking Yagis

Where suitable provision can be made for supporting them, two Yagis mounted one above the other and fed in phase may be preferable to one long Yagi having the same theoretical or measured gain. The pair will require a much smaller turning space for the same gain, and their lower radiation angle can provide interesting results. On long ionospheric paths a stacked pair occasionally may show an apparent gain much greater than the 2 to 3 dB that can be measured locally as the gain from stacking.

Optimum spacing for Yagis with booms

**Fig 20.88**—Conversion from unbalanced coax to a balanced load can be done with a half-wave coaxial balun. A. Electrical length of the looped section should be checked with a dip meter, with ends shorted. B. The half-wave balun gives a 4:1 impedance step up.

**Fig 20.89**—The balun conversion function, with no impedance change is accomplished with quarter-wave lines, open at the top and connected to the coax outer conductor at the bottom. The coaxial sleeve, A, is preferred.

longer than  $1\ \lambda$  is one wavelength, but this may be too much for many builders of 50-MHz antennas to handle. Worthwhile results are possible with as little as  $\frac{1}{2}\ \lambda$  (10 ft), but  $\frac{3}{8}\ \lambda$  (12 ft) is markedly better. The difference between 12 and 20 ft may not be worth the added structural problems involved in the wider spacing, at 50 MHz at least.

The closer spacings give lowered measured gain, but the antenna patterns are cleaner (less power in the high-angle elevation lobes) than with one-wavelength spacing. Extra gain with wider spacings is usually the objective on 144 MHz and higher bands, where the structural problems are not quite as severe as on 50 MHz.

One method for feeding two 50- $\Omega$  antennas, as might be used in a stacked Yagi array, is shown in Fig 20.90. The transmission lines from each antenna, with a balun feeding each antenna (not shown in the drawing for simplicity), to the common feedpoint must be equal in length and an odd multiple of a quarter wavelength. This line acts as a quarter-wave (Q-sec-

tion) impedance transformer and raises the feed impedance of each antenna to  $100\ \Omega$ . When the coaxes are connected in parallel at the coaxial T fitting, the resulting impedance is close to  $50\ \Omega$ .

### Circular Polarization

Polarization is described as "horizontal" or "vertical," but these terms have no meaning once the reference of the Earth's surface is lost. Many propagation factors can cause polarization change—reflection or refraction and passage through magnetic fields (Faraday rotation), for example. Polarization of VHF waves is often random, so an antenna capable of accepting any polarization is useful. Circular polarization, generated with helical antennas or with crossed elements fed  $90^\circ$  out of phase, will respond to any linear polarization.

The circularly polarized wave in effect threads its way through space, and it can be left- or right-hand polarized. These polarization senses are mutually exclusive, but either will respond to any plane (horizontal or vertical) polarization. A wave generated

**Fig 20.90—A method for feeding a stacked Yagi array.** Note that baluns at each antenna are not specifically shown. Modern-day practice is to use current (“choke”) baluns made up of ferrite beads slipped over the outside of the coax and taped to prevent movement. See Transmission Lines chapter for details.

### Car-Engine Heater Keeps Rotator Lubricant Flowing

◊ My antenna rotator manual says that the rotator’s lubricant should flow at temperatures below  $-20^{\circ}\text{F}$ , but during a  $-28^{\circ}$  spell last winter, nothing moved. I attached a magnetically mounted car engine heater to the bottom of the rotator mounting plate, warmed up the rotator, and got it moving again.  
—Richard Mollentine, WA0KKC, Overland Park, Kansas

with right-hand polarization, when reflected from the moon, comes back with left-hand polarization, a fact to be borne in mind in setting up EME circuits. Stations communicating on direct paths should have the same polarization sense.

Both senses can be generated with crossed dipoles, with the aid of a switchable phasing harness. With helical arrays, both senses are provided with two antennas wound in opposite directions.

### Hardwood Dowels Strengthen Antenna Elements

◊ There is a very simple and inexpensive way to strengthen your beam antenna prior to hoisting it to the top of the tower. Most well-stocked hardware stores stock assorted sizes of hardwood dowel. Select dowels that can be snugly inserted inside the boom and elements and placed where they are attached to each other. Carefully redrill any holes blocked by the dowels and assemble the beam as instructed. You will then have a more solid attachment point and can really tighten the U-bolts and fittings without fear of deforming the tubing. Lightweight beams can be strengthened by inserting the dowel in the entire length of the boom. This method can be used to straighten elements that have been damaged. These dowels add very little weight to the antenna. I have done this for over 25 years and am completely satisfied with the results.—H. A. “Tony” Miller, W5BWA, Alexandria, Louisiana

### A QUICK ANTENNA FOR 223 MHz

◊ Here is a functional antenna for 223 MHz that you can make in less than an hour (Fig A). To build it, you’ll need 9 feet of #10 copper wire, 6 inches of small-diameter copper tubing, and a 10-foot length of PVC pipe or some other physical support.

Bend the antenna from one piece of wire. Slide the copper tubing over the top end of the antenna, and adjust how far it extends beyond the wire to get the lowest SWR. (Don’t handle the antenna while transmitting—make adjustments only while receiving.) For more precision, you can move the coaxial feed line’s taps on the antenna’s matching stub (the 12-inch section at the bottom) about an eighth of an inch at a time. My antenna shows an SWR of 1.2 at 223 MHz.—William Bruce Cameron, WA4UZM, Temple Terrace, Florida

**Fig A—WA4UZM’s quick 223-MHz antenna gets you going on  $1\frac{1}{4}$  meters in a hurry.** (The text explains how to adjust it for minimum SWR.) To support the antenna, lash it to a piece of PVC pipe with nylon cable ties.

## ON-GLASS MULTIBAND ANTENNA

With every new car purchase comes the agonizing decision of where to punch the hole for a VHF antenna. With the advent of the dual-band transceiver, the problem has become where to punch two holes. Most of us would rather punch no holes at all!

This on-glass antenna was described in March 1993 *QST* by Robin Rumbolt, WA4TEM. Such antennas couple RF through the windshield glass without the need to drill holes for cables and mounting hardware. This model not only features the ability to disconnect the radiating element quickly (for car washes, and so on), it has multiband capability, too.

### Construction

Rumbolt built the base of the antenna out of heatsink material (see Fig 20.91). He used a piece of bare aluminum heat-sink stock with long, straight fins. Each fin was spaced about  $\frac{1}{4}$  inch apart. You may find similar heat-sink material at your local hamfest flea market. It's cheap and relatively easy to machine. You can also use aluminum channel stock, which is available from a variety of sources.

The first step is to cut out a piece roughly  $1\frac{5}{8}$ -inches square and remove all but the two middle fins. Trim the fins to  $\frac{1}{2}$  inch in height. Round the corners and drill  $\frac{9}{64}$ -inch holes in the centers of both fins.

The antenna coupling plate is cut from a piece of sheet steel. Its dimensions equal those of the antenna mount. (Avoid using aluminum for the coupling plate, since it's very difficult to solder.)

The quick-disconnect assembly is made from two hexagonal brass standoffs just wide enough to fit snugly between the fins. One standoff has a hole threaded through its entire length. The other standoff has a threaded stub on one end and a threaded hole in the other. Carefully drill a  $\frac{9}{64}$ -inch hole through the open end of the second standoff. Using a #6-32  $\times \frac{1}{2}$ -inch screw, assemble the standoff to the base as shown (see Fig 20.92). The radiating element is made of  $\frac{3}{32}$ -inch brass welding rod. Cut a #6-32 thread about  $\frac{1}{4}$  inch up one end. This end is screwed tightly onto the first standoff. If you lack the tools to thread the rod yourself, use  $\frac{1}{16}$ -inch welding rod and solder it to the standoff.

The total antenna length depends on the band you wish to use. See Table 20.21 for approximate lengths for various bands. As you can see in Fig 20.92, the finished section screws onto the stub of the base-mounted standoff. A few twists is all it takes to remove it.

The coupling plate and the antenna base are attached to the windshield with double-sided foam tape (Radio Shack 64-2361). One tape strip isn't wide enough to cover the base and the plate, so apply two strips side-by-side. It's a simple matter to cut the strips, peel off the backing and apply the tape to each piece. Any excess is easily trimmed away. The important thing to remember is not to peel the paper backing from the tape until just before you're ready to install the antenna.

### Mounting

As you search for just the right spot to

mount your antenna, bear in mind that you must ground the coaxial cable shield to the car body near the mount. In most cars, the top center of the front or rear windshields is best. Older cars usually have screws to attach the molding in these areas. These screws can often be used for grounding. If you own a newer car without strategically located screws, you'll have to install one yourself. Whichever approach you use, check the screw with your VOM and ensure that it really makes contact with the chassis of your car. Many screws anchor in metal, but the metal isn't always grounded.

Fig 20.91—The antenna base is fabricated from a piece of heat-sink stock. Cut out a  $1\frac{5}{8}$ -inch section and remove all but the two center fins (A and B). Round off the sharp corners of the fins and trim for a  $\frac{1}{2}$ -inch height (C). Drill a  $\frac{9}{64}$ -inch hole through the centers of both fins (D). The coupling plate is cut from a  $1\frac{5}{8}$ -inch square section of sheet steel. Tin a small area as shown at E.

**Fig 20.92**—The on-glass antenna is made of brass welding rod attached to two threaded standoffs (see text). Drill a #6-32 hole in the bottom standoff as shown. Using a #6-32  $\times$   $\frac{1}{2}$ -inch screw, nut and lock washer, secure the antenna to the base. The total length of the antenna (L) is measured from the tip of the welding rod to the mounting screw. Use the lengths listed in Table 20.21 and then trim as necessary to obtain a low SWR.

Hold the base to your windshield in the area where you intend to install it. Adjust the antenna until it is vertical, then tighten the nut. Remove the mount and spray paint the entire assembly whatever color looks best with your car.

When the paint is dry, clean the glass thoroughly (inside and outside). Check your chosen antenna location one more time. Is it in the path of windshield wipers? If you open the trunk or hatch, will the antenna be crushed?

If everything looks safe, peel the paper from the foam tape and attach the base to the outside glass. Press firmly to ensure that the tape sticks to the surface. Attach the coupling plate to the inside glass directly opposite the base. Solder the center coax conductor to the coupling plate and connect the coax shield to the ground screw or lug.

#### Tuning

With an accurate SWR/power meter,

**Table 20.21**

#### Antenna Lengths for Various Bands

Frequency (MHz)	Length (in.)
145	23 $\frac{1}{4}$
223	15 $\frac{1}{16}$
444	7 $\frac{17}{32}$
880 (cellular telephone)	11 $\frac{3}{8}$ ( $\frac{3}{4}$ $\lambda$ )
920	11 ( $\frac{3}{4}$ $\lambda$ )
1296	7 $\frac{3}{4}$ ( $\frac{3}{4}$ $\lambda$ )

make SWR measurements and begin pruning the antenna for the lowest SWR. If you can't get the SWR below 3:1, check your coax ground at the antenna. This is usually the culprit.

#### Multibanding

Here's the best part—You can create a dual-band antenna by simply mounting a second antenna and quick-disconnect assembly on the same mounting base (see Fig 20.94).

**Fig 20.93**—Use strong foam tape to hold the base and the coupling plate to the windshield. The coaxial cable center conductor is soldered to the coupling plate. The braid is grounded to the car body via a nearby molding screw. The braid must be grounded at the antenna for proper performance.

**Fig 20.94**—The multiband option. You can mount two antennas in the same base. This is ideal for today's dual-band, VHF/UHF transceivers.

## $\frac{1}{4}\lambda$ ANTENNAS FOR HOME, CAR AND PORTABLE USE

Quarter-wave vertical antennas are useful for local communications when size, cost and ease of construction are important. For theoretical information about quarter-wave vertical antennas see earlier parts of this chapter or *The ARRL Antenna Book*.

### Construction Materials

The antennas shown in the following sections are built on a coaxial connector. Use UHF or N connectors for the fixed station antennas. BNC connectors are good for mobile and portable antennas. BNC and N connectors are better than PL-259 connectors for VHF/UHF outdoor use because: (1) they provide a constant impedance over the frequencies of interest, and (2) they are weatherproof when the appropriate connector or cap is attached. The ground-plane antennas require a

panel-mount connector (it has mounting holes to hold the radials).

If the antenna is sheltered from weather, copper wire is sufficiently rigid for the element and radials. Antennas exposed to the weather should be made from  $\frac{1}{16}$ - to  $\frac{1}{8}$ -inch brass or stainless-steel rod.

Radials may be made from  $\frac{3}{16}$ -inch aluminum rod or tubing and mounted on an aluminum sheet. Do not use aluminum for the antenna element because it cannot be easily soldered to the coaxial-connector center pin.

Where the figures call for #4-40 hardware, stainless steel or brass is best. Use cadmium-plated hardware if stainless steel or brass is not available.

### Fixed-Station Antennas

The ground-plane antenna in Fig 20.95 uses female chassis-mount connectors to

support the element and four radials. If you have chosen large-diameter wire or tubing for the radials refer to Fig 20.96. Cut a metal sheet as shown (size is not critical, and the mounting tab is optional). Drill the sheet to accept the coaxial connector on hand (usually  $\frac{1}{16}$  inch) and the 4-40 hardware for the radials and connector. Bend the plate or radials as shown with the aid of a bench vise. Mount the coaxial connector and radials to the plate.

Small diameter ( $\frac{1}{16}$ -inch) radials may be attached directly to the mounting lugs of the coaxial connector with 4-40 hardware. To install  $\frac{3}{32}$ - or  $\frac{1}{8}$ -inch radials, bend a hook at one end of each radial for insertion through the connector lug. (You may need to enlarge the lug holes slightly for  $\frac{1}{8}$ -inch rod.) Solder the radials (and hardware, if used) to the connector using a large soldering iron or propane torch.

Solder the element to the center pin of the connector. If the element does not fit inside the solder cup, use a short section of brass tubing as a coupler (a slotted  $\frac{1}{8}$ -inch-ID tube will fit over an SO-239 or N-receptacle center pin).

One mounting method for fixed-station antennas appears in Fig 20.95. The method shown is probably the easiest and strongest. Alternatively, a tab (Fig 20.96D) or "L" bracket could be fastened to the side of a mast with a hose clamp. Once the antenna is mounted and tested, thoroughly seal the open side of the coaxial connector with RTV sealant, and weatherproof the connections with rust-preventative paint.

### Mobile Applications

In order to achieve a perfect omnidirectional radiation pattern, mobile vertical antennas should be located in the center of the vehicle roof. Practically speaking however, vertical antennas work well anywhere on a metal auto body (although the radiation pattern may not be omnidirectional). In the interest of RF safety, antennas that are not mounted on the roof should be placed as far from the vehicle occupants as is practical.

The mobile antenna shown here is based on a mating pair of BNC connectors. (You could use similar techniques with N connectors.) If you plan to remove the antenna element, obtain a matching connector cap to protect the open jack from weather. The jack may be mounted directly through the vehicle body if you wish. If you do so, select a body panel with sufficient strength to support the antenna, and be sure that there is adequate access to both sides of the panel for connector and cable installation.

Fig 20.95—A simple groundplane antenna for the 144, 222 and 440-MHz bands. The feed line and connector are inside the mast, and a hose clamp squeezes the slotted mast end to tightly grip the plug body. See Table 20.22 for element and radial measurements

Most homemade VHF and UHF mobile antennas are mounted on an  $\frac{1}{16}$ -inch-thick aluminum L bracket, which is fastened to the side of the hood or trunk opening (see Fig 20.97A and Fig 20.97B). If the opening lip slopes at the antenna location, the lower edge of the L bracket should match that slope. Hold the sheet against the inside of the opening lip, orient the sheet so that its top edge is parallel with the ground, and mark where the opening lip crosses the edges. Connect the marks with a straight line, and cut the sheet on that line.

Drill the sheet as required for the coaxial connector, and bend as indicated.

Mount the coaxial connector, and install the cable. Hold the bracket against the side of the opening, drill and secure it with two #6 or #8 sheet-metal screws and lock washers.

The antenna shown here was made for the 2-m band. The element is about  $19\frac{1}{4}$  inches of  $\frac{1}{8}$ -inch brass rod (from a welding-supply store). Refer to Fig 20.97C and D and follow this procedure to install the element in the male BNC connector:

1) Prepare a special insulator for a 1-inch piece of RG-58 cable by removing all of the jacket and shield. Also remove the center-conductor insulation as shown.

2) File or grind an angle on the end of the brass rod.

3) Place the special insulator against the end of the brass rod and lash them together with fine bare wire.

4) Solder the wire, lashing and BNC center pin in place. (Use a light touch; too much heat causes the insulation to swell and makes it difficult to assemble the connector.)

5) Apply heat-shrink tubing to cover the special insulator and lashing. Place the tubing so that at least  $\frac{1}{8}$  inch of the special insulator remains exposed at the center pin.

**Fig 20.96—Methods of mounting  $\frac{3}{16}$ -inch aluminum-rod radials to a VHF/UHF groundplane antenna. At A and B the radials are made approximately  $1\frac{1}{2}$  inches longer than  $\ell$ , then bent ( $45^\circ$ ) and attached to a flat aluminum sheet. At C and D, the radials are somewhat shorter than  $\ell$ , and the corners of the aluminum sheet are bent to provide the  $45^\circ$  angle. In both cases,  $\ell$  is measured from the radial tip to the element. The size of the aluminum sheet is not critical. The mounting tab shown at D is optional; it could be added to the sheet in A and B if desired.**

Fig 20.97—Details of the mobile vertical mount and BNC center-pin connection. A shows a cross section of a typical vehicle hood opening with the hood closed. B shows the lower edge of the L bracket trimmed to match the slope of the hood (this ensures that the antenna is plumb). C shows the BNC center pin, the special insulator made from RG-58 and the end of the element shaped for connection. At D, the special insulator has been lashed to the element with fine bare wire and the center pin positioned. The center pin and lashing should be soldered, and the area indicated should be covered with heat-shrink tubing to prevent contact with the plug body when it is installed. The brass nut serves as eye protection.

6) Place the element in the connector body and fill the back of the connector with epoxy to support the element. Install the BNC nut before the epoxy sets. (The BNC washer, clamp and gasket are discarded.)

7) Solder a #8 brass nut (or other rounded brass object) to the end of the element to serve as eye protection.

This general procedure can be adapted to all of the element materials recommended and to N connectors as well.

**Better Adhesion for Suction-Cup Mounted Antennas**

◇ I have used a suction-cup-mounted Squalo antenna on my car for over 60,000 miles without the suction cups coming loose—after I put silicone grease on the edge of the suction cups. (Apparently, the grease fills voids in the rubber.) The silicone grease has not damaged my car's finish.—Roger Gibson, K4CLK, Raleigh, North Carolina

## A PORTABLE GROUNDPLANE ANTENNA

This idea (shown in **Fig 20.98**) by ARRL Laboratory Engineer Zack Lau, KH6CP/1, first appeared in July 1991 *QST*. The rubber-ducky antennas common on hand-held VHF and UHF transceivers work fine in many situations. That's no surprise, considering that repeaters generally reside high and in the clear so you and your hand-held don't have to. Sometimes, though, you need a more efficient antenna that is just as portable as a hand-held. Here's one: A simple groundplane antenna you can build—for 146, 223 or 440 MHz—in no time flat. It features wire-end loops for safety (sharp, straight wires are hazardous) and convenience (its top loop lets you hang it off high objects for best performance).

### What You Need to Build One

All you'll need are wire (single conductor, #12 THHN), solder and a female coax jack for the connector series of your choice. Many hardware stores sell THHN wire—that is, thermal-insulation, solid-copper house wire—by the foot. Get 7 ft of wire for a 146-MHz antenna, 5 ft of wire for a 223-MHz antenna, or 3 ft of wire for a 440-MHz antenna. The only tools you need are a 100-W soldering iron or gun; a yardstick, long ruler or tape measure; a pair of wire cutters; a  $\frac{1}{2}$ -inch-diameter form for bending the wire loops (a section of hardwood dowel or metal tubing works fine), and a file (for smoothing rough cut-wire edges and filing the coax jack for soldering). You may also find a sharp knife useful for removing the THHN's insulation.

### Building It

To build a 146-MHz antenna, cut three  $24\frac{5}{8}$ -inch pieces from the wire you

**Fig 20.98**—Three wires and a BNC connector make a portable groundplane antenna that puts a rubber ducky to shame. You can build this groundplane design for 146, 223 or 440 MHz.

bought. To build a 223-MHz antenna, cut three  $17\frac{5}{8}$ -inch pieces. To build a 441-MHz antenna, cut three  $10\frac{5}{8}$ -inch pieces.

The photos show how to build the antenna, but they may not communicate why the cut lengths are somewhat longer than the finished antenna's wires. Here's why: The extra wire allows you to bend and shape the loops by hand. The half-inch diameter loop form helps you form the loops easily.

Form an end loop on each wire as shown in **Fig 20.99A**. Strip exactly 4 inches of insulation from the wire. Using your  $\frac{1}{2}$ -inch diameter form, bend the loop and close it—right up against the wire insulation—with a two-turn twist as shown at the bottom of the example in **Fig 20.99A**. Cut off the excess wire (about  $\frac{1}{2}$  inch). Solder the two-turn twist. Do this for each of the antenna's three wires.

Strip exactly 3 inches of insulation from the unlooped end of one of your wires and follow the steps shown in **Fig 20.99B**. Solder the wire to the connector center conductor. (Soldering the wire to a coaxial

**Fig 20.99A**—Making loops on the antenna wires requires that you remove exactly 4 inches of insulation from each. Stripping THHN insulation is easier if you remove its clear plastic jacket first.

jack's center pin takes considerable heat. A 700 to 750°F iron with a large tip, used in a draft-free room, works best. Don't try to do the job with an iron that draws less than 100 W.) Cut off the extra wire (about  $\frac{1}{2}$  inch).

Strip exactly 3 inches of insulation from the unlooped ends of the remaining two wires. Loop their stripped ends—right up to the insulation—through opposing mounting holes on the connector flange. Solder them to the connector. (You may need to file and tin the connector flange to get it to take solder better.) Cut off the excess wire (about  $2\frac{1}{4}$  inches per wire). This completes construction.

### Adjusting the Antenna for Best Performance

Bend the antenna's two lower wires to form 120° angles with the vertical wire. (No, you don't need a protractor: Just position the wires so they just about trisect a circle.) If you have no means of measuring SWR at your antenna's operating frequency, stop adjustment here and start enjoying your antenna. Any hand-held should produce ample RF output into the

**Fig 20.99B**—Remove exactly 3 inches of insulation to attach the vertical wire to the coax connector center pin. This photo shows an SO-239 (UHF-series) jack; the title photo shows a BNC jack. Use whatever your application requires.

Adjusting the antenna for minimum SWR is worth doing if you have an SWR meter or reflected-power indicator that works at your frequency of interest. Connect the meter in line between your handheld and the antenna. Between short, identified test

As you use this groundplane, keep in

mind that its coax connector's center pin wasn't made to bear weight and may break if stressed too much. Barring that, your groundplane should require no maintenance at all. A BNC male to UHF male adaptor can be used between an SO-239 and an HT BNC output connector.

Rigid copper tubing, fittings and assorted hardware can be used to make a really rugged J-pole antenna for 2 m. When copper tubing is used, the entire assembly can be

soldered together, ensuring electrical integrity, and making the whole antenna weather-proof. This material came from an article by Michael Hood, KD8JB, in *The ARRL An-*

*tenna Compendium, Vol. 4.*

No special hardware or machined parts are used in this antenna, nor are insulating materials needed, since the antenna is al-

ways at dc ground. Best of all, even if the parts aren't on sale, the antenna can be built for less than \$15. If you only build one antenna, you'll have enough tubing left over to make most of a second antenna.

## Construction

Copper and brass is used exclusively in this antenna. These metals get along together, so dissimilar metal corrosion is eliminated. Both metals solder well, too. See **Fig 20.100**. Cut the copper tubing to the lengths indicated. Item 9 is a 1 1/4-inch nipple cut from the 20-inch length of 1/2-inch tubing. This leaves 18 3/4 inches for the  $\lambda/4$ -matching stub. Item 10 is a 3 1/4-inch long nipple cut from the 60-inch length of 3/4-inch tubing. The 3/4-wave element should measure 56 3/4 inches long. Remove burrs from the ends of the tubing after cutting, and clean the mating surfaces with sandpaper, steel wool, or emery cloth.

After cleaning, apply a very thin coat of flux to the mating elements and assemble the tubing, elbow, tee, endcaps and stubs. Solder the assembled parts with a propane torch and rosin-core solder. Wipe off excess solder with a damp cloth, being careful not to burn yourself. The copper tubing will hold heat for a long time after you've finished soldering. After soldering, set the assembly aside to cool.

Flatten one each of the 1/2-inch and 3/4-inch pipe clamps. Drill a hole in the flattened clamp as shown in **Fig 20.100B**. Assemble the clamps and cut off the excess metal from the flattened clamp using

the unmodified clamp as a template. Disassemble the clamps.

Assemble the 1/2-inch clamp around the 1/4-wave element and secure with two of the screws, washers, and nuts as shown in **Fig 20.100B**. Do the same with the 3/4-inch clamp around the 3/4-wave element. Set the clamps initially to a spot about 4 inches above the bottom of the "J" on their respective elements. Tighten the clamps only finger tight, since you'll need to move them when tuning.

## Tuning

The J-Pole can be fed directly from 50  $\Omega$  coax through a choke balun (3 turns of the feed coax rolled into a coil about 8 inches in diameter and held together with electrical tape). Before tuning, mount the antenna vertically, about 5 to 10 ft from the ground. A short TV mast on a tripod works well for this purpose. When tuning VHF antennas, keep in mind that they are sensitive to nearby objects—such as your body. Attach the feed line to the clamps on the antenna, and make sure all the nuts and screws are at least finger tight. It really doesn't matter to which element (3/4-wave element or stub) you attach the coaxial center lead. The author has done it both ways with no variation in performance. Tune the antenna by moving the two feed-point clamps equal distances a small amount each time until the SWR is minimum at the desired frequency. The SWR will be close to 1:1.

## Final Assembly

The final assembly of the antenna will

determine its long-term survivability. Perform the following steps with care. After adjusting the clamps for minimum SWR, mark the clamp positions with a pencil and then remove the feed line and clamps. Apply a very thin coating of flux to the inside of the clamp and the corresponding surface of the antenna element where the clamp attaches. Install the clamps and tighten the clamp screws.

Solder the feed line clamps where they are attached to the antenna elements. Now, apply a small amount of solder around the screw heads and nuts where they contact the clamps. Don't get solder on the screw threads! Clean away excess flux with a non-corrosive solvent.

After final assembly and erecting/mounting the antenna in the desired location, attach the feed line and secure with the remaining washer and nut. Weather-seal this joint with RTV. Otherwise, you may find yourself repairing the feed line after a couple years.

## On-Air Performance

Years ago, prior to building the first J-Pole antenna for this station, the author used a standard 1/4-wave ground plane vertical antenna. While he had no problem working various repeaters around town with a 1/4-wave antenna, simplex operation left a lot to be desired. The J-Pole performs just as well as a Ringo Ranger, and significantly better than the 1/4-wave ground-plane vertical.

# VHF/UHF Yagis

Without doubt, the Yagi is king of home-station antennas these days. Today's best designs are computer optimized. For years amateurs as well as professionals designed Yagi arrays experimentally. Now we have powerful (and inexpensive) personal computers and sophisticated software for antenna modeling. These have brought us antennas with improved performance, with little or no element pruning required.

A more complete discussion of Yagi design can be found earlier in this chapter. For more coverage on this topic and on stacking Yagis, see the most recent edition of *The ARRL Antenna Book*.

## 3 AND 5-ELEMENT YAGIS FOR 6 M

Boom length often proves to be the de-

ciding factor when one selects a Yagi design. ARRL Senior Assistant Technical Editor Dean Straw, N6BV, created the designs shown in **Table 20.23**. Straw generated the designs in the table for convenient boom lengths (6 and 12 ft). The 3-element design has about 8 dBi gain, and the 5-element version has about 10 dBi gain. Both antennas exhibit better than 22 dB front-to-rear ratio, and both cover 50 to 51 MHz with better than 1.6:1 SWR.

Element lengths and spacings are given in the table. Elements can be mounted to the boom as shown in **Fig 20.101**. Two muffler clamps hold each aluminum plate to the boom, and two U bolts fasten each element to the plate, which is 0.25 inches thick and 4x4 inches square. Stainless steel is the best choice for hardware, however, galvanized hardware can be substituted. Automotive muffler clamps do not

work well in this application, because they are not galvanized and quickly rust once exposed to the weather.

The driven element is mounted to the boom on a Bakelite plate of similar dimension to the other mounting plates. A 12-inch piece of Plexiglas rod is inserted into the driven element halves. The Plexiglas allows the use of a single clamp on each side of the element and also seals the center of the elements against moisture. Self-tapping screws are used for electrical connection to the driven element.

Refer to **Fig 20.102** for driven element and Hairpin match details. A bracket made from a piece of aluminum is used to mount the three SO-239 connectors to the driven element plate. A 4:1 transmission-line balun connects the two element halves, transforming the 200- $\Omega$  resistance at the Hairpin match to 50  $\Omega$  at the center connector. Note

**Table 20.23**

**Optimized 6-m Yagi Designs (See page 20.34)**

	Spacing From Reflector (in.)	Seg 1  Length (in.)	Seg 2  Length (in.)	Midband Gain F/R
<b>306-06</b>				
Refl	0	36	22.500	8.1 dBi

Dir 1	36	36	19.375	
Dir 2	80	36	18.250	
Dir 3	138	36	15.375	

Note: For all antennas, telescoping tube diameters (in inches) are: Seg1=0.750, Seg2=0.625. See page 20.34 for element details.

**Fig 20.101—The element-to-boom clamp. Galvanized U bolts are used to hold the element to the plate, and 2-inch galvanized muffler clamps hold the plates to the boom.**

that the electrical length of the balun is  $\lambda/2$ , but the physical length will be shorter due to the velocity factor of the particular coaxial cable used. The Hairpin is connected directly across the element halves. The exact center of the hairpin is electrically neutral and should be fastened to the boom. This has the

advantage of placing the driven element at dc ground potential.

The Hairpin match requires no adjustment as such. However, you may have to change the length of the driven element slightly to obtain the best match in your preferred portion of the band. Changing

the driven-element length will not adversely affect antenna performance. *Do not adjust the lengths or spacings of the other elements—they are optimized already.* If you decide to use a gamma match, add 3 inches to each side of the driven element lengths given in the table for both antennas.

**Fig 20.102—Detailed drawing of the feed system used with the 50-MHz Yagi. Balun lengths: For cable with 0.80 velocity factor—7 ft, 10<sup>3</sup>/<sub>8</sub> in. For cable with 0.66 velocity factor—6 ft, 5<sup>3</sup>/<sub>8</sub> in.**

## A PORTABLE 3-ELEMENT 2-M BEAM

In April 1993 *QST*, Nathan Loucks, WBØCMT, described the 2-m beam shown in Fig 20.103. The boom and mast are made from 3/4-inch PVC plumber's pipe. The three pieces of PVC pipe are held together with a PVC T joint and secured by screws. Elements can be made from brass brazing or hobby rods. (If you can't find a 40-inch rod for the reflector, you can solder wire extensions to obtain the full

length.)

Drill holes that provide a snug fit to the elements approximately 1/4 inch or so from the boom ends. Epoxy the director and reflector in place after centering them in these holes. A pair of holes spaced 1/4 inch and centered 16 inches from the reflector hold the two-piece driven element. The short ends of the element halves should ex-

tend about 1/4 inch through the boom. Solder the 50-Ω feed line to the driven element as shown in Fig 20.104.

Loucks used a pair of 4-inch pieces held in place by #12 or #14 jam screws (electrical connectors) to extend and adjust the driven element to allow for operation in various parts of the 2-m band. You can trim the driven element to length for operation in the desired portion of the band if you prefer.

The figures show the beam assembled for vertical polarization. You may want to turn the boom pieces 90° for horizontal polarization for SSB or CW operation.

Fig 20.103—Construction diagram for the 2-m beam antenna. See text for details.

Fig 20.104—Solder the coaxial cable to the driven element pieces as shown.

## High-Performance VHF/UHF Yagis

This construction information is presented as an introduction to the three high-performance VHF/UHF Yagis that follow. All were designed and built by Steve Powlisken, KIFO.

For years the design of long Yagi antennas seemed to be a mystical black art. The problem of simultaneously optimizing 20 or more element spacings and element lengths presented an almost unsolvable set of simultaneous equations. With the unprecedented increase in computer power and widespread availability of antenna analysis software, we are now able to quickly examine many Yagi designs and determine which approaches work and which designs to avoid.

At 144 MHz and above, most operators desire Yagi antennas two or more wavelengths in length. This length ( $2\lambda$ ) is where most classical designs start to fall apart in terms of gain per boom length, bandwidth and pattern quality. Extensive computer and antenna range analysis has proven that the best possible design is a Yagi that has both varying element spacings and varying element lengths.

This logarithmic-design approach (pioneered by Gunter Hoch, DL6WU, and others) starts with closely spaced directors. The director spacings gradually increase until a constant spacing of about  $0.4\lambda$  is reached. Conversely, the director lengths start out longest with the first director and

decrease in length in a decreasing rate of change until they are virtually constant in length. This method of construction results in a wide gain bandwidth. A bandwidth of 7% of the center frequency at the -1 dB forward-gain points is typical for these Yagis even when they are longer than  $10\lambda$ . The log-taper design also reduces the rate of change in driven-element impedance vs frequency. This allows the use of simple dipole driven elements while still obtaining acceptable driven-element SWR over a wide frequency range. Another benefit is that the resonant frequency of the Yagi changes very little as the boom length is increased. The driven-element impedance also changes moderately with

boom length. The tapered approach creates a Yagi with a very clean radiation pattern. Typically, first side lobe levels of  $\approx 17$  dB in the E plane,  $\approx 15$  dB in the H plane, and all other lobes at  $\approx 20$  dB or more are possible on designs from  $2\lambda$  to more than  $14\lambda$ .

The actual rate of change in element lengths is determined by the diameter of the elements (in wavelengths). The spacings can be optimized for an individual boom length or chosen as a best compromise for most boom lengths.

The gain of long Yagis has been the subject of much debate. Recent measurements and computer analysis by both amateurs and professionals indicates that given an optimum design, doubling a Yagi's boom length will result in a maximum theoretical gain increase of about 2.6 dB. In practice, the real gain increase may be less because of escalating resistive losses and the greater possibility of construction error. Fig 20.105 shows the maximum possible gain per boom length expressed in decibels, referenced to an isotropic radiator. The actual number of directors does not play an important part in determining the gain vs boom length as long as a reasonable number of directors are used. The use of more directors per boom length will normally give a wider gain bandwidth, however, a point exists where too many directors will adversely affect all performance aspects.

While short antennas ( $< 1.5\lambda$ ) may show increased gain with the use of quad or loop elements, long Yagis ( $> 2\lambda$ ) will not exhibit measurably greater forward gain or pattern integrity with loop type elements. Similarly, loops used as driven elements and reflectors will not significantly change the properties of a long log-taper Yagi. Multiple-dipole driven-element assemblies will also not result in any significant gain increase per given boom length when compared to single-dipole feeds.

Once a long-Yagi director string is properly tuned, the reflector becomes relatively noncritical. Reflector spacings between  $0.15\lambda$  and  $0.2\lambda$  are preferred. The spacing can be chosen for best pattern and driven-element impedance. Multiple-reflector arrangements will not significantly increase the forward gain of a Yagi that has its directors properly optimized for forward gain. Many multiple-reflector schemes such as trireflectors and corner reflectors have the disadvantage of lowering the driven-element impedance compared to a single optimum-length reflector. The plane or grid reflector, shown in Fig 20.106, may however reduce the intensity of unwanted rear lobes. This can be used to reduce noise pickup on EME or satellite arrays. This type of reflector will usually increase the driven-element impedance compared to a single reflector. This sometimes makes driven-element

matching easier. Keep in mind that even for EME, a plane reflector will add considerable wind load and weight for only a few tenths of a decibel of receive signal-to-noise improvement.

## Yagi Construction

Normally, aluminum tubing or rod is used for Yagi elements. Hard-drawn enamel-covered copper wire can also be used on Yagis above 420 MHz. Resistive losses are inversely proportional to the square of the element diameter and the square root of its conductivity.

Element diameters of less than  $3/16$  inch or 4 mm should not be used on any band. The size should be chosen for reasonable strength. Half-inch diameter is suitable for 50 MHz,  $3/16$  to  $3/8$  inch for 144 MHz and  $3/16$  inch is recommended for the higher bands. Steel, including stainless steel and unprotected brass or copper wire, should not be used for elements.

Boom material may be aluminum tubing, either square or round. High-strength aluminum alloys such as 6061-T6 or 6063-T651 offer the best strength-to-weight advantages. Fiberglass poles have been used (where available as surplus). Wood is a popular low-cost boom material. The wood should be well seasoned and free from knots. Clear pine, spruce and Douglas fir are often used. The wood should be well treated to avoid water absorption and warping.

Fig 20.105—This chart shows maximum gain per boom length for optimally designed long Yagi antennas.

Fig 20.106—Front and side views of a plane-reflector antenna.

**Fig 20.107—Yagi element correction vs boom diameter.** Curve A is for elements mounted through a round or square conductive boom, with the elements in mechanical contact with the boom. Curve B is for insulated elements mounted through a conductive boom, and for elements mounted on top of a conductive boom (elements make electrical contact with the boom). The patterns were corrected to computer simulations to determine Yagi tuning. The amount of element correction is not affected by element diameter.

Elements may be mounted insulated or uninsulated, above or through the boom. Mounting uninsulated elements through a metal boom is the least desirable method

unless the elements are welded in place. The Yagi elements will oscillate, even in moderate winds. Over several years this element oscillation will work open the boom holes.

This will allow the elements to move in the boom and create noise (in your receiver) when the wind blows. Eventually the element-to-boom junction will corrode (aluminum oxide is a good insulator). This loss of electrical contact between the boom and element will reduce the boom's effect and change the resonant frequency of the Yagi.

Noninsulated elements mounted above the boom will perform fine as long as a good mechanical connection is made. Insulating blocks mounted above the boom will also work, but they require additional fabrication. One of the most popular construction methods is to mount the elements through the boom using insulating shoulder washers. This method is lightweight and durable. Its main disadvantage is difficult disassembly, making this method of limited use for portable arrays.

If a conductive boom is used, element lengths must be corrected for the mounting method used. The amount of correction is dependent upon the boom diameter in wavelengths. See Fig 20.107. Elements mounted through the boom and not insulated require the greatest correction. Mounting on top of the boom or through the boom on insulated shoulder washers requires about half of the through-the-boom correction. Insulated elements mounted at least one element diameter above the boom require no correction over the free-space length.

The three following antennas have been optimized for typical boom lengths on each band.

## A HIGH-PERFORMANCE 432-MHz YAGI

This 22-element, 6.1-λ, 432-MHz Yagi was originally designed for use in a 12-Yagi EME array built by K1FO. A lengthy evaluation and development process preceded its construction. Many designs were considered and then analyzed on the computer. Next, test models were constructed and evaluated on a home-made antenna range. The resulting design is based on WIEJ's computer-optimized spacings.

The attention paid to the design process has been worth the effort. The 22-element Yagi not only has exceptional forward gain (17.9 dBi), but has an unusually "clean" radiation pattern. The measured E-plane pattern is shown in Fig 20.108. Note that a 1-dB-per-division axis is used to show pattern detail. A complete description of the design process and construction methods appears in December 1987 and January 1988 *QST*.

Like other log-taper Yagi designs, this one can easily be adapted to other boom

lengths. Versions of this Yagi have been built by many amateurs. Boom lengths ranged between 5.3 λ (20 elements) and 12.2 λ (37 elements).

The size of the original Yagi (169 inches long, 6.1 λ) was chosen so the antenna could be built from small-diameter boom material (7/8 inch and 1 inch round 6061-T6 aluminum) and still survive high winds and ice loading. The 22-element Yagi weighs about 3.5 pounds and has a wind load of approximately 0.8 square ft. This allows a high-gain EME array to be built with manageable wind load and weight. This same low wind load and weight lets the tropo operator add a high-performance 432-MHz array to an existing tower without sacrificing antennas on other bands.

Table 20.24 lists the gain and stacking specifications for the various length Yagis. The basic Yagi dimensions are shown in Table 20.25. These are free-

space element lengths for 3/16-inch-diameter elements. Boom corrections for the element mounting method must be added in. The element-length correction column gives the length that must be added to keep the Yagi's center frequency optimized for use at 432 MHz. This correction is required to use the same spacing pattern over a wide range of boom lengths. Although any length Yagi will work well, this design is at its best when made with 18 elements or more (4.6 λ). Element material of less than 3/16-inch diameter is not recommended because resistive losses will reduce the gain by about 0.1 dB, and wet-weather performance will be worse.

Quarter-inch-diameter elements could be used if all elements are shortened by 3 mm. The element lengths are intended for use with a slight chamfer (0.5 mm) cut into the element ends. The gain peak of the array is centered at 437 MHz. This allows acceptable wet-weather performance,

**Fig 20.108—Measured E-plane pattern for the 22-element Yagi. Note: This antenna pattern is drawn on a linear dB grid, rather than on the standard ARRL log-periodic grid, to emphasize low sidelobes.**

while reducing the gain at 432 MHz by only 0.05 dB.

The gain bandwidth of the 22-element Yagi is 31 MHz (at the  $-1$  dB points). The SWR of the Yagi is less than 1.4:1 between 420 and 440 MHz. **Fig 20.109** is a network analyzer plot of the driven-element SWR vs frequency. These numbers indicate just how wide the frequency response of a log-taper Yagi can be, even with a simple dipole driven element. In fact, at one antenna gain contest, some ATV operators conducted gain vs frequency measurements from 420 to 440 MHz. The 22-element Yagi beat all entrants including those with so-called broadband feeds.

To peak the Yagi for use on 435 MHz (for satellite use), you may want to shorten all the elements by 2 mm. To peak it for use on 438 MHz (for ATV applications), shorten all elements by 4 mm. If you want to use the Yagi on FM between 440 MHz and 450 MHz, shorten all the elements by 10 mm. This will provide 17.6 dBi gain at 440 MHz, and 18.0 dBi gain at 450 MHz. The driven element may have to be adjusted if the element lengths are shortened.

Although this Yagi design is relatively broadband, pay close attention to copying the design exactly. Metric dimensions are used because they are convenient for a Yagi sized for 432 MHz. Element holes should be drilled within  $\pm 2$  mm. Element lengths should be kept within  $\pm 0.5$  mm. Elements can be accurately constructed if they are first

**Table 20.24**

\*Gain is approximate real gain based upon gain measurements made on six different-length Yagis.

**Fig 20.109—SWR performance of the 22-element Yagi in dry weather.**

rough cut with a hack saw and then held in a vise and filed to the exact length.

Larger arrays require more attention to making all Yagis identical. Elements are mounted on shoulder insulators and run through the boom (see **Fig 20.110**). The element retainers are stainless-steel push nuts.

These are made by several companies, including Industrial Retaining Ring Co in Irvington, New Jersey, and AuVeco in Ft Mitchell, Kentucky. Local industrial hardware distributors can usually order them for you. The element insulators are not critical. Teflon or black polyethylene are probably

**Fig 20.110—Element-mounting detail.** Elements are mounted through the boom using plastic insulators. Stainless steel push-nut retaining rings hold the element in place.

the best materials. The Yagi in the photographs is made with black Delryn insulators, available from Rutland Arrays in New Cumberland, Pennsylvania.

The driven element uses a UG-58 connector mounted on a small bracket. The UG-58 should be the type with the press-in center pin. UG-58s with center pins held in by "C" clips will usually leak water. Some connectors use steel retaining clips, which will rust and leave a conductive

**Fig 20.111—Several views of the driven element and T match.**

stripe across the insulator. The T-match wires are supported by the UT-141 balun. RG-303 or RG-142 Teflon-insulated cable could be used if UT-141 cannot be ob-

tained. Fig 20.111 shows details of the driven-element construction. Driven element dimensions are given in Fig 20.112.

Dimensions for the 22-element Yagi are listed in Table 20.26. Fig 20.113 details the Yagi's boom layout. Element material can be either  $\frac{3}{16}$ -inch 6061-T6 aluminum rod or hard aluminum welding rod.

A 24-ft-long, 10.6- $\lambda$ , 33-element Yagi was also built. The construction methods used were the same as the 22-element Yagi. Telescoping round boom sections of 1,  $1\frac{1}{8}$ , and  $1\frac{1}{4}$  inches in diameter were used. A boom support is required to keep boom sag acceptable. At 432 MHz, if boom sag is much more than two or three inches, H-plane pattern distortion will occur. Greater amounts of boom sag will reduce the gain of a Yagi. Table 20.27 lists the proper dimensions for the antenna when built with the previously given boom diameters. The boom layout is shown in Fig 20.114, and the driven element is described in Fig 20.115. The 33-element Yagi exhibits the same clean pattern traits as the 22-element Yagi (see Fig 20.116). Measured gain of the 33-element Yagi is 19.9 dBi at 432 MHz. A measured gain sweep of the 33-element Yagi gave a  $\approx 1$  dB gain bandwidth of 14 MHz with the  $\approx 1$  dB points at 424.5 MHz and 438.5 MHz.

## A HIGH-PERFORMANCE 144-MHz YAGI

This 144-MHz Yagi design uses the latest log-tapered element spacings and lengths. It offers near-theoretical gain per boom length, an extremely clean pattern and wide bandwidth. The design is based upon the spacings used in a 4.5- $\lambda$  432-MHz computer-developed design by W1EJ. It is quite similar to the 432-MHz Yagi described elsewhere in this chapter. Refer to that project for additional construction diagrams and photographs.

Mathematical models do not always directly translate into real working examples. Although the computer design

provided a good starting point, the author, Steve Powlishe, K1FO, built several test models before the final working Yagi was obtained. This hands-on tuning included changing the element-taper rate in order to obtain the flexibility that allows the Yagi to be built with different boom lengths.

The design is suitable for use from 1.8  $\lambda$  (10 elements) to 5.1  $\lambda$  (19 elements). When elements are added to a Yagi, the center frequency, feed impedance and front-to-back ratio will range up and down. A modern tapered design will mini-

mize this effect and allow the builder to select any desired boom length. This Yagi's design capabilities per boom length are listed in Table 20.28.

The gain of any Yagi built around this design will be within 0.1 to 0.2 dB of the maximum theoretical gain at the design frequency of 144.2 MHz. The design is intentionally peaked high in frequency (calculated gain peak is about 144.7 MHz). It has been found that by doing this, the SWR bandwidth and pattern at 144.0 to 144.3 MHz will be better, the Yagi will be less affected by weather and its performance in arrays will be more predictable. This design starts to drop off in performance if built with fewer than 10 elements. At less than 2  $\lambda$ , more traditional designs perform well.

Table 20.29 gives free-space element lengths for  $\frac{1}{4}$ -inch-diameter elements. The use of metric notation allows for much easier dimensional changes during the design stage. Once you become familiar with the metric system, you'll probably find that construction is easier without the burden of cumbersome English fractional units. For  $\frac{3}{16}$ -inch-diameter elements, lengthen all parasitic elements by 3 mm. If  $\frac{3}{8}$ -inch-diameter elements are used,

shorten all of the directors and the reflector by 6 mm. The driven element will have to be adjusted for the individual Yagi if the 12-element design is not adhered to.

For the 12-element Yagi, 1/4-inch-diameter elements were selected because smaller-diameter elements become rather flimsy at 2 m. Other diameter elements can be used as described previously. The 2.5-λ boom was chosen because it has an excellent size and wind load vs gain and pattern trade-off. The size is also convenient; three 6-ft-long pieces of aluminum tubing can be used without any waste. The relatively large-diameter boom sizes (1 1/4 and 1 3/8 inches) were chosen, as they provide

Fig 20.117—Boom layout for the 12-element 144-MHz Yagi. Lengths are given in millimeters to allow precise duplication.

Fig 20.119—H- and E-plane pattern for the 12-element 144-MHz Yagi.

an extremely rugged Yagi that does not require a boom support. The 12-element 17-ft-long design has a calculated wind survival of close to 120 mi/h! The absence of a boom support also makes vertical polarization possible.

Longer versions could be made by telescoping smaller-size boom sections into the last section. Some sort of boom support will be required on versions longer than 22 ft. The elements are mounted on shoulder insulators and mounted through the boom. However, elements may be mounted, insulated or uninsulated, above

or through the boom, as long as appropriate element length corrections are made. Proper tuning can be verified by checking the depth of the nulls between the main lobe and first side lobes. The nulls should be 5 to 10 dB below the first side-lobe level at the primary operating frequency. The boom layout for the 12-element model is shown in Fig 20.117. The actual corrected element dimensions for the 12-element 2.5-λ Yagi are shown in Table 20.30.

The design may also be cut for use at 147 MHz. There is no need to change element spacings. The element lengths should be shortened by 17 mm for best operation between 146 and 148 MHz. Again, the driven element will have to be adjusted as required.

The driven-element size (1/2-inch diameter) was chosen to allow easy impedance matching. Any reasonably sized driven element could be used, as long as appropriate length and T-match adjustments are made. Different driven-element dimensions are required if you change the boom length. The calculated natural driven-element impedance is given as a guideline. A balanced T-match was chosen because it's easy to adjust for best SWR and provides a balanced radiation pattern. A 4:1 half-wave coaxial balun is used, although impedance-transforming quarter-wave sleeve baluns could also be used. The calculated natural impedance will be useful in determining what impedance transformation will be required at the 200-Ω balanced feedpoint. The ARRL Antenna Book contains information on calculating folded-dipole and T-match driven-element parameters. A balanced feed is important for best operation on this antenna.

MATERIAL: RG-142/U OR RG-303/U  
TEFLON-INSULATED COAXIAL CABLE

(C)

Gamma matches can severely distort the pattern balance. Other useful driven-element arrangements are the Delta match and the folded dipole, if you're willing to sacrifice some flexibility. **Fig 20.118** details the driven-element dimensions.

A noninsulated driven element was chosen for mounting convenience. An insulated driven element may also be used. A grounded driven element may be less affected by static build-up. On the other hand, an insulated driven element allows the operator to easily check his feed lines

for water or other contamination by the use of an ohmmeter from the shack.

**Fig 20.119** shows computer-predicted E- and H-plane radiation patterns for the 12-element Yagi. The patterns are plotted on a 1-dB-per-division linear scale instead of the usual ARRL polar-plot graph. This expanded scale plot is used to show greater pattern detail. The pattern for the 12-element Yagi is so clean that a plot done in the standard ARRL format would be almost featureless, except for the main lobe and first sidelobes.

The excellent performance of the 12-element Yagi is demonstrated by the reception of Moon echoes from several of the larger 144-MHz EME stations with only one 12-element Yagi. Four of the 12-element Yagis will make an excellent starter EME array, capable of working many EME QSOs while being relatively small in size. The advanced antenna builder can use the information in **Table 20.28** to design a "dream" array of virtually any size.

## A HIGH-PERFORMANCE 222-MHz YAGI

Modern tapered Yagi designs are easily applied to 222 MHz. This design uses a spacing progression that is in between the 12-element 144-MHz design, and the 22-element 432-MHz design presented elsewhere in this chapter. The result is a design with maximum gain per boom length, a clean, symmetrical radiation pattern, and wide bandwidth. Although it was designed for weak-signal work (tropospheric scatter and EME), the design is suited to all modes of 222-MHz operation, such as packet radio, FM repeater operation and control links.

The spacings were chosen as the best compromise for a 3.9- $\lambda$  16-element Yagi. The 3.9- $\lambda$  design was chosen, like the 12-

element 144-MHz design, because it fits perfectly on a boom made from three 6-ft-long aluminum tubing sections. The design is quite extensible, and models from 12 elements (2.4  $\lambda$ ) to 22 elements (6.2  $\lambda$ ) can be built from the dimensions given in **Table 20.31**. Note that free-space lengths are given. They must be corrected for the element mounting method. Specifications

for various boom lengths are shown in **Table 20.32**.

### Construction

Large-diameter (1 1/4 and 1 3/8-inch diameter) boom construction is used, eliminating the need for boom supports. The Yagi can also be used vertically polarized. Three-sixteenths-inch-diameter alumi-

num elements are used. The exact alloy is not critical; 6061-T6 was used, but hard aluminum welding rod is also suitable. Quarter-inch-diameter elements could also be used if all elements are shortened by 3 mm. Three-eighths-inch-diameter elements would require 10 mm shorter lengths. Elements smaller than  $\frac{3}{16}$ -inch-diameter are not recommended. The elements are insulated and run through the boom. Plastic shoulder washers and stainless-steel retainers are used to hold the elements in place. The various pieces needed to build the Yagi may be obtained from Rutland Arrays in New Cumberland, Pennsylvania. **Fig 20.120** details the boom layout for the 16-element Yagi. **Table 20.33** gives the dimensions for the 16-element Yagi as built. The driven element is fed with a T match and a 4:1 balun. See **Fig 20.121** for construction details. See the 432-MHz Yagi project elsewhere in this chapter for additional photographs and construction diagrams.

The Yagi has a relatively broad gain and SWR curve, as is typical of a tapered design, making it usable over a wide frequency range. The example dimensions are intended for use at 222.0 to 222.5 MHz. The 16-element Yagi is quite usable to more than 223 MHz. The best compromise for covering the entire band is to shorten all parasitic elements by 4 mm. The driven element will have to be adjusted in length for best match. The

position of the T-wire shorting straps may also have to be moved.

The aluminum boom provides superior strength, is lightweight, and has a low wind-load cross section. Aluminum is doubly attractive, as it will long outlast wood and fiberglass. Using state-of-the-art designs, it is unlikely that significant performance increases will be achieved in the next few years. Therefore, it's in your best interest to build an antenna that will last many years. If suitable wood or fiberglass poles are readily available, they may be used without any performance degradation, at least when the wood is new and dry. Use the free-space element lengths given in **Table 20.31** for insulated-boom construction.

The pattern of the 16-element Yagi is shown in **Fig 20.122**. Like the 144-MHz Yagi, a 1-dB-per-division plot is used to detail the pattern accurately. This 16-element design makes a good building block for EME or tropo DX arrays. Old-style narrow-band Yagis often perform unpredictably when used in arrays. The theoretical 3.0-dB stacking gain is rarely observed. The 16-element Yagi (and other versions of the design) reliably provides stacking gains of nearly 3 dB. (The spacing dimensions listed in **Table 20.33** show just over 2.9 dB stacking gain.) This has been found to be the best compromise between gain, pattern integrity and array size. Any phasing-line losses will subtract

**Fig 20.122—H- and E-plane patterns for the 16-element 222-MHz Yagi at A. The driven-element T-match dimensions were chosen for the best SWR compromise between wet and dry weather conditions. The SWR vs frequency curve shown at B demonstrates the broad frequency response of the Yagi design.**

# Propagation

## 21

Radio waves, like light waves and all other forms of electromagnetic radiation, normally travel in straight lines. Obviously this does not happen all the time, because long-distance communication depends on radio waves traveling beyond the horizon. How radio waves propagate in other than straight-line paths is a complicated subject, but one that need not be a mystery. This chapter, by Emil Pocock, W3EP, provides basic understanding of the principles of electromagnetic radiation, the structure of the Earth's atmosphere and solar-terrestrial interactions necessary for a working knowledge of radio propagation. More detailed discussions and the underlying mathematics of radio propagation physics can be found in the references listed at the end of this chapter.

### FUNDAMENTALS OF RADIO WAVES

Radio belongs to a family of electromagnetic radiation that includes infrared (radiation heat), visible light, ultraviolet, X-rays and the even shorter-wavelength gamma and cosmic rays. Radio has the longest wavelength and thus the lowest frequency of this group. See **Table 21.1**. Electromagnetic waves result from the interaction of an electric and a magnetic field. An oscillating electric charge in a piece of wire, for example, creates an electric field and a corresponding magnetic

**Fig 21.1—Electric and magnetic field components of the electromagnetic wave. The polarization of a radio wave is the same direction as the plane of its electric field.**

field. The magnetic field in turn creates an electric field, which creates another magnetic field, and so on.

These two fields sustain themselves as a composite *electromagnetic wave*, which propagates itself into space. The electric and magnetic components are oriented at

right angles to each other and 90° to the direction of travel. The polarization of a radio wave is usually designated the same as its electric field. This relationship can be visualized in **Fig 21.1**. Unlike sound waves or ocean waves, electromagnetic waves need no propagating medium, such as air or water. This property enables electromagnetic waves to travel through the vacuum of space.

### Velocity

Radio waves, like all other electromagnetic radiation, travel nearly 300,000 km (186,400 mi) per second in a vacuum. Radio waves travel more slowly through any other medium. The decrease in speed

**Table 21.1**  
**The Electromagnetic Spectrum**

Radiation	Frequency	Wavelength
X-ray	$3 \times 10^5$ THz and higher	10 Å and shorter
Ultraviolet	800 THz - $3 \times 10^5$ THz	4000 - 10 Å
Visible light	400 THz - 800 THz	8000 - 4000 Å
Infrared	300 GHz - 400 THz	1 mm - .0008 mm
Radio	10 kHz - 300 GHz	30,000 km - 1 mm

**Fig 21.2—Radio energy disperses as the square of the distance from its source. For the change of one distance unit shown the signal is only one quarter as strong. Each spherical section has the same surface area.**

through the atmosphere is so slight that it is usually ignored, but sometimes even this small difference is significant. The speed of a radio wave in a piece of wire, by contrast, is about 95% that of free space, and the speed can be even slower in other media.

The speed of a radio wave is always the product of wavelength and frequency, whatever the medium. That relationship can be stated simply as:

$$c = f\lambda$$

where

$c$  = speed in m/s

$f$  = frequency in hertz

$\lambda$  = wavelength in m

The *wavelength* ( $\lambda$ ) of any radio frequency can be determined from this simple formula. In free space, where the speed is  $3 \times 10^8$  m/s, the wavelength of a 30-MHz radio signal is thus 10 m. Wavelength decreases in other media because the propagating speed is slower. In a piece of wire, the wavelength of a 30-MHz signal shortens to about 9.5 m. This factor must be taken into consideration in antenna designs and other applications.

### Wave Attenuation and Absorption

Radio waves weaken as they travel, whether in the near vacuum of cosmic space or within the Earth's atmosphere. *Free-space attenuation* results from the dispersal of radio energy from its source. See Fig 21.2. Attenuation grows rapidly with distance because signals weaken with the square of the distance traveled. If the distance between transmitter and receiver is increased from 1 km to 10 km (0.6 to 6 mi), the signal will be only one-hundredth as strong. Free-space attenuation is a major factor governing signal strength, but radio signals undergo a variety of other losses as well.

**Fig 21.3—Radio waves are refracted as they pass at an angle between dissimilar media. The lines represent the crests of a moving wave front and the distance between them is the wavelength. The direction of the wave changes because one end of the wave slows down before the other as it crosses the boundary between the two media. The wavelength is simultaneously shortened, but the wave frequency (number of crests that pass a certain point in a given unit of time) remains constant.**

Energy is lost to *absorption* when radio waves travel through media other than a vacuum. Radio waves propagate through the atmosphere or solid material (like a wire) by exciting electrons, which then reradiate energy at the same frequency. This process is not perfectly efficient, so some radio energy is transformed into heat and retained by the medium. The amount of radio energy lost in this way depends on the characteristics of the medium and on the frequency. Attenuation in the atmosphere is minor from 10 MHz to 3 GHz, but at higher frequencies, absorption due to water vapor and oxygen can be high.

Radio energy is also lost during refraction, diffraction and reflection—the very phenomena that allow long-distance propagation. Indeed, any form of useful propagation is accompanied by attenuation. This may vary from the slight losses encountered by refraction from sporadic-E clouds near the maximum usable frequency, to the more considerable losses involved with tropospheric forward scatter or D-Layer absorption in the lower HF bands. These topics will be covered later. In many circumstances, total losses can become so great that radio signals become too weak for communication.

### Refraction

Electromagnetic waves travel in straight lines until they are deflected by something. Radio waves are *refracted*, or bent, slightly when traveling from one medium to another. Radio waves behave no differently from other familiar forms

of electromagnetic radiation in this regard. The apparent bending of a pencil partially immersed in a glass of water demonstrates this principle quite dramatically.

Refraction is caused by a change in the velocity of a wave when it crosses the boundary between one propagating medium and another. If this transition is made at an angle, one portion of the wavefront slows down (or speeds up) before the other, thus bending the wave slightly. This is shown schematically in Fig 21.3.

The amount of bending increases with the ratio of the *refractive indices* of the two media. Refractive index is simply the velocity of a radio wave in free space divided by its velocity in the medium. Radio waves are commonly refracted when they travel through different layers of the atmosphere, whether the highly charged ionospheric layers 100 km (60 mi) and higher, or the weather-sensitive area near the Earth's surface. When the ratio of the refractive indices of two media is great enough, radio waves can be *reflected*, just like light waves striking a mirror. The Earth is a rather lossy reflector, but a metal surface works well if it is several wavelengths in diameter.

Radio waves can also be *diffracted* or bent around solid objects with sharp edges. Fig 21.4 depicts a wavefront passing over an idealized knife edge. That portion of a wave adjacent to the edge is slowed down slightly, thus making the wave front appear to bend around it. The net effect is to allow some wave energy to appear behind an otherwise solid object.

The direction of radio waves can also be altered through *scattering*. The effect seen by a beam of light attempting to penetrate fog is a good example of light-wave scattering. Even on a clear night, a highly directional search light is visible due to a

**Fig 21.4—Radio waves are diffracted around sharp edges, such as this idealized knife edge. The lower portion of the wave is slowed as it approaches the edge, causing a portion of the signal to bend around it.**

small amount of atmospheric scattering perpendicular to the beam. Radio waves are similarly scattered when they encounter randomly arranged objects of wavelength size or smaller, such as masses of electrons or water droplets. When the density of scattering objects becomes great enough, they behave more like a propagating medium with a characteristic refractive index.

If the scattering objects are arranged in some alignment or order, scattering takes place only at certain angles. A rainbow provides a good analogy for *field-aligned scattering* of light waves. The arc of a rainbow can be seen only at a precise angle away from the sun, while the colors result from the variance in scattering across the light-wave frequency range. Ionospheric electrons can be field-aligned by magnetic forces in auroras and under other unusual circumstances. Scattering in such cases is best perpendicular to the Earth's magnetic field lines.

## Reflection

At amateur frequencies above 30 MHz, reflections from a variety of large objects, such as water towers, buildings, airplanes, mountains and the like can provide a useful means of extending over-the-horizon paths several hundred km. Two stations need only beam toward a common reflector, whether stationary or moving. Contrary to common sense notions, the best position for a reflector is not midway between two stations. Signal strength increases as the reflector approaches one end of the path, so the most effective reflectors are those closest to one station or the other.

Maximum range is limited by the radio line-of-sight distance of both stations to the reflector and by reflector size and shape. The reflectors must be many wavelengths in size and ideally have flat surfaces. Large airplanes make fair reflectors and may provide the best opportunity for long-distance contacts. The calculated limit for airplane reflections is 900 km (560 mi), assuming the largest jets fly no higher than 12,000 m (40,000 ft), but actual airplane reflection contacts are likely to be considerably shorter.

## Knife-Edge Diffraction

The crest of a range of hills or mountains at least  $100 \lambda$  long can serve as a reasonable *knife-edge diffracter* at radio frequencies. Hill crests that are sharp, clear of trees and horizontal make the best edges, but even rounded hills may serve as a diffracting edge. Only a small portion of the signal energy will be diffracted behind the mountains, but it may make it possible to complete paths of 100 km (62 mi) or more that might otherwise be obstructed

by the terrain. See Fig 21.5. Knife-edge diffraction works in both directions, so communications paths over what appear to be imposing mountain ranges might actually be possible, especially in the VHF range and higher. Natural knife edges are so variable that some experimentation will be needed for optimal signal strength in the shadow zone.

## Ground Waves

A *ground wave* is the result of a special form of diffraction that primarily affects longer-wavelength vertically polarized radio waves. It is most apparent in the 80- and 160-m amateur bands, where practical ground-wave distances may extend beyond 200 km (120 mi). The term ground wave is often mistakenly applied to any short-distance communication, but the actual mechanism is unique to the longer-wave bands.

Radio waves are bent slightly as they pass over a sharp edge, but the effect extends to edges that are considerably rounded. At medium and long wavelengths, the curvature of the Earth looks like a rounded edge. Bending results when the lower part of the wave front loses energy due to currents induced in the ground. This slows down the lower part of the wave, causing the entire wave to tilt forward slightly. This tilting follows the curvature of the Earth, thus allowing low- and medium-wave radio signals to propagate over distances well beyond line of sight.

Ground wave is most useful during the day at 1.8 and 3.5 MHz, when D-layer absorption makes skywave propagation more difficult. Vertically polarized anten-

nas with excellent ground systems provide the best results. Ground-wave losses are reduced considerably over saltwater and are worst over dry and rocky land.

## SKY-WAVE PROPAGATION AND THE SUN

The Earth's atmosphere is composed primarily of nitrogen (78%), oxygen (21%) and argon (1%), with smaller amounts of a dozen other gases. Water vapor can account for as much as 5% of the atmosphere under certain conditions. This ratio of gases is maintained until an altitude of about 80 km (50 mi), when the mix begins to change. At the highest levels, helium and hydrogen predominate.

Solar radiation acts directly or indirectly on all levels of the atmosphere. Adjacent to the surface of the Earth, solar warming controls all aspects of the weather, powering wind, rain and other familiar phenomena. *Solar ultraviolet (UV) radiation* creates small concentrations of ozone ( $O_3$ ) molecules between 10 and 50 km (6 and 30 mi). Most UV radiation is absorbed by this process and never reaches the Earth.

At even higher altitudes, UV and X-ray radiation partially ionize atmospheric gases. Electrons freed from gas atoms eventually recombine with positive ions to recreate neutral gas atoms, but this takes some time. In the low-pressure environment at the highest altitudes, atoms are spaced far apart and the gases may remain ionized for many hours. At lower altitudes, recombination happens rather quickly, and only constant radiation can keep any appreciable portion of the gas ionized.

Fig 21.5—VHF and UHF diffraction allows contacts to be made behind a mountain.

## **Propagation Summary, by Band**

### **Medium Frequencies (300 kHz-3 MHz)**

The only amateur medium-frequency band is situated just above the domestic AM broadcast band. Ground wave provides reliable communication out to 150 km (90 mi) or during the day, when no other form of propagation is available. Long-distance paths are made at night via the  $F_2$  layer.

#### **1.8-2.0 MHz (160 m)**

The top band, as it is sometimes called, suffers from extreme daytime D-layer absorption. Even at high radiation angles, virtually no signal can pass through to the F layer, so daytime communication is limited to ground-wave coverage. At night, the D layer quickly disappears and worldwide 160-m communication becomes possible via  $F_2$ -layer skip. Atmospheric and man-made noise limit propagation. Tropical and midlatitude thunderstorms cause high levels of static in summer, making winter evenings the best time to work DX at 1.8 MHz. A proper choice of receiving antenna can often significantly reduce the amount of received noise while enhancing desired signals.

### **High Frequencies (3-30 MHz)**

A wide variety of propagation modes are useful on the HF bands. The lowest two bands in this range share many daytime characteristics with 160 m. The transition between bands primarily useful at night or during the day appears around 10 MHz. Most long-distance contacts are made via  $F_2$ -layer skip. Above 21 MHz, more exotic propagation, including TE, sporadic E, aurora and meteor scatter, begin to be practical.

#### **3.5-4.0 MHz (80 m)**

The lowest HF band is similar to 160 m in many respects. Daytime absorption is significant, but not quite as extreme as at 1.8 MHz. High-angle signals may penetrate to the E and F layers. Daytime communication range is typically limited to 400 km (250 mi) by ground-wave and skywave propagation. At night, signals are often propagated halfway around the world. As at 1.8 MHz, atmospheric noise is a nuisance, making winter the most attractive season for the 80-m DXer.

#### **7.0-7.3 MHz (40 m)**

The popular 40-m band has a clearly defined skip zone during the day. D-layer absorption is not as severe as on the lower bands, so short-distance skip via the E and F layers is possible. During the day, a typical station can cover a radius of approximately 800 km (500 mi). Ground-wave propagation is not important. At night, reliable worldwide communication via  $F_2$  is common on the 40-m band.

Atmospheric noise is less troublesome than on 160 and 80 m, and 40-m DX signals are often of sufficient strength to override even high-level summer static. For these reasons, 40 m is the lowest-frequency

amateur band considered reliable for DX communication in all seasons. Even during the lowest point in the solar cycle, 40 m may be open for worldwide DX throughout the night.

#### **10.1-10.15 MHz (30 m)**

The 30-m band is unique because it shares characteristics of both daytime and nighttime bands. D-layer absorption is not a significant factor. Communication up to 3000 km (1900 mi) is typical during the daytime, and this extends halfway around the world via all-darkness paths. The band is generally open via  $F_2$  on a 24-hour basis, but during a solar minimum, the MUF on some DX paths may drop below 10 MHz at night. Under these conditions, 30 m adopts the characteristics of the daytime bands at 14 MHz and higher. The 30-m band shows the least variation in conditions over the 11-year solar cycle, thus making it generally useful for long-distance communication anytime.

#### **14.0-14.35 MHz (20 m)**

The 20-m band is traditionally regarded as the amateurs' primary long-haul DX favorite. Regardless of the 11-year solar cycle, 20 m can be depended on for at least a few hours of worldwide  $F_2$  propagation during the day. During solar maximum periods, 20 m will often stay open to distant locations throughout the night. Skip distance is usually appreciable and is always present to some degree. Daytime E-layer propagation may be detected along very short paths. Atmospheric noise is not a serious consideration, even in the summer. Because of its popularity, 20 m tends to be very congested during the daylight hours.

#### **18.068-18.168 MHz (17 m)**

The 17-m band is similar to the 20-m band in many respects, but the effects of fluctuating solar activity on  $F_2$  propagation are more pronounced. During the years of high solar activity, 17 m is reliable for daytime and early-evening long-range communication, often lasting well after sunset. During moderate years, the band may open only during sunlight hours and close shortly after sunset. At solar minimum, 17 m will open to middle and equatorial latitudes, but only for short periods during midday on north-south paths.

#### **21.0-21.45 MHz (15 m)**

The 15-m band has long been considered a prime DX band during solar cycle maxima, but it is sensitive to changing solar activity. During peak years, 15 m is reliable for daytime  $F_2$ -layer DXing and will often stay open well into the night. During periods of moderate solar activity, 15 m is basically a daytime-only band, closing shortly after sunset. During solar minimum periods, 15 m may not open at all except for infrequent north-south transequatorial circuits. Sporadic E

is observed occasionally in early summer and mid-winter, although this is not common and the effects are not as pronounced as on the higher frequencies.

#### **24.89-24.99 MHz (12 m)**

This band offers propagation that combines the best of the 10- and 15-m bands. Although 12 m is primarily a daytime band during low and moderate sunspot years, it may stay open well after sunset, during the solar maximum. During years of moderate solar activity, 12 m opens to the low and middle latitudes during the daytime hours, but it seldom remains open after sunset. Periods of low solar activity seldom cause this band to go completely dead, except at higher latitudes. Occasional daytime openings, especially in the lower latitudes, are likely over north-south paths. The main sporadic-E season on 24 MHz lasts from late spring through summer and short openings may be observed in mid-winter.

#### **28.0-29.7 MHz (10 m)**

The 10-m band is well known for extreme variations in characteristics and variety of propagation modes. During solar maxima, long-distance  $F_2$  propagation is so efficient that very low power can produce loud signals halfway around the globe. DX is abundant with modest equipment. Under these conditions, the band is usually open from sunrise to a few hours past sunset. During periods of moderate solar activity, 10 m usually opens only to low and transequatorial latitudes around noon. During the solar minimum, there may be no  $F_2$  propagation at any time during the day or night.

Sporadic E is fairly common on 10 m, especially May through August, although it may appear at any time. Short skip, as it is sometimes called on the HF bands, has little relation to the solar cycle and occurs regardless of F-layer conditions. It provides single-hop communication from 300 to 2300 km (190 to 1400 mi) and multiple-hop opportunities of 4500 km (2800 mi) and farther.

Ten meters is a transitional band in that it also shares some of the propagation modes more characteristic of VHF. Meteor scatter, aurora, auroral E and transequatorial spread-F provide the means of making contacts out to 2300 km (1400 mi) and farther, but these modes often go unnoticed at 28 MHz. Techniques similar to those used at VHF can be very effective on 10 m, as signals are usually stronger and more persistent. These exotic modes can be more fully exploited, especially during the solar minimum when  $F_2$  DXing has waned.

#### **Very High Frequencies (30-300 MHz)**

A wide variety of propagation modes are useful in the VHF range. F-layer skip appears on 50 MHz during solar cycle peaks. Sporadic E and several other E-layer phenomena are most effective in the

VHF range. Still other forms of VHF ionospheric propagation, such as field-aligned irregularities (FAI) and transequatorial spread F (TE), are rarely observed at HF. Tropospheric propagation, which is not a factor at HF, becomes increasingly important above 50 MHz.

#### **50-54 MHz (6 m)**

The lowest amateur VHF band shares many of the characteristics of both lower and higher frequencies. In the absence of any favorable ionospheric propagation conditions, well-equipped 50-MHz stations work regularly over a radius of 300 km (190 mi) via tropospheric scatter, depending on terrain, power, receiver capabilities and antenna. Weak-signal troposcatter allows the best stations to make 500-km (310-mi) contacts nearly any time. Weather effects may extend the normal range by a few hundred km, especially during the summer months, but true tropospheric ducting is rare.

During the peak of the 11-year sunspot cycle, worldwide 50-MHz DX is possible via the  $F_2$  layer during daylight hours.  $F_2$  backscatter provides an additional propagation mode for contacts as far as 4000 km (2500 mi) when the MUF is just below 50 MHz. TE paths as long as 8000 km (5000 mi) across the magnetic equator are common around the spring and fall equinoxes of peak solar cycle years.

Sporadic E is probably the most common and certainly the most popular form of propagation on the 6-m band. Single-hop E-skip openings may last many hours for contacts from 600 to 2300-km (370 to 1400 mi), primarily during the spring and early summer. Multiple-hop  $E_s$  provides transcontinental contacts several times a year, and contacts between the US and South America, Europe and Japan via multiple-hop E-skip occur nearly every summer.

Other types of E-layer ionospheric propagation make 6 m an exciting band. Maximum distances of about 2300 km (1400 mi) are typical for all types of E-layer modes. Propagation via FAI often provides additional hours of contacts immediately following sporadic E events. Auroral propagation often makes its appearance in late afternoon when the geomagnetic field is disturbed. Closely related auroral-E propagation may extend the 6-m range to 4000 km (2500 mi) and sometimes farther across the northern states and Canada, usually after midnight. Meteor scatter provides brief contacts during the early morning hours, especially during one of the dozen or so prominent annual meteor showers.

#### **144-148 MHz (2 m)**

Ionospheric effects are significantly reduced at 144 MHz, but they are far from absent. F-layer propagation is unknown except for TE, which is responsible for the current 144-MHz terrestrial DX  
(Continued on page 21.6)

record of nearly 8000 km (5000 mi). Sporadic E occurs as high as 144 MHz less than a tenth as often as at 50 MHz, but the usual maximum single-hop distance is the same, about 2300 km (1400 mi). Multiple-hop sporadic-E contacts greater than 3000 km (1900 mi) have occurred from time to time across the continental US, as well as across Southern Europe.

Auroral propagation is quite similar to that found at 50 MHz, except that signals are weaker and more Doppler-distorted. Auroral-E contacts are rare. Meteor-scatter contacts are limited primarily to the periods of the great annual meteor showers and require much patience and operating skill. Contacts have been made via FAI on 144 MHz, but its potential has not been fully explored.

Tropospheric effects improve with increasing frequency, and 144 MHz is the lowest VHF band at which weather plays an important propagation role. Weather-induced enhancements may extend the normal 300- to 600-km (190- to 370-mi) range of well-equipped stations to 800 km (500 mi) and more, especially during the summer and early fall. Tropospheric ducting extends this range to 2000 km (1200 mi) and farther over the continent and at least to 4000 km (2500 mi) over some well-known all-water paths, such as that between California and Hawaii.

#### **222-225 MHz (135 cm)**

The 135-cm band shares many characteristics with the 2-m band. The normal working range of 222-MHz stations is nearly as good as comparably equipped 144-MHz stations. The 135-cm band is slightly more sensitive to tropospheric effects, but ionospheric modes are more difficult to use. Aurora and meteor-scatter signals are somewhat weaker than at 144 MHz, and sporadic-E contacts on 222 MHz are extremely rare. FAI and TE may also be well within the possibilities of 222 MHz, but reports of these modes on the 135-cm band are uncommon. Increased activity on 222-MHz will eventually reveal the extent of the propagation modes on the highest of amateur VHF bands.

#### **Ultra-High Frequencies (300-3000 MHz) and Higher**

Tropospheric propagation dominates the bands at UHF and higher, although some forms of E-layer propagation are still useful at 432 MHz. Above 10 GHz, atmospheric attenuation increasingly becomes the limiting factor over long-distance paths. Reflections from airplanes, mountains and other stationary objects may be useful adjuncts to propagation at 432 MHz and higher.

#### **420-450 MHz (70 cm)**

The lowest amateur UHF band marks the highest frequency on which ionospheric propagation is commonly observed. Aurora signals are weaker and more Doppler distorted; the range is usually less than at 144 or 222 MHz. Meteor scatter is much more difficult than on the lower bands, because bursts are significantly weaker and of much shorter duration. Although sporadic E and FAI are unknown as high as 432 MHz and probably impossible, TE may be possible.

Well-equipped 432-MHz stations can expect to work over a radius of at least 300 km (190 mi) in the absence of any propagation enhancement. Tropospheric refraction is more pronounced at 432 MHz and provides the most frequent and useful means of extended range contacts. Tropospheric ducting supports contacts of 1500 km (930 mi) and farther over land. The current 432-MHz terrestrial DX record of more than 4000 km (2500 mi) was accomplished via ducting over water.

#### **902-928 MHz (33-cm) and Higher**

Ionospheric modes of propagation are nearly unknown in the bands above 902 MHz. Aurora scatter may be just within amateur capabilities at 902 MHz, but signal levels will be well below those at 432 MHz. Doppler shift and distortion will be considerable, and the signal bandwidth may be quite wide. No other ionospheric propagation modes are likely, although high-powered research radars have received echoes from auroras and meteors as high as 3 GHz.

Almost all extended-distance work in the UHF and microwave bands is accomplished with the aid of tropospheric enhancement. The frequencies above 902 MHz are very sensitive to changes in the weather. Tropospheric ducting occurs more frequently than in the VHF bands and the potential range is similar. At 1296 MHz, 2000-km (1200-mi) continental paths and 4000-km (2500-mi) paths between California and Hawaii have been spanned many times. Contacts of 1000 km (620 mi) have been made on all bands through 10 GHz in the US and over 1600 km (1000 mi) across the Mediterranean Sea. Well-equipped 903- and 1296-MHz stations can work reliably up to 300 km (190 mi), but normal working ranges generally shorten with increasing frequency.

Other tropospheric effects become evident in the GHz bands. Evaporation inversions, which form over very warm bodies of water, are usable at 3.3 GHz and higher. It is also possible to complete paths via scattering from rain, snow and hail in the lower GHz bands. Above 10 GHz, attenuation caused by atmospheric water vapor and oxygen become the most significant limiting factors in long-distance communication.

## Structure of the Earth's Atmosphere

The atmosphere, which reaches to more than 600 km (370 mi) altitude, is divided into a number of regions, shown in Fig 21.6. The weather-producing *troposphere* lies between the surface and an average altitude of 10 km (6 mi). Between 10 and 50 km (6 and 30 mi) are the stratosphere and the imbedded ozonosphere, where ultraviolet absorbing ozone reaches its highest concentrations. About 99% of atmospheric gases are contained within these two lowest regions.

Above 50 km to about 600 km (370 mi) is the ionosphere, notable for its effects on radio propagation. At these altitudes, atomic oxygen and nitrogen predominate under very low pressure. High-energy solar UV and X-ray radiation ionize these gases, creating a broad region where ions are created in relative abundance. The ionosphere is subdivided into distinctive D, E and F regions.

The magnetosphere begins around 600 km (370 mi) and extends as far as 160,000 km (100,000 mi) into space. The predominant component of atmospheric gases gradually shifts from atomic oxygen, to helium and finally to hydrogen at the highest levels. The lighter gases may reach escape velocity or be swept off the atmosphere by the solar wind. At about 3,200 and 16,000 km (2000 and 9900 mi), the Earth's magnetic field traps energetic electrons and protons in two bands, known as the Van Allen belts. These have only a minor effect on terrestrial radio propagation.

### The Ionosphere

The ionosphere plays a basic role in long-distance communication in all the amateur bands from 1.8 MHz to 30 MHz. Ionospheric effects are less apparent in the very high frequencies (30-300 MHz), but they persist at least through 432 MHz. As early as 1902, Oliver Heaviside and Arthur E. Kennelly independently suggested the existence of a layer in the upper atmosphere that could account for the long-distance radio transmissions made the previous year by Guglielmo Marconi and others. Edward Appleton confirmed the existence of the Kennelly-Heaviside layer during the early 1920s and used the letter E on his diagrams to designate the electric waves that were apparently reflected from it.

In 1924, Appleton discovered two additional layers in the *ionosphere*, as he and Robert Watson-Watt named this atmospheric region, and noted them with the letters D and F. Appleton was reluctant to alter this arbitrary nomenclature for fear

Fig 21.6—Regions of the atmosphere.

of discovering yet other layers, so it has stuck to the present day. The basic physics of ionospheric propagation was largely worked out by the 1920s, yet both amateur and professional experimenters made further discoveries through the 1930s and 1940s. Sporadic E, aurora, meteor scatter and several types of field-aligned scattering were among additional ionospheric phenomena that required explanation.

### Ionospheric Refraction

The refractive index of an ionospheric layer increases with the density of free-moving electrons. In the most dense regions of the F layer, that density can reach a trillion electrons per cubic meter ( $10^{12}$  e/m<sup>3</sup>). Even at this high level, radio waves are refracted gradually over a considerable vertical distance, usually amounting to tens of km. Radio waves become useful for terrestrial propagation only when they are refracted enough to bring them back to Earth. See Fig 21.7.

Although refraction is the primary

mechanism of ionospheric propagation, it is usually more convenient to think of the process as a reflection. The *virtual height* of an ionospheric layer is the equivalent altitude of a reflection that would produce the same effect as the actual refraction. The virtual height of any ionospheric layer can be determined using an ionospheric sounder, or *ionosonde*, a sort of vertically oriented radar. The ionosonde sends pulses that sweep over a wide frequency range, generally from 2 MHz to 6 MHz or higher, straight up into the ionosphere. The frequencies of any echoes are recorded against time and then plotted as distance on an ionogram. Fig 21.8 depicts a simple ionogram.

The highest frequency that returns echoes at vertical incidence is known as the *vertical incidence* or *critical frequency*. The critical frequency is almost totally a function of ion density. The higher the ionization at a particular altitude, the higher becomes the critical frequency. Physicists are more apt to call this

**Fig 21.7**—Gradual refraction in the ionosphere allows radio signals to be propagated long distances. It is often convenient to imagine the process as a reflection with an imaginary reflection point at some virtual height above the actual refracting region. The other figures in this chapter show ray paths as equivalent reflections, but you should keep in mind that the actual process is a gradual refraction. The other figures in this chapter show ray paths as equivalent reflections, but you should keep in mind that the actual process is a gradual refraction.

**Fig 21.8**—Simplified vertical incidence ionogram showing echoes returned from the E, F<sub>1</sub> and F<sub>2</sub> layers. The critical frequencies of each layer (4.1, 4.8 and 6.8 MHz) can be read directly from the ionogram scale.

**Fig 21.9**—The relationships between critical frequency, maximum usable frequency (MUF) and skip zone can be visualized in this simplified, hypothetical case. The critical frequency is 7 MHz, allowing frequencies below this to be used for short-distance ionospheric communication by stations in the vicinity of point M. These stations cannot be communicated by the ionosphere at 14 MHz. Stations at points B and E (and beyond) can communicate because signals at this frequency are refracted back to Earth because they encounter the ionosphere at an oblique angle of incidence. At greater distances, higher frequencies can be used because the MUF is higher at the larger angles of incidence (low launch angles). In this figure, the MUF for the path between points A and F, with a small launch angle, is shown to be 28 MHz. Each pair of stations can communicate at frequencies at or below the MUF of the path between them, but not below the LUF—see text.

**Fig 21.10**—Signals at the MUF propagated at a low angle to the horizon provide the longest possible one-hop distances. In this example, 28-MHz signals entering the ionosphere at higher angles are not refracted enough to bring them back to Earth.

the *plasma* frequency, because technically gases in the ionosphere are in a plasma, or partially ionized state. F-layer critical frequencies commonly range from about 1 MHz to as high as 15 MHz.

### Maximum and Lowest Usable Frequencies

When the frequency of a vertically incident signal is raised above the critical frequency of an ionospheric layer, that portion of the ionosphere is unable to refract the signal back to Earth. However, a signal above the critical frequency may be returned to Earth if it enters the layer at an oblique angle, rather than at vertical incidence. This is fortunate because it permits two widely separated stations to communicate on significantly higher frequencies than the critical frequency. See **Fig 21.9**.

The highest frequency supported by the ionosphere between two stations is the *maximum usable frequency* (MUF) for that path. If the separation between the stations is increased, a still higher frequency can be supported at lower launch angles. The MUF for this longer path is higher than the MUF for the shorter path. When the distance is increased to the maximum one-hop distance, the launch angle of the signals between the two stations is zero (that is, the ray path is tangential to the Earth at the two stations) and the MUF for this path is the highest that can be supported by that layer of the ionosphere at that location. This maximum distance is about 4000 km (2500 mi) for the F<sub>2</sub> layer and about 2300 km (1400 mi) for the E layer.

The MUF is a function of path, time of day, season, location, solar UV and X-ray radiation levels and ionospheric disturbances. For vertically incident waves, the

**Table 21.2**  
**Maximum Usable Frequency**  
**Factors (MUFF)**

Layer	Maximum Critical Frequency (MHz)	MUFF	Useful Operating Frequencies (MHz)
F <sub>2</sub>	15.0	3.3-4.0	1-60
F <sub>1</sub> *	5.5	4.0	10-20
E*	4.0	4.8	5-20
E <sub>s</sub>	30.0	5.3	20-160
D*	Not observed	—	None

\* Daylight only

MUF is the same as the critical frequency. For path lengths at the limit of one-hop propagation, the MUF can be several times the critical frequency. See **Table 21.2**. The ratio between the MUF and the critical frequency is known as the *maximum usable frequency factor* (MUFF).

The term *skip zone* is closely related to MUF. When two stations are unable to communicate with each other on a particular frequency because the ionosphere is unable to refract the signal from one to the other through the required angle — that is, the frequency is below the MUF — the stations are said to be in the skip zone for that frequency. Stations within the skip zone may be able to work each other at a lower frequency, or by ground wave if they are close enough. There is no skip zone at frequencies below the critical frequency.

The MUF at any time on a particular path is just that — the *maximum* usable frequency. Frequencies below the MUF will also propagate along the path, but ionospheric absorption and noise at the receiving location (perhaps due to thunderstorms, local or distant) may make the received signal-to-noise ratio too low to be usable. In this case, the frequency is said to be below the *lowest usable frequency* (LUF). This occurs most frequently below 10 MHz, where atmospheric and man-made noises are most troublesome. The LUF can be lowered somewhat by the use of high power and directive antennas, or through the use of communications modes that permit re-

duced receiver bandwidth or are less demanding of SNR — CW instead of SSB, for example. This is not true of the MUF, which is limited by the physics of ionospheric refraction, no matter how high your transmitter power or how narrow your receiver bandwidth. The LUF can be higher than the MUF, in which case there is no frequency that supports communication on the particular path at that time.

### Ionospheric Fading

HF signal strengths typically rise and fall over periods of a few seconds to several minutes, and rarely hold at a constant level for very long. Fading is generally caused by the interaction of several radio waves from the same source arriving along different propagation paths. Waves that arrive in phase combine to produce a stronger signal, while those out of phase cause destructive interference and a lower net signal strength. Short-term variations in ionospheric conditions may change individual path lengths or signal strengths enough to cause fading. Even signals that arrive primarily over a single path may vary as the propagating medium changes. Fading may be most notable at sunrise and sunset, especially near the MUF, when the ionosphere undergoes dramatic transformations. Other ionospheric traumas, such as auroras and geomagnetic storms, also produce severe forms of HF fading.

### The 11-Year Solar Cycle

The density of ionospheric layers depends on the amount of solar radiation reaching the Earth, but solar radiation is not constant. Variations result from daily and seasonal motions of the Earth, the sun's own 27-day rotation and the 11-year cycle of solar activity. One visual indicator of both the sun's rotation and the solar cycle is the periodic appearance of dark spots on the sun, which have been observed continuously since the mid18th century. On average, the number of *sunspots* reaches a maximum every 10.7 years, but the period has varied between 7 and 17 years. Cycle 19 peaked in 1958, with an average sunspot number of over 200, the highest recorded to date.

**Fig 21.11** shows average monthly sunspot numbers for the past four cycles.

Sunspots are cooler areas on the sun's surface associated with high magnetic activity. Active regions adjacent to sun-spot groups, called *plages*, are capable of producing great flares and sustained bursts of radiation in the radio through X-ray spectrum. During the peak of the 11-year solar cycle, average solar radiation increases along with the number of flares and sunspots. The ionosphere becomes more intensely ionized as a consequence, resulting in higher critical frequencies, particularly in the F<sub>2</sub> layer. The possibilities for long-distance communications are considerably improved during solar maxima, especially in the higher-frequency bands.

One key to forecasting F-layer critical frequencies, and thus long-distance propagation, is the intensity of ionizing UV and X-ray radiation. Until the advent of satellites, UV and X-ray radiation could not be measured directly, because they were almost entirely absorbed in the upper atmosphere. The sunspot number provided the most convenient approximation of general solar activity. The sunspot number is not a simple count of the number of visual spots, but rather the result of a complicated formula that takes into consideration size, number and grouping. The sunspot number varies from near zero during the solar-cycle minimum to over 200.

Another method of gauging solar activity is the *solar flux*, which is a measure of the intensity of 2800-MHz (10.7 cm) radio noise coming from the sun. The 2800-MHz radio flux correlates well with the intensity of ionizing UV and X-ray radiation and provides a convenient alternative to sunspot numbers. It commonly

**Fig 21.11—Average monthly sunspot numbers for Solar Cycles 19 to 22.**

**Fig 21.12—Approximate conversion between solar flux and sunspot number.**

varies on a scale of 60-300 and can be related to sunspot numbers, as shown in **Fig 21.12**. The Dominion Radio Astrophysical Observatory, Penticton, British Columbia, measures the 2800-MHz solar flux daily at local noon. (Prior to June 1991, the Algonquin Radio Observatory, Ontario, made the measurements.) Radio station WWV broadcasts the latest solar-flux index at 18 minutes after each hour; WWVH does the same at 45 minutes after the hour. The Penticton solar flux is employed in a wide variety of other applications. Daily, weekly, monthly and even 13-month smoothed average solar flux readings are commonly used in propagation predictions.

High flux values generally result in higher MUFs, but the actual procedures for predicting the MUF at any given hour and path are quite complicated. Solar flux is not the sole determinant, as the angle of the sun to the Earth, season, time of day, exact location of the radio path and other factors must all be taken into account. MUF forecasting a few days or months ahead involves additional variables and even more uncertainties.

### The Sun's 27-Day Rotation

Sunspot observations also reveal that the sun rotates on its own axis. The sun is composed of extremely hot gases and does not turn uniformly. At the equator, the period is just over 25 days, but it approaches 35 days at the poles. Sunspots that affect the Earth's ionosphere, which appear almost entirely within 35° of the sun's equator, take about 26 days for one rotation. After taking into account the Earth's movement around the sun, the apparent period of solar rotation is about 27 days.

Active regions must face the Earth in

**Fig 21.13—Geomagnetic activity (measured as the A-index) also follows an 11-year cycle. Average values over the past few cycles show that geomagnetic activity peaks before and after the peak of solar flux.**

the proper orientation to have an impact on the ionosphere. They may face the Earth only once before rotating out of view, but they often persist for several solar rotations. The net effect is that solar activity often appears in 27-day cycles corresponding to the sun's rotation, even though the active regions themselves may last for several solar rotations.

### Solar-Ionospheric Disturbances

The sun's surface sometimes erupts into cataclysmic events known as *solar flares*. Solar flares release huge amounts of energy in the form of electromagnetic radiation in a wide frequency range from HF radio to X-rays and cosmic rays, as well as ejecting particles, including electrons and protons. The first indications of a solar flare reach the Earth in eight minutes as a visible brightness near a sunspot group, increases in UV and X-ray radiation and high levels of noise in the VHF radio band. The flare and associated radiation may last only a minute or two, but its effects can be dramatic.

The extra X-ray radiation causes an immediate increase in D- and E-layer ionization known as a *sudden ionospheric distur-*

*bance* (SID). Extreme D-layer absorption may cause a short-term blackout of all HF communications on the sun-facing side of the Earth. Signals in the 2 to 30-MHz range may completely disappear. In extreme cases, nearly all background noise will be gone as well. SIDs may last up to an hour, when ionospheric conditions temporarily return to normal. Cosmic rays penetrate deep into the ionosphere at the poles. This radiation produces intense ionization and consequent absorption of HF signals known as a *polar cap absorption* (PCA) event. A PCA event may last for days.

When a solar flare occurs, most of the time the electrons and protons ejected from the sun do not reach the Earth, because their trajectory takes them in another direction. If they do reach Earth, they do so 20 to 40 hours after the flare. As these relatively low-energy charged particles sweep past, they distort the Earth's geomagnetic field, causing a *geomagnetic storm*. This results in acceleration of the particles to energy levels that permit them to penetrate into the ionosphere at the poles. This tremendous influx causes auroral displays at mid-latitudes and can disrupt HF communications for several hours or longer. Extraordinary radio noise and interference can accompany geomagnetic storms and associated auroras, especially at HF. Radio emissions from solar flares may be heard as sudden increases in noise on the VHF bands.

Many geomagnetic storms result from particle clouds unrelated to solar flares. These clouds come from coronal holes, disappearing filaments and coronal mass ejections from the sun.

Effects of ionospheric storms at HF vary considerably. Communications may be temporarily blacked out during a sudden ionospheric disturbance, but ionospheric paths may be generally noisy, weakened or disrupted for several days. Transpolar signals at 14 MHz and higher may be considerably attenuated and take on a hollow multipath sound. The number of geomagnetic storms varies considerably from year to year, with peak geomagnetic activity following the peak of solar activity. See **Fig 21.13**.

Geomagnetic activity is monitored by devices known as magnetometers, which may be as simple as a magnetic compass rigged to record its movements. Small variations in the geomagnetic field are scaled to two measures known as the K and A indices. The *K index* provides an indication of magnetic activity during the previous three hours on a finite scale of 0-9. Very quiet conditions are reported as 0 or 1, while geomagnetic storm levels begin at 4. Daily geomagnetic conditions are summa-

**Table 21.3  
Geomagnetic Indices**

Description	Typical K	A Range
Quiet	0-1	0-7
Unsettled	2	8-15
Active	3	16-29
Minor storm	4	30-49
Major storm	5	50-99
Severe storm	6-9	100 and greater

**Fig 21.14—Typical electron densities for the various ionospheric regions.**

rized in an *A index* that corresponds to daily K index values. See **Table 21.3**. A worldwide network of magnetometers monitors the Earth's magnetic field, because magnetic activity varies with location.

At 18 minutes past the hour, radio stations WWV and WWVH broadcast the latest solar flux number, the average planetary A-Index and the latest Boulder K-Index. In addition, they broadcast a descriptive account of the condition of the geomagnetic field and a forecast for the next three hours. You should keep in mind that the A-Index is a description of what happened *yesterday*. Strictly speaking, the K-Index is valid only for Boulder, Colorado. However, the trend of the K-Index is very important for propagation analysis and forecasting. A rising K foretells worsening HF propagation conditions, particularly for transpolar paths. At the same time, a rising K alerts VHF operators to the possibility of enhanced auroral activity, particularly when the K-Index rises above 3.

### D-Layer Propagation

The *D layer* is the lowest region of the ionosphere, situated between 55 and 90 km (30 and 60 mi). See **Fig 21.14**. It is ionized primarily by the strong ultraviolet emission of solar hydrogen and short X-rays, both of which penetrate through the upper atmosphere. The D layer exists only during daylight, because constant radiation is needed to replenish ions that quickly recombine into neutral molecules. The D layer abruptly disappears at night so far as amateur MF and HF signals are concerned. D-layer ionization varies a small amount over the solar cycle. It is unsuitable as a refracting medium for any radio signals.

### Daytime D-Layer Absorption

Nevertheless, the D layer plays an important role in HF communications. During daylight hours, radio energy as high as 5 MHz is effectively absorbed by the D layer, severely limiting the range of daytime 1.8- and 3.5-MHz signals. Signals at 7 MHz and 10 MHz pass through the D layer and on to the E and F layers only at relatively high angles. Low-angle waves, which must travel a much longer distance through the D layer, are subject to greater absorption. As the frequency increases above 10 MHz, radio waves pass through the D layer with increasing ease.

### Nighttime D Layer

D-layer ionization falls 100-fold as soon as the sun sets and the source of ionizing radiation is removed. Low-band HF signals are then free to pass through to the

E layer (also greatly diminished at night) and on to the F layer, where the MUF is almost always high enough to propagate 1.8- and 3.5-MHz signals half way around the world. Long-distance propagation at 7 and 10 MHz generally improves at night as well, because absorption is less and low-angle waves are able to reach the F layer.

### D-Layer Ionospheric Forward Scatter

Radio signals in the 25-100 MHz range can be scattered by ionospheric irregularities, turbulence and stratification in the D and lower reaches of the E layers. Signals propagated by ionospheric forward scatter undergo very high losses, so signals are apt to be very weak. Typical scatter distances at 50 MHz are 800-1500 km (500-930 mi). This is not a common mode of propagation, but under certain conditions, ionospheric forward scatter can be very useful.

Ionospheric forward scatter is best during daylight hours from 10 AM to 2 PM local time, when the sun is highest in the sky and D-layer ionization peaks. It is worst at night. Scattering may be marginally more effective during the summer and during the solar cycle maximum due to somewhat higher D-layer ionization. The maximum path length of about 2000 km (1200 mi) is limited by the height of the scattering region, which is centered about 70 km (40 mi). Ionospheric scatter signals are typically weak, fluttery and near the noise level. Ionization from meteors sometimes temporarily raises signals well out of the noise for up to a few seconds at a time.

This mode may find its greatest use when all other forms of propagation are absent, primarily because ionospheric scatter signals are so weak. For best results at 28 and 50 MHz, a 3-element Yagi or larger, several hundred watts of power and a sensitive receiver are required. The paths are direct. CW is preferred, although, under optimal conditions, ionospheric scatter signals may be consistent enough to support SSB communications. Scattering is not efficient below 25 MHz. The very best-equipped pairs of 144-MHz stations may also be able to complete ionospheric scatter contacts.

### E-Layer Propagation

The *E layer* lies between 90 and 150 km (60 and 90 mi) altitude, but a narrower region centered at 95 to 120 km (60 to 70 mi) is more important for radio propagation. E-layer nitrogen and oxygen atoms are ionized by short UV and long X-ray radiation. The normal E layer exists primarily during daylight hours, because like

the D layer, it requires a constant source of ionizing radiation. Recombination is not as fast as in the denser D layer and absorption is much less. The E layer has a daytime critical frequency that varies between 3 and 4 MHz with the solar cycle. At night, the normal E layer all but disappears.

### Daytime E Layer

The E layer plays a small role in propagating HF signals during daytime hours. Its usual critical frequency of 3 to 4 MHz, with a maximum MUF factor of about 4.8, suggests that single-hop E-layer skip might be useful between 5 and 20 MHz at distances up to 2300 km (1400 mi). In practice this is not the case, because the potential for E-layer skip is severely limited by D-layer absorption. Signals radiated at low angles at 7 and 10 MHz, which might be useful for the longest-distance contacts, are largely absorbed by the D layer. Only high-angle signals pass through the D layer at these frequencies, but high-angle E-layer skip is typically limited to 1200 km (750 mi) or so. Signals at 14 MHz penetrate the D layer at lower angles at the cost of some absorption, but the casual operator may not be able to distinguish between signals propagated by the E layer or higher-angle F-layer propagation.

An astonishing variety of other propagation modes finds their home in the E layer, and this perhaps more than makes up for its ordinary limitations. Each of these other modes—sporadic E, field-aligned irregularities, aurora, auroral E and meteor scatter—are aberrant forms of propagation with unique characteristics. They are primarily useful only on the highest HF and lower VHF bands.

### Sporadic E

*Short skip*, long familiar on the 10-m band during the summer months, affects the VHF bands as high as 222 MHz. *Sporadic E* ( $E_s$ ), as this phenomenon is properly called, commonly propagates 28, 50 and 144-MHz radio signals between 500 and 2300 km (300 and 1400 mi). Signals are apt to be exceedingly strong, allowing even modest stations to make  $E_s$  contacts. At 21 MHz, the skip distance may only be a few hundred km. During the most intense  $E_s$  events, skip may shorten to less than 200 km (120 mi) on the 10-m band and disappear entirely on 15 m. Unusual multiple-hop  $E_s$  has supported contacts up to 10,000 km (6200 mi) on 28 and 50 MHz and more than 3,000 km (1900 mi) on 144 MHz. The first confirmed 220-MHz  $E_s$  contact was made in June 1987, but such contacts are likely to

remain very rare.

Sporadic E at midlatitudes (roughly 15 to 45°) may occur at any time, but it is most common in the Northern Hemisphere during May, June and July, with a less-intense season at the end of December and early January. Its appearance is independent of the solar cycle. Sporadic E is most likely to occur from 9 AM to noon local time and again early in the evening between 5 PM and 8 PM. Midlatitude E<sub>s</sub> events may last only a few minutes to many hours. In contrast, sporadic E is an almost constant feature of the polar regions at night and the equatorial belt during the day.

Efforts to predict midlatitude E<sub>s</sub> have not been successful, probably because its causes are complex and not well understood. Studies have demonstrated that thin and unusually dense patches of ionization in the E layer, between 100 and 110 km (60 and 70 mi) altitude and 10 to 100 km (6 to 60 mi) in extent, are responsible for most E<sub>s</sub> reflections. Sporadic-E clouds may form suddenly, move quickly from their birthplace, and dissipate within a few hours. Professional studies have recently focused on the role of heavy metal ions,

probably of meteoric origin, and wind shears as two key factors in creating the dense patchy regions of E-layer ionization.

Sporadic-E clouds exhibit an MUF that can rise from 28 MHz through the 50-MHz band and higher in just a few minutes. When the skip distance on 28 MHz is as short as 400 or 500 km (250 or 310 mi), it is an indication that the MUF has reached 50 MHz for longer paths at low launch angles. Contacts at the maximum one-hop sporadic-E distance, about 2300 km (1400 mi), should then be possible at 50 MHz. E-skip contacts as short as 700 km (435 mi) on 50 MHz, in turn, may indicate that 144-MHz contacts in the 2300-km (1400 mi) range can be completed. See Fig 21.15. Sporadic-E openings occur about a tenth as often at 144 MHz in comparison to 50 MHz and for much shorter periods.

Sporadic E can also have a detrimental effect on HF propagation by masking the F<sub>2</sub> layer from below. HF signals may be prevented from reaching the higher levels of the ionosphere and the possibilities of long F<sub>2</sub> skip. Reflections from the tops of sporadic-E clouds can also have a mask-

ing effect, but they may also lengthen the F<sub>2</sub> propagation path with a top-side intermediate hop that never reaches the Earth.

### E-Layer Field-Aligned Irregularities

Amateurs have experimented with a little-known scattering mode known as E-layer *field-aligned irregularities* (FAI) at 50 and 144 MHz since 1978. FAI commonly appears directly after sporadic-E events and may persist for several hours. Oblique-angle scattering becomes possible when electrons associated with E<sub>s</sub> clouds become aligned vertically along magnetic field lines.

Most reports suggest that 8 PM to midnight may be the most productive time for FAI. Stations attempting FAI contacts point their antennas toward a common scattering region that corresponds to an active or recent E<sub>s</sub> reflection point. The best direction must be probed experimentally, for the result is rarely along the great-circle path. Stations in south Florida, for example, have completed 144-MHz FAI contacts with north Texas when participating stations were beamed toward a common scattering region over northern Alabama.

FAI-propagated signals are weak and fluttery, reminiscent of aurora signals. Doppler shifts of as much as 3 kHz have been observed in some tests. Stations running as little as 100 W and a single Yagi should be able to complete FAI contacts during the most favorable times, but higher power and larger antennas may yield better results. Contacts have been made on 50 and 144 MHz and 222-MHz FAI seems probable as well. Expected maximum distances should be similar to other forms of E-layer propagation, or about 2300 km (1400 mi).

### Aurora

Radar signals as high as 3000 MHz have been scattered by the *aurora borealis* or northern lights (*aurora australis* in the Southern Hemisphere), but amateur aurora contacts are common only from 28 through 432 MHz. By pointing directional antennas generally north toward the center of aurora activity, oblique paths between stations up to 2300 km (1400 mi) apart can be completed. See Fig 21.16. High power and large antennas are not necessary. Stations with small Yagis and as little as 10 W output have used auroras on frequencies as high as 432 MHz, but contacts at 902 MHz and higher are exceedingly rare. Aurora propagation works just as well in the Southern Hemisphere, in which case antennas must be pointed south.

The appearance of auroras is closely

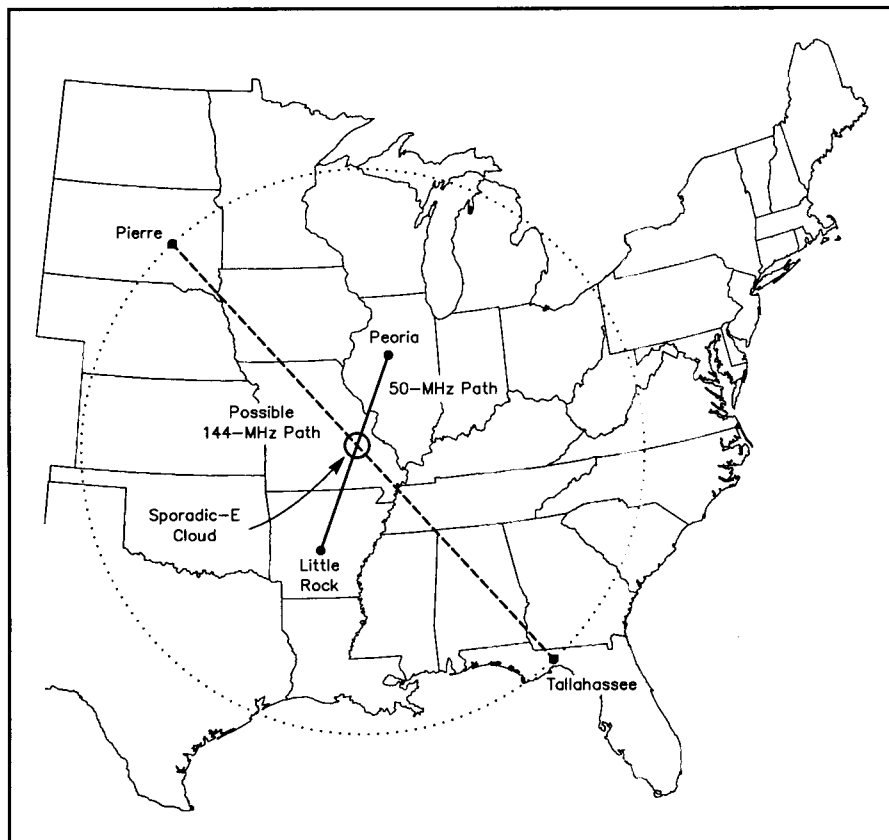

Fig 21.15—50 MHz sporadic-E contacts of 700 km (435 mi) or shorter (such as between Peoria and Little Rock) indicate that the MUF on longer paths is above 144 MHz. Using the same sporadic-E region reflecting point, 144-MHz contacts of 2200 km (1400 mi), such as between Pierre and Tallahassee, should be possible.

**Fig 21.16—Point antennas generally north to make oblique long-distance contacts on 28 through 432 MHz via aurora scattering. Optimal antenna headings may shift considerably to the east or west depending on the location of the aurora.**

linked to solar activity. During massive geomagnetic storms, high-energy particles flow into the ionosphere near the polar regions, where they ionize the gases of the E layer and higher. This unusual ionization produces spectacular visual auroral displays, which often spread southward into the midlatitudes. Auroral ionization in the E layer scatters radio signals in the VHF and UHF ranges.

In addition to scattering radio signals, auroras have other effects on worldwide radio propagation. Communication below 20 MHz is disrupted in high latitudes, primarily by absorption, and is especially noticeable over polar and near polar paths. Signals on the AM broadcast band through the 40-m band late in the afternoon may become weak and watery. The 20-m band may close down altogether. Satellite operators have also noticed that 144-MHz downlink signals are often weak and distorted when satellites pass near the polar regions. At the same time, the MUF in equatorial regions may temporarily rise dramatically, providing transequatorial paths at frequencies as high as 50 MHz.

Auroras occur most often around the spring and fall equinoxes (March-April and September-October), but auroras may appear in any month. Aurora activity generally peaks about two years before and after solar cycle maximum. Radio aurora activity is usually heard first in late afternoon and may reappear later in the evening. Auroras may be anticipated by following the A- and K-index reports on WWV. A K index of five or greater and an A index of at least 30 are indications that

a geomagnetic storm is in progress and an aurora likely. The probability, intensity and southerly extent of auroras increase as the two index numbers rise. Stations north of 42° latitude in North America experience many aurora openings each year, while those in the Gulf Coast states may hear aurora signals no more than once a year, if that often.

Aurora-scattered signals are easy to identify. On 28- and 50-MHz SSB, signals sound very distorted and somewhat wider than normal; at 144 MHz and above, the distortion may be so severe that only CW is useful. Aurora CW signals have a distinctive note variously described as a buzz, hiss or mushy sound. This characteristic aurora signal is due to Doppler broadening, caused by the movement of electrons within the aurora. An additional Doppler shift of 1 kHz or more may be evident at 144 MHz and several kilohertz at 432 MHz. This second Doppler shift is the result of massive electrical currents that sweep electrons toward the sun side of the Earth during magnetic storms. Doppler shift and distortion increase with higher frequencies, while signal strength dramatically decreases.

It is not necessary to see an aurora to make aurora contacts. Useful auroras may be 500-1000 km (310-620 mi) away and below the visual horizon. Antennas should be pointed generally north and then probed east and west to peak signals, because auroral ionization is field aligned. This means that for any pair of stations, there is an optimal direction for aurora scatter. Offsets from north are usually greatest

when the aurora is closest and often provide the longest contacts. There may be some advantage to antennas that can be elevated, especially when auroras are high in the sky.

### **Auroral E**

Radio auroras may evolve into a propagation mode known as *auroral E* at 28, 50 and rarely 144 MHz. Doppler distortion disappears and signals take on the characteristics of sporadic E. The most effective antenna headings shift dramatically away from oblique aurora paths to direct great-circle bearings. The usual maximum distance is 2300 km (1400 mi), typical for E-layer modes, but 28- and 50-MHz auroral-E contacts of 5000 km (3100 mi) are sometimes made across Canada and the northern US, apparently using two hops. Contacts at 50 MHz between Alaska and the east coasts of Canada and the northern US have been completed this way. Transatlantic 50-MHz auroral-E paths are also likely, although only one such contact has been reported.

Typically, 28- and 50-MHz auroral E appears across the northern third of the US and southern Canada when aurora activity is diminishing. This usually happens after midnight on the eastern end of the path. Auroral-E signals sometimes have a slightly hollow sound to them and build slowly in strength over an hour or two, but otherwise they are indistinguishable from sporadic E. Auroral-E paths are almost always east-west oriented, perhaps because there are few stations at very northern latitudes to take advantage of this propagation.

Auroral E may also appear while especially intense auroras are still in progress, as happened during the great aurora of March 1989. On that occasion, 50-MHz propagation shifted from Doppler-distorted aurora paths to clear-sounding auroral E over a period of a few minutes. Many 6-m operators as far south as Florida and Southern California made single- and double-hop auroral-E contacts across the country. At about the same time, the MUF reached 144 MHz for stations west of the Great Lakes to the Northeast, the first time auroral E had been reported so high in frequency. At least two other rare instances of 2-m auroral E have been reported.

### **Meteor Scatter**

Contacts between 800 and 2300 km (500 and 1400 mi) can be made at 28 through 432 MHz via reflections from the ionized trails left by meteors as they travel through the ionosphere. The kinetic energy of meteors no larger than grains of rice are sufficient to ionize a column of air

**Table 21.4**  
**Major Annual Meteor Showers**

Name	Peak Dates	Approximate Rate (meteors/hour)
Quadrantids	Jan 3	50
Arietids	Jun 7-8	60
Perseids	Aug 11-13	80
Orionids	Oct 20-22	20
Geminids	Dec 12-13	60

20 km (12 mi) long in the E layer. The particle itself evaporates and never reaches the ground, but the ionized column may persist for a few seconds to a minute or more before it dissipates. This is enough time to make very brief contacts by reflections from the ionized trails. Millions of meteors enter the Earth's atmosphere every day, but few have the required size, speed and orientation to the Earth to make them useful for meteor-scatter propagation.

Radio signals in the 30- to 100-MHz range are reflected best by meteor trails, making the 50-MHz band prime for meteor-scatter work. The early morning hours around dawn are usually the most productive, because the Earth's rotation contributes to the high speed of meteors heading into the Earth's path. Meteor contacts ranging from a second or two to more than a minute can be made nearly any morning at 28 or 50 MHz. Meteor-scatter contacts at 144 MHz and higher are more difficult because reflected signal strength and duration drop sharply with increasing frequency. A meteor trail that provides 30 seconds of communication at 50 MHz will last only a few seconds at 144 MHz, and less than a second at 432 MHz.

Meteor scatter opportunities are somewhat better during July and August because the average number of meteors entering the Earth's atmosphere peaks during those months. The best times are during one of the great annual meteor showers, when the number of useful meteors may increase ten-fold over the normal rate of five to ten per hour. See **Table 21.4**. A meteor shower occurs when the Earth passes through a relatively dense stream of particles, thought to be the remnants of a comet, that are also in orbit around the sun. The most-productive showers are relatively consistent from year to year, although several can produce great storms periodically.

Because meteors provide only fleeting moments of communication even during one of the great meteor showers, special operating techniques are often used to increase the chances of completing a contact. Prearranged schedules between two

stations establish times, frequencies and precise operating standards. Usually, each station transmits on alternate 15-second periods until enough information is pieced together a bit at a time to confirm contact. Nonscheduled random meteor contacts are common on 50 MHz and 144 MHz, but short transmissions and alert operating habits are required.

It is helpful to run several hundred watts to a single Yagi, but meteor-scatter can be used by modest stations under optimal conditions. During the best showers, a few watts and a small directional antenna are sufficient at 28 or 50 MHz. At 144 MHz, at least 100 W output and a long Yagi are needed for consistent results. Proportionately higher power is required for 222 and 432 MHz even under the best conditions.

### F-Layer Propagation

The region of the F layers, from 150 km (90 mi) to over 400 km (250 mi) altitude, is by far the most important for long-distance HF communications. F-region oxygen atoms are ionized primarily by ultraviolet radiation. During the day, ionization reaches maxima in two distinct layers. The *F<sub>1</sub>* layer forms between 150 and 250 km (90 and 160 mi) and disappears at night. The *F<sub>2</sub>* layer extends above 250 km (160 mi), with a peak of ionization around 300 km (190 mi). At night, F-region ionization collapses into one broad layer at 300-400 km (190-250 mi) altitude. Ions recombine very slowly at these altitudes, because molecular density is relatively low. Maximum ionization levels change significantly with time of day, season and year of the solar cycle.

#### *F<sub>1</sub>* Layer

The daytime *F<sub>1</sub>* layer is not important to HF communication. It exists only during daylight hours and is largely absent in winter. Radio signals below 10 MHz are not likely to reach the *F<sub>1</sub>* layer, because they are either absorbed by the D layer or refracted by the E layer. Signals higher than 20 MHz that pass through both of the lower ionospheric regions are likely to pass through the *F<sub>1</sub>* layer as well, because the *F<sub>1</sub>* MUF rarely rises above 20 MHz. Absorption diminishes the strength of any signals that continue through to the *F<sub>2</sub>* layer during the day. Some useful *F<sub>1</sub>*-layer refraction may take place between 10 and 20 MHz during summer days, yielding paths as long as 3000 km (1900 mi), but these would be practically indistinguishable from *F<sub>2</sub>* skip.

#### *F<sub>2</sub>* and Nighttime F Layers

The *F<sub>2</sub>* layer forms between 250 and 400 km (160 and 250 mi) during the day-

time and persists throughout the night as a single consolidated F region 50 km (30 mi) higher in altitude. Typical ion densities are the highest of any ionospheric layer, with the possible exception of some unusual E-layer phenomenon. In contrast to the other ionospheric layers, *F<sub>2</sub>* ionization varies considerably with time of day, season and position in the solar cycle, but it is never altogether absent. These two characteristics make the *F<sub>2</sub>* layer the most important for long-distance HF communications.

The *F<sub>2</sub>*-layer MUF is nearly a direct function of UV solar radiation, which in turn follows closely the solar cycle. During the lowest years of the cycle, the daytime MUF may climb above 14 MHz for only a few hours a day. In contrast, the MUF may rise beyond 50 MHz during peak years and stay above 14 MHz throughout the night. The virtual height of *F<sub>2</sub>* averages 330 km (210 mi), but varies between 200 and 400 km (120 and 250 mi). Maximum one-hop distance is about 4000 km (2500 mi), but it may be effectively longer when the MUF is above 40 MHz. Near-vertical incidence skywave propagation just below the critical frequency provides reliable coverage out to 200-300 km (120-190 mi) with no skip zone. It is most often observed on 7 MHz during the day.

In general, both *F<sub>2</sub>*-layer ionization and MUF build rapidly at sunrise, usually reach a maximum in the afternoon, and then decrease to a minimum prior to sunrise. Depending on the season, the MUF is generally highest within 20° of the equator and lower toward the poles. For this reason, transequatorial paths may be open at a particular frequency when all other paths are closed.

In contrast to all the other ionospheric layers, daytime ionization in the winter *F<sub>2</sub>* layer averages four times the level of the summer at the same period in the solar cycle, doubling the MUF. The reasons for this *winter anomaly* are complex, but the consequences are significant to long-range propagation. Wintertime *F<sub>2</sub>* conditions are much superior to those in summer, because the MUF is much higher.

#### Multihop F-Layer Propagation

Most HF communication beyond 4000 km (2500 mi) takes place via multiple ionospheric hops. Radio signals are reflected from the Earth back toward space for additional ionospheric refractions. A series of ionospheric refractions and terrestrial reflections commonly create paths half-way around the Earth. Each hop involves additional attenuation and absorption, so the longest-distance signals tend to be the weakest. Even so, it is possible

for signals to be propagated completely around the world and arrive back at their originating point. Multiple reflections within the F layer may bypass ground reflections altogether, creating what are known as *chordal hops*, with lower total attenuation. It takes a radio signal about 0.15 second to make a round-the-world trip.

Multihop paths can take on many different configurations, as shown in the examples of **Fig 21.17**. E-layer (especially sporadic E) and F-layer hops may be mixed. In practice, multihop signals arrive via many different paths, which often increases the problems of fading. Analyzing multihop paths is complicated by the effects of D- and E-layer absorption, possible reflections from the tops of sporadic-E layers, disruptions in the auroral zone and other phenomena.

### F-Layer Long Path

Most HF communication takes place along the shortest great-circle path between two stations. Short-path propagation is always less than 20,000 km (12,000 mi)—halfway around the Earth. Nevertheless, it may be possible at times to make the same contact in exactly the opposite direction via the *long path*. The long-path distance will be 40,000 km (25,000 mi) minus the short-path length. Signal strength via the long path is usually considerably less than the more direct short-path. When both paths are open simultaneously, there may be a distinctive sort of echo on received signals. The time interval of the echo represents the difference between the short-path and long-path distances.

Sometimes there is a great advantage to using the long path when it is open, because signals can be stronger and fading less troublesome. There are times when the short path may be closed or disrupted by E-layer blanketing, D-layer absorption or F-layer gaps, especially when operating just below the MUF. Long paths that predominantly cross the night side of the Earth, for example, are sometimes useful because they generally avoid blanketing and absorption problems. Daylight-side long paths may take advantage of higher F-layer MUFs that occur over the sunlit portions of the Earth.

### F-Layer Gray-Line

Gray-line paths can be considered a special form of long-path propagation that take into account the unusual ionospheric configuration along the twilight region between night and day. The gray line, as the twilight region is sometimes called, extends completely around the world. It is

**Fig 21.17—**Multihop paths can take many different configurations, including a mixture of E- and F-layer hops. (A) Two F-layer hops. Five or more consecutive F-layer hops are possible. (B) An E-layer hookup to the F layer. (C) A top-side E-layer reflection can shorten the distance of two F-layer hops. (D) Refraction in the E layer above the MUF is insufficient to return the signal to Earth, but it can go on to be refracted in the F layer. (E) The Pedersen ray, which originates from a signal launched at a relatively high angle above the horizon into the E or F region, may result in a single-hop path, 5000 km (3100 mi) or more. This is considerably further than the normal 4000-km (2500 mi) maximum F-region single-hop distance, where the signal is launched at a very low takeoff angle. The Pedersen ray can easily be disrupted by any sort of ionospheric gradient.

not precisely a line, for the distinction between daylight and darkness is a gradual transition due to atmospheric scattering. On one side, the gray line heralds sunrise and the beginning of a new day; on the opposite side, it marks the end of the day and sunset.

The ionosphere undergoes a significant

**Fig 21.18—**The gray line encircles the Earth, but the tilt of the equator to the poles varies over  $46^\circ$  with the seasons. Long-distance contacts can often be made halfway around the Earth along the gray line, even as low as 1.8 and 3.5 MHz. The strength of the signals, characteristic of gray-line propagation, indicates that multiple Earth-ionosphere hops are not the only mode of propagation, since losses in many such hops would be very great. Chordal hops, where the signals are confined to the ionosphere for at least part of the journey, are involved.

transformation between night and day. As day begins, the highly absorbent D and E layers are recreated, while the F-layer MUF rises from its pre-dawn minimum. At the end of the day, the D and E layers quickly disappear, while the F-layer MUF continues its slow decline from late afternoon. For a brief period just along the gray-line transition, the D and E layers are not well formed, yet the  $F_2$  MUF usually remains higher than 5 MHz. This provides a special opportunity for stations at 1.8 and 3.5 MHz.

Normally, long-distance communication on the lowest two amateur bands can take place only via all-darkness paths because of daytime D-layer absorption. The gray-line propagation path, in contrast, extends completely around the world. See **Fig 21.18**. This unusual situation lasts less than an hour at sunrise and sunset when the D-layer is largely absent, and may support contacts that are difficult or impossible at other times.

The gray line generally runs north-south, but it varies by  $23^\circ$  either side of true north as measured at the equator over the course of the year. This variation is caused by the tilt in the Earth's axis. The gray line is exactly north-south through the poles at the equinoxes (March 21 and September 21) and is at its  $23^\circ$  extremes on June 21 and December 21. Over a one-year period, the gray line crosses a  $46^\circ$  sector of the Earth north and south of the

**Fig 21.19—Schematic of a simple backscatter path. Stations A and B are too close to make contact via normal F-layer ionospheric refraction. Signals scattered back from a distant point on the Earth's surface (S), often the ocean, may be accessible to both and create a backscatter circuit.**

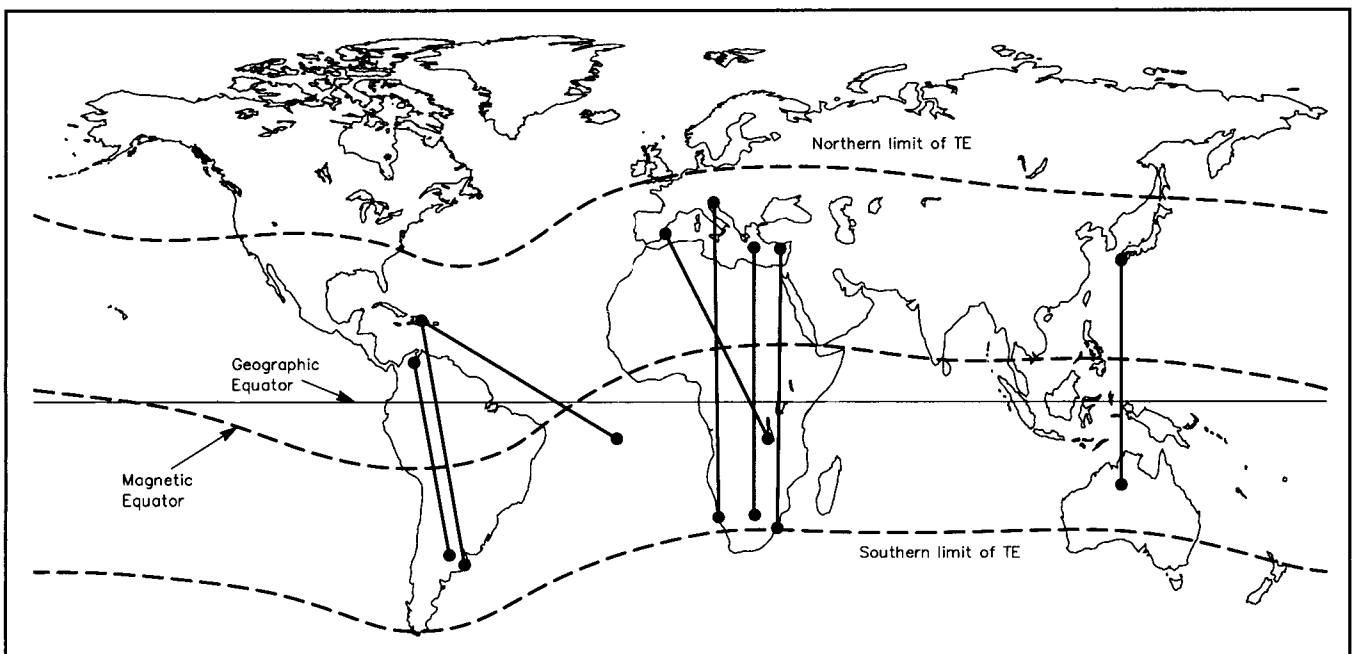

**Fig 21.20—Backscatter path across the gray line. Stations A and B are too close to make contact via normal ionospheric refraction, but may hear each other's signals scattered from point S. Station A makes use of a high-angle refraction on the day side of the gray line, where the MUF is high. Station B makes use of a night-time refraction, with a lower MUF and lower angle of propagation. Note that station A points away from B to complete the circuit.**

equator, providing optimum paths to slightly different parts of the world each day. Many commonly available computer programs plot the gray line on a flat map or globe. The *ARRL Operating Manual* provides sunrise and sunset times over the entire year for several hundred worldwide locations. The position of the gray line on any date can also be plotted manually on a globe from these data.

#### **F-Layer Backscatter and Sidescatter**

Special forms of F-layer scattering can create unusual paths within the skip zone. *Backscatter* and *sidescatter* signals are usually observed just above the MUF for the direct path and allow communications not normally possible by other means. They also provide a useful clue to propagation conditions, because reception of backscatter or sidescatter signals suggests that the MUF is just below the operating frequency. Backscattered signals are generally weak and have a characteristic hollow sound. Useful communication distances range from 100 km (60 mi) to the normal one-hop distance of 4000 km (2500 mi).

Backscatter and sidescatter are closely related and the terminology does not precisely distinguish between the two. Backscatter usually refers to single-hop signals that have been scattered by the Earth or the ocean at some distant point back toward the transmitting station. Two stations spaced a few hundred km apart can often communicate via a backscatter path near

**Fig 21.21—Transequatorial spread-F propagation takes place between stations equidistant across the geomagnetic equator. Distances up to 8000 km (5000 mi) are possible on 28 through 432 MHz. Note the geomagnetic equator is considerably south of the geographic equator in the Western Hemisphere.**

the MUF. See Fig 21.19.

Sidescatter usually refers to a circuit that is oblique to the normal great-circle path. Two stations can make use of a common side-scattering region well off the direct path, often toward the south. European and North American stations sometimes complete 28-MHz contacts via a scattering region over Africa. US and Finnish 50-MHz operators observed a similar effect early one morning in November 1989 when they made contact by beaming off the coast of West Africa.

When backscattered signals cross an area where there is a sharp gradient in ionospheric density, such as between night and day, the path may take on a different geometry, as shown in Fig 21.20. In this case, stations can communicate because backscattered signals return via the day side ionosphere on a shorter hop than the night side. This is possible because the dayside MUF is higher and thus the skip distance shorter. The net effect is to create a backscatter path between two stations within the normal skip zone.

### Transequatorial Spread-F

Discovered in 1947, *transequatorial spread-F* (TE) supports propagation between 5000 and 8000 km (3100 and 5000 mi) across the equator from 28 MHz to as high as 432 MHz. Stations attempting TE contacts must be nearly equidistant from the geomagnetic equator. Many contacts have been made at 50 and 144 MHz between Europe and South Africa, Japan and Australia and the Caribbean region and South America. Fewer contacts have been made on the 222-MHz band. TE signals have been heard at 432 MHz, but so far, no two-way contacts have resulted.

Unfortunately for most continental US stations, the geomagnetic equator dips south of the geographic equator in the Western Hemisphere, as shown in Fig 21.21, making only the most southerly portions of Florida and Texas within TE range. TE contacts from the southeastern part of the country may be possible with Argentina, Chile and even South Africa.

Transequatorial spread-F peaks between 5 PM and 10 PM during the spring and fall equinoxes, especially during the peak years of the solar cycle. The lowest probability is during the summer. Quiet geomagnetic conditions are required for TE to form. Signals have a rough aurora-like note, sometimes termed *flutter fading*. High power and large antennas are not required to work TE, as VHF stations with 100 W and single long Yagis have been successful.

The best explanation of TE propagation

Fig 21.22—Cross-section of a transequatorial spread-F signal path, showing the effects of ionospheric bulging and a double refraction above the normal MUF.

Fig 21.23—Propagation prediction chart for East Coast to Europe that appeared in QST for December 1994. An average 2800-MHz (10.7-cm) solar flux of 82 was assumed for the mid-December to mid-January period. On 10% of these days, the highest frequency propagated was predicted at least as high as the uppermost curve (the Highest Possible Frequency, or HPF, approximately 21 MHz), and for 50% of the days as high as the middle curve, the MUF. The broken lines show the Lowest Usable Frequency (LUF) for a 1500-W CW transmitter.

suggests that the F<sub>2</sub> layer near the equator bulges and intensifies slightly, particularly during solar maxima. Irregular field-aligned ionization forms shortly after sunset in an area 100-200 km (60-120 mi) north and south of the geomagnetic equator and 500-3000 km (310-1900 mi) wide. For this reason, the mode is sometimes called *transequatorial field-aligned irregularities*. It moves west with the setting sun. The MUF may increase to twice its normal level 15° either side of the geomagnetic equator.

Field alignment of ionospheric irregularities favors refraction along magnetic field lines, that is north-south. VHF and UHF signals are refracted twice over the geomagnetic equator at angles that normally would be insufficient to bring the signals back toward Earth. See Fig 21.22. The geometry is such that two shallow

Table 21.5

### Shortwave Broadcasting Bands

Frequency (MHz)	Band (m)
2.300-2.495	120
3.200-3.400	90
3.900-4.000	75
4.750-5.060	60
5.959-6.200	49
7.100-7.300	41
9.500-9.900	31
11.650-12.050	25
13.600-13.800	22
15.100-15.600	19
17.550-17.900	16
21.450-21.850	13
25.600-26.100	11

reflections in the F<sub>2</sub> layer can create north-south terrestrial paths up to 8000 km (5000 mi).

Spread-F propagation also occurs over the polar regions, but because of low population densities, amateurs have rarely reported making use of it. Near the northern magnetic pole (located in extreme northeastern Canada), spread-F is a nearly permanent feature of winter. During summer, it appears most summer nights and at least half the time during the day. There is a greater probability of polar spread-F appearing during the equinox periods and during the solar cycle maximum. Field-alignment in the polar regions suggests that some form of backscatter signals, similar to aurora, would be most likely.

### MUF PREDICTION

F-layer MUF prediction is key to forecasting HF communications paths at particular frequencies, dates and times, but forecasting is complicated by several variables. Solar radiation varies over the course of the day, season, year and solar cycle. These regular intervals provide the main basis for prediction, yet recurrence is far from reliable. In addition, forecasts are predicated on a quiet geomagnetic field, but the condition of the Earth's mag-

## MUF Prediction on the Home Computer

Like predicting the weather, predicting propagation—even with the best computer software available—is *not* an exact science. The processes occurring as a signal is propagated from one point on the Earth to another are enormously complicated and subject to an incredible number of variables. Experience and a knowledge of propagation conditions (as related to solar activity) are needed when you actually get on the air to check out the bands. Keep in mind, too, that ordinary computer programs are written mainly to calculate propagation for great-circle paths via the F layer. Scatter, skew-path, auroral and other such propagation modes may provide contacts when computer predictions indicate no contacts are possible.

Brief information about prediction programs for the IBM PC and compatible computers follows. The programs can be divided roughly into two categories. The first includes programs best suited for quick, on-the-fly predictions. Programs such as MINIMUF, IONSOUND or MINIPROP are excellent tools for assessing what bands are likely to be open in the near future, usually using recent propagation indices broadcast on WWV as data input—to see, for example, whether 21 MHz is likely to be open tomorrow morning on the path from Kansas City to Berlin, given a solar flux averaging 95 over the last several days.

The second category includes programs designed for long-term analysis and station planning. These programs require more investment in computer hardware, and will often take a considerable period of time to do their complex calculations. Most long-term planning programs benefit greatly from the use of a math coprocessor, although most of them will run, even if slowly, without a math coprocessor in the system. ASAPS, IONCAP and CAPMAN typify this category of heavy-duty propagation programs.

**Table 21.7** summarizes the features and attributes of these programs. Each program is copyrighted unless otherwise indicated.

### ASAPS V2.2

ASAPS, for Advanced Stand-Alone Prediction System, was developed in Australia. It rivals IONCAP (see below) in its analysis capability but performs calculations in significantly less time. It is also interactive with the user; transmit power levels, antennas and other parameters may be changed and the new results

viewed almost instantly without further menu entries. Available from: IPS Radio and Space Services.

### IONCAP, Version PC.27

IONCAP, short for Ionospheric Communications Analysis and Prediction, was written by an agency of the US government. This program is considered by many amateurs and professionals alike as the most comprehensive and best HF prediction program available. The program has been under development for almost 30 years, and was ported to PCs from a mainframe environment. It offers no menu; rather, an ASCII input file containing instructions and data must be prepared for program execution. This is public-domain software. (CAUTION: Under federal law, this software cannot be given to nonUS citizens without export approval.) Available from: National Technical Information Service.

### IONSOUND HDX, IONSOUND, IONSOUND PRO

There are now three versions of IONSOUND, at price levels from \$15 to \$75. The low-end IONSOUND HDX program is tailored specifically for the locations shown in the "How's DX?" column in *QST*. It provides calculated data that one would not expect from a program of its price class. Its bigger brothers, of course, provide more features—IONSOUND PRO is the top of the line model. Graphs present mode chirp plots (frequency versus delay time versus intensity), much as an ionsonde oblique-incidence sounder might produce. For each path calculation, the user must first answer several screens of questions, such as noise environment at the terminal points, receiver bandwidth, required S/N ratio, order of layer modes and so on. Available from Skywave Technologies.

### MINIMUF, Version 3.5

Written in BASIC, this was the first prediction program to become available for use on home computers. The program was published in Dec 1982 *QST* (R. B. Rose, "MINIMUF, A Simplified MUF-Prediction Program for Microcomputers," pp 36-38). This is public-domain software that has been customized by many subsequent software writers. The core algorithm's accuracy suffers outside the range from 250 to 6000 miles. MINIMUF calculations do not consider the E region, further limiting its accuracy.

netic field is most difficult to predict weeks or months ahead. For professional users of HF communications, uncertainty is a nuisance for maintaining reliable communications paths, while for many amateurs it provides an aura of mystery and chance that adds to the fun of DXing. Nevertheless, many amateurs want to know what to expect on the HF bands to make best use of available on-the-air time, plan contest strategy, ensure successful net operations or engage in other activities.

## MUF Forecasts

Long-range forecasts several months ahead, such as those published in *QST* and

other journals, provide only the most general form of prediction. A series of 30 charts, similar to **Fig 21.23**, forecast average propagation for a one-month period over specific paths each month in *QST*. The charts assume a single average solar flux value for the entire period. Early editions of *The ARRL Operating Manual* included a similar series of such charts for three representative sunspot values and a variety of paths.

The uppermost curve shows the highest frequency that will be propagated on at least 10% of the days. The given values might be exceeded considerably on a few rare days. On at least half the days, propa-

gation will be possible as high as the middle curve. Propagation will exceed the lowest curve on at least 90% of the days. The MUF on any particular day cannot be determined from the charts, but the calculated time of the MUF is reliable.

Short-range forecasts a few days ahead still depend on predictions of solar radiation and geomagnetic indices, but the previous 27-day history and current conditions improve these estimates considerably. Daily forecasts are even more reliable, as they are based on measurements of solar and geomagnetic activity no more than a few hours old. Forecasts can be made at home using

### MINIPROP PLUS, Version 2.0

MINIPROP has undergone several revisions since it first appeared. It was written primarily for the amateur community, and has an excellent user interface, with great graphics. In addition to the customary propagation data, it provides sunrise-sunset and gray-line information, along with a world map showing either long- or short-path propagation graphically. MINIPROP PLUS also produces a unique "DX Compass" showing the MUF in 12 azimuth directions for a given time of day. Available from Sheldon C. Shallon, W6EL.

### Application Tips

Because of the lag in F-layer response to a rapid increase in solar activity, it is best to use either a 5, 15 or 90-day running average of the 2800-MHz (10.7-cm) solar flux for prediction calculations. The type of application determines which is best. The 5-day mean is a short-term dynamic input; the 90-day mean is appropriate for long-term planning. The ultimate test, of course, of a prediction program is to get on the air and listen to the signals arriving from the part of the world you just modeled!

several popular programs for the personal computer, including IONCAP, IONSOUND, MINIMUF and MINIPROP PLUS. These are described in more detail in the accompanying sidebar.

### Direct Observation

Propagation conditions can be determined directly by listening to the HF band. The simplest method is to tune higher in frequency until no more long-distance stations are heard. This point is roughly just above the MUF to anywhere in the world at that moment. The highest usable amateur band would be the next lowest one. If HF stations seem to disappear around

23 MHz, for example, the 15-m band at 21 MHz might make a good choice for DXing. By carefully noting station locations as well, the MUF in various directions can also be determined quickly.

The shortwave broadcast bands (see Table 21.5) are most convenient for MUF browsing, because there are many high-powered stations on regular schedules. Take care to ensure that programming is actually transmitted from the originating country. A Radio Moscow or BBC program, for example, may be relayed to a transmitter outside Russia or England for retransmission. An excellent guide to shortwave broadcast stations is the *World*

*Radio TV Handbook*, available through the ARRL.

### WWV and WWVH

The standard time stations WWV (Ft Collins, Colorado) and WWVH (Kauai, Hawaii), which transmit on 2.5, 5, 10, 15 and 20 MHz, are also popular for propagation monitoring. They transmit 24 hours a day. Daily monitoring of these stations for signal strength and quality can quickly provide a good basic indication of propagation conditions. In addition, each hour they broadcast the geomagnetic A and K indices, the 2800-MHz (10.7-cm) solar flux, and a short forecast of conditions for

the next day. These are heard on WWV at 18 minutes past each hour and on WWVH at 45 minutes after the hour. The same information is also available by telephoning the recorded message at 303-497-3235. The K index is updated every three hours, while the A index and solar flux are updated after 2100 UTC. These data are useful for making predictions on home computers, especially when averaged over several days of solar flux observations.

## Beacons

Automated beacons in the higher amateur bands can also be useful adjuncts to propagation watching. Beacons are ideal for this purpose because most are designed to transmit 24 hours a day. Among the best organized beacon system is one designed by the Northern California DX Foundation for the 20-m band. Nine beacons on five continents transmit in successive one-minute intervals, with the tenth minute silent. More on this system, along with a longer list of HF, VHF and UHF beacons, can be found in *The ARRL Operating Manual*. Other interested groups publish updated lists of beacons with call sign, frequency, location, transmitter mode, power, and antenna. Beacons often include location as part of their automated

message, and many can be located from their call sign. Thus, even casual scanning of beacon subbands can be useful. **Table 21.6** provides the frequencies where beacons useful to HF propagation are most commonly placed.

## PROPAGATION IN THE TROPOSPHERE

All radio communication involves propagation through the troposphere for at least part of the signal path. Radio waves traveling through the lowest part of the atmosphere are subject to refraction, scattering and other phenomena, much like ionospheric effects. Tropospheric conditions are rarely significant below 30 MHz, but they are very important at 50 MHz and higher. Much of the long-distance work on the VHF, UHF and microwave bands depends on some form of tropospheric propagation. Instead of watching solar activity and geomagnetic indices, those who use tropospheric propagation are much more concerned about the weather.

### Line of Sight

At one time it was thought that communications in the VHF range and higher would be restricted to line-of-sight paths. Although this has not proven to be the case

even in the microwave region, the concept of line of sight is still useful in understanding tropospheric propagation. In the vacuum of space or in a completely homogeneous medium, radio waves do travel essentially in straight lines, but these conditions are almost never met in terrestrial propagation.

Radio waves traveling through the troposphere are ordinarily refracted slightly earthward. The normal drop in temperature, pressure and water-vapor content with increasing altitude change the index of refraction of the atmosphere enough to cause refraction. Under average conditions, radio waves are refracted toward Earth enough to make the horizon appear 1.15 times farther away than the visual horizon. Under unusual conditions, tropospheric refraction may extend this range significantly.

A simple formula can be used to estimate the distance to the radio horizon under average conditions:

$$d = \sqrt{2h}$$

where

d = distance to the radio horizon, miles  
h = height above average terrain, ft,

$$d = \sqrt{17h}$$

where

d = distance to the radio horizon, km  
h = height above average terrain, m.

The distance to the radio horizon for an antenna 30 m (98 ft) above average terrain is thus 22.6 km (14 mi), a station on top of a 1000-m (3280-ft) mountain has a radio horizon of 130 km (80 mi).

## Atmospheric Absorption

Atmospheric gases, most notably oxygen and water vapor, absorb radio signals, but neither is a significant factor below 10 GHz. Attenuation from rain becomes important at 3.3 GHz, where signals passing through 20 km (12 mi) of heavy showers incur an additional 0.2 dB loss. That same rain would impose 12 dB additional loss at 10 GHz and losses continue to increase with frequency. Heavy fog is similarly a problem only at 5.6 GHz and above. More detailed information about atmospheric absorption in the microwave bands can be found in the *ARRL UHF/Microwave Experimenter's Manual*.

## Tropospheric Scatter

Contacts beyond the radio horizon out to a working distance of 100 to 500 km (60 to 310 mi), depending on frequency, equipment and local geography, are made every day without the aid of obvious propagation enhancement. At 1.8 and

**Table 21.6**  
**Popular Beacon Frequencies**

Frequencies (MHz)	Comments
14.100	Northern California DX Foundation beacons
28.2-28.3	Several dozen beacons worldwide
50.0-50.1	Most US beacons are within 50.06-50.08 MHz
70.03-70.13	Beacons in England, Ireland, Gibraltar and Cyprus

**Fig 21.24—Tropospheric-scatter path geometry.** The lower boundary of the common scattering volume is limited by the take-off angle of both stations. The upper boundary of 10 km (6 mi) altitude is the limit of efficient scattering in the troposphere. Signal strength increases with the scattering volume.

3.5 MHz, local communication is due mostly to ground wave. At higher frequencies, especially in the VHF range and above, the primary mechanism is scattering in the troposphere, or *troposcatter*.

Most amateurs are unaware that they use troposcatter even though it plays an essential role in most local communication. Water vapor droplets, small gradients in the index of refraction of the lower atmosphere due to turbulence, changes in temperature and humidity, clouds, dust and other naturally occurring particles scatter a portion of the radio signal. That tiny part that is scattered forward and toward the Earth creates the over-the-horizon paths. Troposcatter path losses are considerable and increase with frequency.

The maximum distance that can be linked via troposcatter is limited by the height of a scattering volume common to two stations, shown schematically in Fig 21.24. The highest altitude for which scattering is efficient at amateur power levels is about 10 km (6 mi). An application of the distance-to-the-horizon formula yields 800 km (500 mi) as the limit for troposcatter paths, but typical maxima are more like half that. Tropospheric scatter varies little with season or time of day, but it is difficult to assess the effect of weather on troposcatter alone. Variations in tropospheric refraction, which is very sensitive to the weather, probably account for most of the observed day-to-day differences in troposcatter signal strength.

Troposcatter does not require special operating techniques or equipment, as it is used unwittingly all the time. In the absence of all other forms of propagation, especially at VHF and above, the usual working range is essentially the maximum troposcatter distance. Ordinary working range increases most dramatically with antenna height, because that lowers the take-off angle to the horizon. Working range increases less quickly with antenna gain and transmitter power. For this reason, a mountaintop is the choice location for extending ordinary troposcatter working distances.

### Rain Scatter in the Troposphere

Scatter from raindrops is a special case of troposcatter practical in the 1296-MHz to 10-GHz range. Stations simply point their antennas toward a common area of rain. A certain portion of radio energy is scattered by the raindrops, making possible over-the-horizon or obstructed-path contacts, even with low power. The theoretical range for rain scatter is as great as 600 km (370 mi), but the experience of amateurs in the microwave bands suggests that expected distances are less than

200 km (120 mi). Snow and hail make less efficient scattering media unless the ice particles are partially melted. Smoke and dust particles are too small for extraordinary scattering, even in the microwave bands.

### Refraction and Ducting in the Troposphere

Radio waves are refracted by natural gradients in the index of refraction of air with altitude, due to changes in temperature, humidity and pressure. Refraction under standard atmospheric conditions extends the radio horizon somewhat beyond the visual line of sight. Favorable weather conditions further enhance normal tropospheric refraction, lengthening the useful VHF and UHF range by several hundred kilometers and increasing signal strength. Higher frequencies are more sensitive to refraction, so its effects may be observed in the microwave bands before they are apparent at lower frequencies.

Ducting takes place when refraction is so great that radio waves are bent back to the surface of the Earth. When tropospheric ducting conditions exist over a wide geographic area, signals may remain very strong over distances of 1500 km (930 mi) or more. Ducting results from the gradient created by a sharp increase in temperature with altitude, quite the opposite of normal atmospheric conditions. A simultaneous drop in humidity contributes to increased refractivity. Useful temperature inversions form between 250 and 2000 m (800-6500 ft) above ground. The elevated inversion and the Earth's surface act something like the boundaries of a natural open-ended waveguide. Radio waves of the right frequency range caught inside the duct will be propagated for long distances with relatively low losses. Several common weather conditions can create temperature inversions.

### Radiation Inversions in the Troposphere

Radiation inversions are probably the most common and widespread of the various weather conditions that affect propagation. Radiation inversions form only over land after sunset as a result of progressive cooling of the air near the Earth's surface. As the Earth cools by radiating heat into space, the air just above the ground is cooled in turn. At higher altitudes, the air remains relatively warmer, thus creating the inversion. A typical radiation-inversion temperature profile is shown in Fig 21.25.

The cooling process may continue through the evening and predawn hours, creating inversions that extend as high as

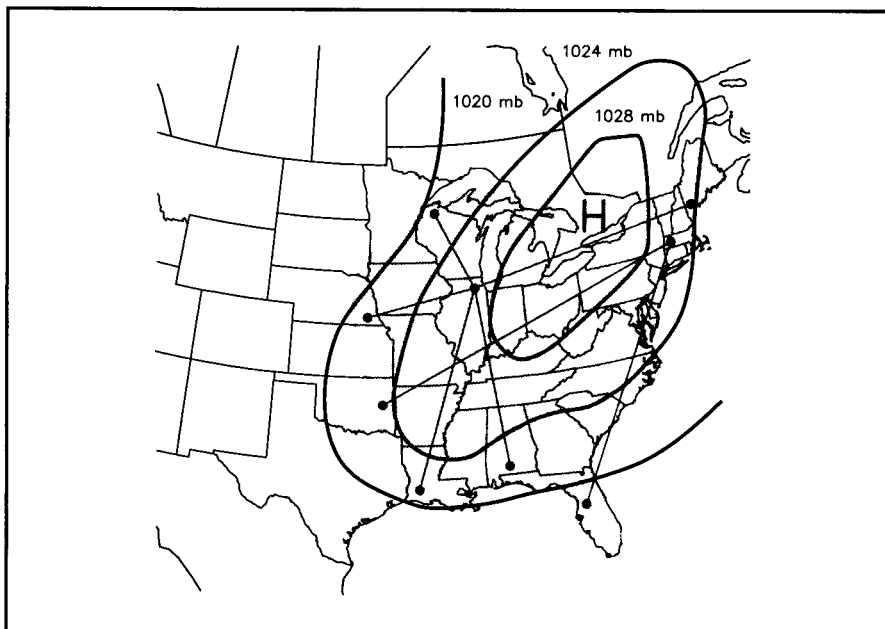

**Fig 21.25—Temperature and dewpoint profile of an early-morning radiation inversion. Fog may form near the ground. The midday surface temperature would be at least 30°C.**

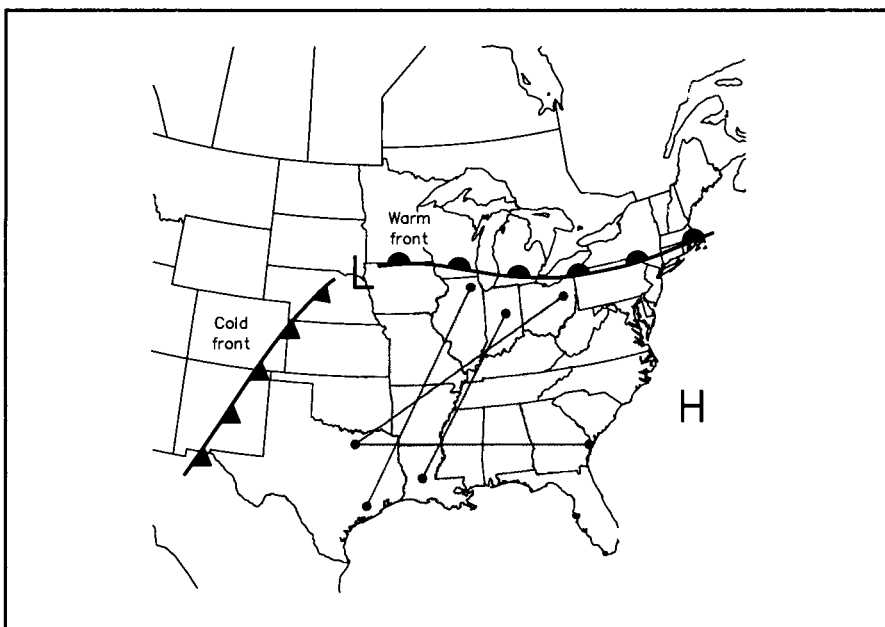

**Fig 21.26—Temperature and humidity profile across an elevated duct at 1000 m altitude. Such inversions typically form in summertime high-pressure systems. Note the air is very dry in the inversion.**

500 m (1500 feet). Radiation inversions are most common during clear, calm, summer evenings. They are more distinct in dry climates, in valleys and over open ground. Their formation is inhibited by wind, wet ground and cloud cover. Although radiation inversions are common and widespread, they are rarely strong enough to cause true ducting. The enhanced conditions so often observed after sunset during the summer are usually a result of this mild kind of inversion.

**Fig 21.27—**Surface weather map for September 13, 1993, shows that the eastern US was dominated by a sprawling high-pressure system. The shaded portion shows the area in which ducting conditions existed on 144 through 1286 MHz and higher.

**Fig 21.28—**Surface weather map for June 2, 1980, with a typical spring wave cyclone over the southeastern quarter of the US. The shaded portion shows where ducting conditions existed.

### High-Pressure Weather Systems

Large, sluggish, high-pressure systems (or anticyclones) create the most dramatic and widespread tropospheric ducts. Inversions in high-pressure systems are created by air that is sinking. As air descends, it is compressed and heated. Layers of warmer air—temperature inversions—often form between 500 and 3000 m

(1500-10,000 ft) altitude, as shown in Fig 21.26. Ducts usually intensify during the evening and early morning hours, when surface temperatures drop and suppress the tendency for daytime ground-warmed air to rise. In the Northern Hemisphere, the longest and strongest radio paths usually lie to the south of high-pressure centers. See Fig 21.27.

Sluggish high-pressure systems likely

to contain strong temperature inversions are common in late summer over the eastern half of the US. They generally move southeastward out of Canada and linger for days over the Midwest, providing many hours of extended propagation. The southeastern part of the country and the lower Midwest experience the most high-pressure openings; the upper Midwest and East Coast somewhat less frequently; the western mountain regions rarely.

Semipermanent high-pressure systems, which are nearly constant climatic features in certain parts of the world, sustain the longest and most exciting ducting paths. The Eastern Pacific High, which migrates northward off the coast of California during the summer, has been responsible for the longest ducting paths reported to date. Countless contacts in the 4000-km (2500 mi) range have been made from 144 MHz through 5.6 GHz between California and Hawaii. The Bermuda High is a nearly permanent feature of the Caribbean area, but during the summer it moves north and often covers the southeastern US. It has supported contacts in excess of 2800 km (1700 mi) from Florida and the Carolinas to the West Indies, but its full potential has not been exploited. Other semipermanent highs lie in the Indian Ocean, the western Pacific and off the coast of western Africa.

### Wave Cyclone

The wave cyclone is a more dynamic weather system that usually appears during the spring over the middle part of the American continent. The wave begins as a disturbance along a boundary between cooler northern and warmer southern air masses. Southwest of the disturbance, a cold front forms and moves rapidly eastward, while a warm front moves slowly northward on the eastward side. When the wave is in its open position, as shown in Fig 21.28, north-south radio paths 1500 km (930 mi) and longer may be possible in the area to the east of the cold front and south of the warm front, known as the warm sector. East-west paths nearly as long may also open in the southerly parts of the warm sector.

Wave cyclones are rarely productive for more than a day, because the eastward-moving cold front eventually closes off the warm sector. Wave cyclone temperature inversions are created by a southwesterly flow of warm, dry air above 1000 m (3200 ft) that covers relatively cooler and moister gulf air flowing northward near the Earth's surface. Successive waves spaced two or three days apart may form along the same frontal boundary.

## Warm Fronts and Cold Fronts

Warm fronts and cold fronts sometimes bring enhanced tropospheric conditions, but rarely true ducting. A warm front marks the surface boundary between a mass of warm air flowing over an area of relatively cooler and more stationary air. Inversion conditions may be stable enough several hundred kilometers ahead of the warm front to create extraordinary paths.

A cold front marks the surface boundary between a mass of cool air that is trying to wedge itself under more stationary warm air. The warmer air is pushed aloft in a narrow band behind the cold front, creating a strong but highly unstable temperature inversion. The best chance for enhancement occurs parallel to and behind the passing cold front.

## Advective Winds

Certain kinds of wind may also create useful inversions. The *Chinook* wind that blows off the eastern slopes of the Rockies can flood the Great Plains with warm and very dry air, primarily in the springtime. If the ground is cool or snow-covered, a strong inversion can extend as far as Canada to Texas and east to the Mississippi River. Similar kinds of *foehn* winds, as these mountain breezes are called, can be found in the Alps, Caucasus Mountains and other places.

The land breeze is a light, steady, cool wind that blows 50 to 100 km (30 to 60 mi) across coastal areas. Land breezes develop after sunset on clear summer evenings. The land cools more quickly than the adjacent ocean. Air cooled over the land flows near the surface of the Earth toward the ocean to displace relatively warmer air that is rising. See Fig 21.29. The warmer ocean air, in turn, travels at 200-300 m (600-1000 ft) altitude to replace the cool surface air. The land-sea circulation of cool air near the ground and warm air aloft creates a mild inversion that may remain for hours. Land-breeze inversions often bring enhanced conditions and occasionally allow contacts in excess of 800 km (500 mi) along coastal areas.

In southern Europe, a hot, dry wind known as the *sirocco* sometimes blows northward from the Sahara Desert over relatively cooler and moister Mediterranean air. Sirocco inversions can be very strong and extend from Israel and Lebanon westward past the Straits of Gibraltar. Sirocco-type inversions are probably responsible for record-breaking microwave contacts in excess of 1500 km (930 mi) across the Mediterranean.

## Evaporation Inversion

Over warm water, such as the Caribbean

Fig 21.29—Land-breeze convection along a coast after sunset creates a temperature inversion over the land.

and other tropical seas, evaporation inversions may create ducts that are useful in the microwave region between 3.3 and 24 GHz. This inversion depends on a sharp drop in water-vapor content rather than on an increase in temperature to create ducting conditions. Air just above the surface of water at least 30°C is saturated because of evaporation. Humidity drops significantly within 3 to 10 m (10 to 30 ft) altitude, creating a very shallow but stable duct. Losses due to water vapor absorption may be intolerable at the highest ducting frequencies, but breezes may raise the effective height of the inversion and open the duct to longer wavelengths. Stations must be set up right on the beaches to ensure being inside an evaporation inversion.

## Tropospheric Fading

Tropospheric turbulence and small changes in the weather are responsible for most fading at VHF and higher. Local weather conditions, such as precipitation, warm air rising over cities and the effects of lakes and rivers, can all contribute to tropospheric instabilities that affect radio propagation. Fast-flutter fading at 28 MHz and above is often the result of an airplane that temporarily creates a second propagation path. Flutter results as the phase relationship between the ordinary tropospheric signal and that reflected by the airplane change with the airplane's movement.

## EXTRATERRESTRIAL PROPAGATION

Communication of all sorts into space has become increasingly important. Amateurs confront extraterrestrial propagation

when accessing satellite repeaters or using the moon as a reflector. Special propagation problems arise from signals that travel from the Earth through the ionosphere (or a substantial portion of it) and back again. Tropospheric and ionospheric phenomena, so useful for terrestrial paths, are unwanted and serve only as a nuisance for space communication. A phenomenon known as Faraday rotation may change the polarization of radio waves traveling through the ionosphere, presenting special problems to receiving weak signals. Cosmic noise also becomes an important factor when antennas are intentionally pointed into space.

## Faraday Rotation

Magnetic and electrical forces rotate the polarization of radio waves passing through the ionosphere. For example, signals that leave the Earth as horizontally polarized, and return after a reflection from the moon may not arrive with the same polarization. An additional 20 dB of path loss is incurred when polarization is shifted by 90°, an intolerable amount when signals are marginal.

Faraday rotation is difficult to predict and its effects change over time and with operating frequency. At 144 MHz, the polarization of space waves may shift back into alignment with the antenna within a few minutes, so often just waiting can solve the Faraday problem. At 432 MHz, it may take half an hour or longer for the polarization to become realigned. Use of circular polarization completely eliminates this problem, but creates a new one for EME paths. The sense of circularly polarized signals is reversed with reflection, so two complete antenna systems are

normally required, one with left-hand and one with right-hand polarization.

## Earth-Moon-Earth

Amateurs have used the moon as a reflector on the VHF and UHF bands since 1960. Maximum allowable power and large antennas, along with the best receivers, are normally required to overcome the extreme free-space and reflection losses involved in Earth-Moon-Earth (EME) paths. More modest stations make EME contacts by scheduling operating times when the Moon is at perigee on the horizon. The Moon, which presents a target only one-half degree wide, reflects only 7% of the radio signals that reach it. Techniques have to be designed to cope with Faraday rotation, cosmic noise, Doppler shift (due to the Moon's movements) and other difficulties. In spite of the problems involved, hundreds of stations have made contacts via the Moon on all bands from 50 MHz to 10 GHz. The techniques of EME communication are discussed in the chapter on **Repeaters, Satellites, EME and DFing**.

## Satellites

Accessing amateur satellites generally does not involve huge investments in antennas and equipment, yet station design does have to take into account special challenges of space propagation. Free-space loss is a primary consideration, but it is manageable when satellites are only a few hundred kilometers distant. Free-space path losses to satellites in high Earth orbits are considerably greater, and appropriately larger antennas and higher powers are needed.

Satellite frequencies below 30 MHz can be troublesome. Ionospheric absorption and refraction may prevent signals from reaching space, especially to satellites at very low elevations. In addition, man-made and natural sources of noise are high. VHF and especially UHF are largely immune from these effects, but free-space path losses are greater. Problems related to polarization, including Faraday rotation, intentional or accidental satellite tumbling and the orientation of a satellite's antenna in relation to terrestrial antennas, are largely overcome by using circularly polarized antennas. More on using satellites can be found in the chapter on **Repeaters, Satellites, EME and DFing**.

## NOISE AND PROPAGATION

Noise simply consists of unwanted radio signals that interfere with desired communications. In some instances, noise imposes the practical limit on the lowest usable frequencies. Noise may be classified by its sources: man-made, terrestrial

and cosmic. Interference from other transmitting stations on adjacent frequencies is not usually considered noise and may be controlled, to a some degree anyway, by careful station design.

## Man-Made Noise

Many unintentional radio emissions result from man-made sources. Broadband radio signals are produced whenever there is a spark, such as in contact switches, electric motors, gasoline engine spark plugs and faulty electrical connections. Household appliances, such as fluorescent lamps, microwave ovens, lamp dimmers and anything containing an electric motor may all produce undesirable broadband radio energy. Devices of all sorts, especially computers and anything controlled by microprocessors, television receivers and many other electronics also emit radio signals that may be perceived as noise well into the UHF range. In many cases, these sources are local and can be controlled with proper measures. See the **EMI** chapter.

High-voltage transmission lines and associated equipment, including transformers, switches and lightning arresters, can generate high-level radio signals over a wide area, especially if they are corroded or improperly maintained. Transmission lines may act as efficient antennas at some frequencies, adding to the noise problem. Certain kinds of street lighting, neon signs and industrial equipment also contribute their share of noise.

## Lightning

Static is a common term given to the ear-splitting crashes of noise commonly heard on nearly all radio frequencies, although it is most severe on the lowest frequency bands. Atmospheric static is primarily caused by lightning and other natural electrical discharges. Static may result from close-by thunderstorms, but most static originates with tropical storms. Like any radio signals, lightning-produced static may be propagated over long distances by the ionosphere. Thus static is generally higher during the summer, when there are more thunderstorms, and at night, when radio propagation generally improves. Static is often the limiting factor on 1.8 and 3.5 MHz, making winter a more favorable time for using these frequencies.

## Precipitation Static

Precipitation static is an almost continuous hash-type noise that builds in intensity, abruptly ends, and then builds again in cycles of a few seconds to as long as a minute. Precipitation static most often accompanies summer thunderstorms, but

it occurs with winter rain and snow as well. Passing raindrops or snowflakes induce an electrical charge on an antenna, especially Yagi arrays on tall towers. When the voltage builds to some critical level, it discharges into the atmosphere, sometimes with an audible pop, and then begins recharging. Precipitation static can be a nuisance from HF well into the VHF range.

## Cosmic Sources

The sun, distant stars, galaxies and other cosmic features all contribute radio noise well into the gigahertz range. These cosmic sources are perceived primarily as a more-or-less constant background noise at HF. In the VHF range and higher, specific sources of cosmic noise can be identified and may be a limiting factor in terrestrial and space communications. The sun is by far the greatest source of radio noise, but its effects are largely absent at night. The center of our own galaxy is nearly as noisy as the sun. Galactic noise is especially noticeable when high-gain VHF and UHF antennas, such as may be used for satellite or EME communications, are pointed toward the center of the Milky Way. Other star clusters and galaxies are also radio hot-spots in the sky. Finally, there is a much lower cosmic background noise that seems to cover the entire sky.

# Station Setup and Accessory Projects

## 22

**A**lthough many hams never try to build a major project, such as a transmitter, receiver or amplifier, they do have to assemble the various components into a working station. There are many benefits to be derived from assembling a safe, comfortable, easy-to-operate collection of radio gear, whether the shack is at home, in the car or in a field. This chapter, written by Wally Blackburn, AA8DX, covers the many aspects of setting up an efficient station.

This chapter will detail some of the “how tos” of setting up a station for fixed,

mobile and portable operation. Such topics as station location, finding adequate power sources, station layout and cable routing are covered, along with some of the practical aspects of antenna erection and maintenance.

Regardless of the type of installation you are attempting, good planning greatly increases your chances of success. Take the time to think the project all the way through, consider alternatives, and make rough measurements and sketches during your planning and along the way. You will

save headaches and time by avoiding “shortcuts.” What might seem to save time now may come back to haunt you with extra work when you could be enjoying your shack.

One of the first considerations should be to determine what type of operating you intend to do. While you do not want to strictly limit your options later, you need to consider what you want to do, how much you have to spend and what room you have to work with. There is a big difference between a casual operating position and a “big gun” contest station, for example.

## Fixed Stations

### SELECTING A LOCATION

Selecting the right location for your station is the first and perhaps the most important step in assembling a safe, comfortable, convenient station. The exact location will depend on the type of home you have and how much space can be devoted to your station. Fortunate amateurs will have a spare room to devote to housing the station; some may even have a separate building for their exclusive use. Most must make do with a spot in the cellar or attic, or a corner of the living room is pressed into service.

Examine the possibilities from several angles. A station should be comfortable; odds are good that you’ll be spending a lot of time there over the years. Some unfinished basements are damp and drafty—not an ideal environment for several hours of leisurely hamming. Attics have their drawbacks, too; they can be stifling during warmer months. If possible, locate your station away from the heavy traffic areas of your home. Operation of your station should not interfere with family life. A night of chasing DX on 80 m may be exciting to you, but the other members

**Fig 22.1—**Danny, KD4HQV, appreciates the simplicity that his operating position affords. (Photo courtesy Conard Murray, WS4S)

**Fig 22.2—VE6AFO's QSL card reveals an impressive array of gear. Although many hams would appreciate having this much space to devote to a station, most of us must make do with less.**

**Fig 22.3—Scott, KA9FOX, operated this well laid-out station, W9UP, during a recent contest. (Photo courtesy NØBSH)**

of your household may not share your enthusiasm.

Keep in mind that you must connect your station to the outside world. The location you choose should be convenient to a good power source and an adequate ground. If you use a computer and modem, you may need access to a telephone jack. There should be a fairly direct route to the outside for running antenna feed lines, rotator control cables and the like.

Although most homes will not have an "ideal" space meeting all requirements, the right location for you will be obvious after you scout around. The amateurs whose stations are depicted in **Figs 22.1 through 22.3** all found the right spot for them. Weigh the trade-offs and decide which features you can do without and which are necessary for your style of operation. If possible pick an area large enough for future expansion.

## THE STATION GROUND

Grounding is an important factor in overall station safety, as detailed in the **Safety** chapter. An effective ground system is necessary for every amateur station. The mission of the ground system is two-fold. First, it reduces the possibility of electrical shock if something in a piece of equipment should fail and the chassis or cabinet becomes "hot." If connected to a properly grounded outlet, a three-wire electrical system grounds the chassis. Much amateur equipment still uses the ungrounded two-wire system, however. A ground system to prevent shock hazards is generally referred to as *dc ground*.

The second job the ground system must perform is to provide a low-impedance path to ground for any stray RF current inside the station. Stray RF can cause

equipment to malfunction and contributes to RFI problems. This low-impedance path is usually called *RF ground*. In most stations, dc ground and RF ground are provided by the same system.

## Ground Noise

Noise in ground systems can affect our sensitive radio equipment. It is usually related to one of three problems:

- 1) Insufficient ground conductor size
- 2) Loose ground connections
- 3) Ground loops

These matters are treated in precise scientific research equipment and certain industrial instruments by attention to certain rules. The ground conductor should be at least as large as the largest conductor in the primary power circuit. Ground conductors should provide a solid connection to both ground and to the equipment being grounded. Liberal use of lock washers and star washers is highly recommended. A loose ground connection is a tremendous source of noise, particularly in a sensitive receiving system.

Ground loops should be avoided at all costs. A short discussion of what a ground loop is and how to avoid them may lead you down the proper path. A ground loop is formed when more than one ground current is flowing in a single conductor. This commonly occurs when grounds are "daisy-chained" (series linked). The correct way to ground equipment is to bring all ground conductors out radially from a common point to either a good driven earth ground or a cold-water system. If one or more earth grounds are used, they should be bonded back to the service entrance panel. Details appear in the **Safety** chapter.

Ground noise can affect transmitted and received signals. With the low audio levels required to drive amateur transmitters, and the ever-increasing sensitivity of our receivers, correct grounding is critical.

## STATION POWER

Amateur Radio stations generally require a 120-V ac power source. The 120-V ac is then converted to the proper ac or dc levels required for the station equipment. Power supply theory is covered in the **Power Supplies** chapter, and safety issues are covered in the **Safety** chapter. If your station is located in a room with electrical outlets, you're in luck. If your station is located in the basement, an attic or another area without a convenient 120-V source, you will have to run a line to your operating position.

## Surge Protection

Typically, the ac power lines provide an adequate, well-regulated source of electrical power for most uses. At the same time, these lines are fraught with frequent power surges that, while harmless to most household equipment, may cause damage to more sensitive devices such as computers or test equipment. A common method of protecting these devices is through the use of surge protectors. More information on these and lightning protection is in the **Safety** chapter.

## STATION LAYOUT

Station layout is largely a matter of personal taste and needs. It will depend mostly on the amount of space available, the equipment involved and the types of operating to be done. With these factors in mind, some basic design considerations apply to all stations.

**Fig 22.4**—The basement makes a good location if it is dry. A ready-to-assemble computer desk makes an ideal operating table at a reasonable price. This setup belongs to WK8H. (Photo courtesy AA8DX)

### The Operating Table

The operating table may be an office or computer desk, a kitchen table or a custom-made bench. What you use will depend on space, materials at hand and cost. The two most important considerations are height and size of the top. Most commercial desks are about 29 inches above the floor. This is a comfortable height for most adults. Heights much lower or higher than this may cause an awkward operating position.

The dimensions of the top are an important consideration. A deep (36 inches or more) top will allow plenty of room for equipment interconnections along the back, equipment about midway and room for writing toward the front. The length of the top will depend on the amount of equipment being used. An office or computer desk makes a good operating table. These are often about 36 inches deep and 60 inches wide. Drawers can be used for storage of logbooks, headphones, writing materials, and so on. Desks specifically designed for computer use often have built-in shelves that can be used for equipment stacking. Desks of this type are available ready-to-assemble at most discount and home improvement stores. The low price and adaptable design of these desks make them an attractive option for an operating position. An example is shown in Fig 22.4.

### Stacking Equipment

No matter how large your operating table is, some vertical stacking of equipment may be necessary to allow you to reach everything from your chair. Stacking pieces of equipment directly on top of one another is not a good idea because most amateur equipment needs air flow around it for cooling. A shelf like that

**Fig 22.5**—A simple but strong equipment shelf can be built from readily available materials. Use  $\frac{3}{4}$ -inch plywood along with glue and screws for the joints for adequate strength.

**Fig 22.6**—Example station layout as seen from the front (A) and the top (B). The equipment is spaced far enough apart that air circulates on all sides of each cabinet.

shown in Fig 22.5 can improve equipment layout in many situations. Dimensions of the shelf can be adjusted to fit the size of your operating table.

### Arranging the Equipment

When you have acquired the operating table and shelving for your station, the next

task is arranging the equipment in a convenient, orderly manner. The first step is to provide power outlets and a good ground as described in a previous section. Be conservative in estimating the number of power outlets for your installation; radio equipment has a habit of multiplying with time, so plan for the future at the outset.

**Fig 22.6** illustrates a sample station layout. The rear of the operating table is spaced about 1½ ft from the wall to allow easy access to the rear of the equipment. This installation incorporates two separate operating positions, one for HF and one for VHF. When the operator is seated at the HF operating position, the keyer and transceiver controls are within easy reach. The keyer, keyer paddle and transceiver are the most-often adjusted pieces of equipment in the station. The speaker is positioned right in front of the operator for the best possible reception. Accessory equipment not often adjusted, including the amplifier, antenna switch and rotator control box, is located on the shelf above the transceiver. The SWR/power meter and clock, often consulted but rarely touched, are located where the operator can view them without head movement. All HF-related equipment can be reached without moving the chair.

This layout assumes that the operator is right-handed. The keyer paddle is operated with the right hand, and the keyer speed and transceiver controls are operated with the left hand. This setup allows the operator to write or send with the right hand without having to cross hands to adjust the controls. If the operator is left-handed, some repositioning of equipment is necessary, but the idea is the same. For best results during CW operation, the paddle should be weighted to keep it from "walking" across the table. It should be oriented such that the operator's entire arm from wrist to elbow rests on the table top to prevent fatigue.

Some operators prefer to place the station transceiver on the shelf to leave the table top clear for writing. This arrangement leads to fatigue from having an unsupported arm in the air most of the time. If you rest your elbows on the table top, they will quickly become sore. If you rarely operate for prolonged periods, however, you may not be inconvenienced by having the transceiver on the shelf. The real secret to having a clear table top for logging, and so on, is to make the operating table deep enough that your entire arm from elbow to wrist rests on the table with the front panels of the equipment at your fingertips. This leaves plenty of room for paperwork, even with a microphone and keyer paddle on the table.

The VHF operating position in this station is similar to the HF position. The amplifier and power supply are located on the shelf. The station triband beam and VHF beam are on the same tower, so the rotator control box is located where it can be seen and reached from both operating positions. This operator is active on packet

**Fig 22.7**—It was back to basics for Elias, K4IX, during a recent Field Day.

**Fig 22.8**—Richard, WB5DGR, uses a homebrew 1.5-kW amplifier to seek EME contacts from this nicely laid out station.

**Fig 22.9**—Labels on the cables make it much easier to rearrange things in the station. Labeling ideas include masking tape, cardboard labels attached with string and labels attached to fasteners found on plastic bags (such as bread bags).

radio on a local VHF repeater, so the computer, printer, terminal node controller and modem are all clustered within easy reach of the VHF transceiver.

This sample layout is intended to give you ideas for designing your own station. Study the photos of station layouts presented here, in other chapters of this *Handbook* and in *QST*. Visit the shacks of amateur friends to view their ideas. Station layout is always changing as you acquire

new gear, dispose of old gear, change operating habits and interests or become active on different bands. Configure the station to suit your interests, and keep thinking of ways to refine the layout. **Figs 22.7** and **22.8** show station arrangements tailored for specific purposes.

Equipment that is adjusted frequently sits on the table top, while equipment requiring infrequent adjustment is perched on a shelf. All equipment is positioned so the operator does not have to move the chair to reach anything at the operating position.

## Aids for Hams with Disabilities

A station used by an amateur with physical disabilities or sensory impairments may require adapted equipment or particular layout considerations. The station may be highly customized to meet the operator's needs or just require a bit of "tweaking."

The myriad of individual needs makes describing all of the possible adaptive methods impractical. Each situation must be approached individually, with consideration to the operator's particular needs.

However, many types of situations have already been encountered and worked through by others, eliminating the need to start from scratch in every case.

An excellent resource is the Courage Handi-Ham System. The Courage Handi-Ham System, a part of the Courage Center, provides a number of services to hams (and aspiring hams) with disabilities. These include study materials, equipment loans, adapted equipment, a newsletter and much more. Information needed to reach the Courage Handi-Hams is in the **References** chapter.

## INTERCONNECTING YOUR EQUIPMENT

Once you have your equipment and get it arranged, you will have to interconnect it all. No matter how simple the station, you will at least have antenna, power and microphone or key connections. Equipment such as amplifiers, computers, TNCs and so on add complexity. By keeping your equipment interconnections well organized and of high quality, you will avoid problems later on.

Often, ready-made cables will be available. But in many cases you will have to make your own cables. A big advantage of making your own cables is that you can customize the length. This allows more flexibility in arranging your equipment and avoids unsightly extra cable all over the place. Many manufacturers supply connectors with their equipment along with pinout information in the manual.

**Fig 22.10**—The back of this Ten-Tec Omni VI HF transceiver shows some of the many types of connectors encountered in the amateur station. Note that this variety is found on a single piece of equipment. (Photo courtesy AA8DX)

This allows you to make the necessary cables in the lengths you need for your particular installation.

Always use high quality wire, cables and connectors in your shack. Take your time and make good mechanical and electrical connections on your cable ends. Sloppy cables are often a source of trouble. Often the problems they cause are intermittent and difficult to track down. You can bet that they will crop up right in the middle of a contest or during a rare DX QSO! Even worse, a poor quality connection could cause RFI or even create a fire hazard. A cable with a poor mechanical connection could come loose and short a power supply to ground or apply a voltage where it should not be. Wire and cables should have good quality insulation that is rated high enough to prevent shock hazards.

Interconnections should be neatly bundled and labeled. Wire ties, masking tape or paper labels with string work well. See **Fig 22.9**. Whatever method you use, proper labeling makes disconnecting and reconnecting equipment much easier. **Fig 22.10** illustrates the number of potential interconnections in a modern, full-featured transceiver.

### Wire and Cable

The type of wire or cable to use depends on the job at hand. The wire must be of sufficient size to carry the necessary current. Use the tables in the **Component Data** chapter to find this information. Never use underrated wire; it will be a fire hazard. Be sure to check the insulation too. For high-voltage applications, the insulation must be rated at least a bit higher than the intended voltage. A good rule of thumb is to use a rating at least twice what is needed.

Use good quality coaxial cable of sufficient size for connecting transmitters,

transceivers, antenna switches, antenna tuners and so on. RG-58 might be fine for a short patch between your transceiver and SWR bridge, but is too small to use between your legal-limit amplifier and Transmatch.

Hookup wire may be stranded or solid. Generally, stranded is a better choice since it is less prone to break under repeated flexing. Many applications require shielded wire to reduce the chances of RF getting into the equipment. RG-174 is a good choice for control, audio and some low-power applications. Shielded microphone or computer cable can be used where more conductors are necessary. For more information, see the **Transmission Lines** chapter.

### Connectors

While the number of different types of connectors is mind-boggling, many manufacturers of amateur equipment use a few standard types. If you are involved in any group activities such as public service or emergency-preparedness work, check to see what kinds of connectors others in the group use and standardize connectors wherever possible. Assume connectors are not waterproof, unless you specifically buy one clearly marked for outdoor use (and assemble it correctly).

#### Audio, Power and Control Connectors

The simplest form of connector is found on terminal blocks. Although it is possible to strip the insulation from wire and wrap it around the screw, this method is not ideal. The wire tends to “squirm” out from under the screw when tightening, allowing strands to hang free, possibly shorting to other screws.

Terminal lugs, such as those in **Fig 22.11**, solve the problem. These lugs may be crimped (with the proper tool), soldered

**Fig 22.11**—The wires on one side of this terminal block have connectors; the others do not. The connectors make it possible to secure different wire sizes to the strip and also make it much easier to change things around.

(A)

(B)

(C)

**Fig 22.12**—The plugs shown at A are often used to connect equipment to remote power supplies. The multipin connectors at B are used for control, signal and power lines. The DIN plug at C offers shielding and is often used for connecting accessories to transceivers.

or both. Terminal lugs are available in different sizes. Use the appropriate size for your wire to get the best results.

Some common multipin connectors are shown in **Fig 22.12**. The connector in **Fig 22.12A** is often referred to as a "Cinch-Jones connector." It is frequently used for connections to power supplies from various types of equipment. Supplying from two to eight conductors, these connectors are keyed so that they go together only one way. They offer good mechanical and electrical connections, and the pins are large enough to handle high current. If your cable is too small for the strain relief fitting, build up the outer jacket with a few layers of electrical tape until the strain relief clamps securely. The strain relief will keep your wires from breaking away under flexing or from a sudden tug on the cable.

The plug in **Fig 22.12B** is usually called a "molex" connector. This plug consists of an insulated outer shell that houses the individual male or female "fingers." Each finger is individually soldered or crimped onto a conductor of the cable and inserted in the shell, locking into place. These connectors are used on many brands of amateur gear for power and accessory connections.

**Fig 22.12C** shows a DIN connector. Commonly having five to eight pins, these connectors are a European standard that have found favor with amateur equipment manufacturers around the world. They are generally used for accessory connections. A smaller version, the Miniature DIN, is becoming popular. It is most often used in portable gear but can be found on some full-size equipment as well.

### **The ARRL-Recommended 12-V Power Connector**

As mentioned above, it is very useful to have equipment used for emergency-preparedness and public service work share common connectors. A good choice for a 12-V power connector is the MOLEX Series 1545 connector. The ARRL Field Services Department recommends this connector for use in promoting compatibility and interchangeability among VHF/UHF equipment at disaster and public event sites. The 1545 connector is widely available and is rated at 25 V, 8 A.

An in-line fuse between the power source and first connector is recommended. See **Fig 22.13** for an illustration of the connector and recommended polarity. The polarity should always be verified prior to connecting equipment and power supplies.

Various types of phone plugs are shown in **Fig 22.14**. The 1/4-inch (largest) is usually used on amateur equipment for head-

**Fig 22.13**—As a result of a study commissioned by the ARRL Volunteer Resources Committee, the Field Services Department is recommending the MOLEX Series 1545 connector for use in promoting compatibility and interchangeability among personal VHF/UHF radio equipment at disaster and public event sites. Polarity should always be verified prior to connecting radios and power supplies. The 1545 connector is rated at 25 V, 8 A. Wire size requirement is #18 AWG or greater. An in-line fuse between the power source and first connector is recommended. The connector is available at Radio Shack stores, part #274-222.

phone and Morse key connections. They are available with plastic and metal bodies. The metal is usually a better choice because it provides shielding and is more durable.

**Fig 22.14** also shows the 1/8-inch phone plug. These plugs, sometimes called miniature phone plugs, are used for earphone, external speaker, key and control lines. There is also a subminiature (3/32-inch) phone plug that is not common on amateur gear.

The phono, or RCA, plug shown in **Fig 22.15** is popular among amateurs. It is used for everything from amplifier relay-control lines, to low-voltage power lines, to low-level RF lines, to antenna lines. Several styles are available, but the best choice is the shielded type with the screw-

**Fig 22.15**—Phono plugs have countless uses around the shack. They are small and shielded; the type with the metal body is easy to grip. Be careful not to use too much heat when soldering the ground (outer) conductor—you may melt the insulation.

**Fig 22.14**—The phone-plug family. The 1/4-inch type is often used for headphone and key connections on amateur equipment. The three-circuit version is used with stereo headphones. The mini phone plug is commonly used for connecting external speakers to receivers and transceivers. A submini-phone plug is shown in the foreground for comparison. The shielded style with metal barrel is more durable than the plastic style.

**Fig 22.16**—The four-pin mike connector is common on modern transmitters and receivers. More elaborate rigs use the eight-pin type. The extra conductors may be used for switches to remotely control the frequency or to power a preamplifier built into the mike case.

Fig 22.17—The PL-259, or UHF, connector is almost universal for amateur HF work and is popular for equipment operating in the VHF range. Steps A through E are described in detail in the text.

#### 83-58FCP

2) Fan braid slightly and fold back over cable.

1. Strip cable — *don't nick braid, dielectric or conductor*. Slide ferrule, then coupling ring on cable. Flare braid slightly by rotating conductor and dielectric in circular motion.

2. Slide body on dielectric, barb going under braid until flange is against outer jacket. Braid will fan out against body flange.

3. Slide nut over body. Grasp cable with hand and push ferrule over barb until braid is captured between ferrule and body flange. Squeeze crimp tip only of center contact with pliers; alternate-solder tip.

3) Position adapter to dimension shown. Press braid down over body of adapter and trim to  $3/8"$ . Bare  $5/8"$  of conductor. Tin exposed center conductor.

4) Screw the plug assembly on adapter. Solder braid to shell through solder holes. Solder conductor to contact sleeve.

#### 83-1SP (PL-259) PLUG WITH ADAPTERS (UG-176/U OR UG-175/U)

1) Cut end of cable even. Remove vinyl jacket  $3/4"$  — *don't nick braid*. Slide coupling ring and adapter on cable.

5) Screw coupling ring on plug assembly.

Fig 22.18—Crimp-on connectors and adapters for use with standard PL-259 connectors are popular for connecting to RG-58 and RG-59 type cable. (Courtesy Amphenol Electronic Components, RF Division, Bunker Ramo Corp)

on metal body. As with the phone plugs, the metal bodies provide shielding and are very durable.

Nowhere is there more variation than among microphone connectors. Manufacturers seem to go out of their way to use incompatible connectors! The most popular types of physical connectors are the four- and eight-pin microphone connectors shown in Fig 22.16. The simplest connectors provide three connections: audio, ground and push-to-talk (PTT). More complex connectors allow for such things as control lines from the microphone for frequency changes or power to the micro-

phone for a preamplifier. When connecting a microphone to your rig, especially an after-market one, consult the manual. Follow the manufacturer's recommendations for best results.

If the same microphone will be used for multiple rigs with incompatible connectors, one or more adapters will be necessary. Adapters can be made with short pieces of cable and the necessary connectors at each end.

### RF Connectors

There are many different types of RF connectors for coaxial cable, but the three

most common for amateur use are the UHF, Type N and BNC families. The type of connector used for a specific job depends on the size of the cable, the frequency of operation and the power levels involved.

The so-called UHF connector is found on most HF and some VHF equipment. It is the only connector many hams will ever see on coaxial cable. PL-259 is another name for the UHF male, and the female is also known as the SO-239. These connectors are rated for full legal amateur power at HF. They are poor for UHF work because they do not present a constant

## BNC CONNECTORS

### Standard Clamp

1. Cut cable and even. Strip jacket. Fray braid and strip dielectric. *Don't nick braid or center conductor.* Tin center conductor.

2. Taper braid. Slide nut, washer, gasket and clamp over braid. Clamp inner shoulder should fit squarely against end of jacket.

3. With clamp in place, comb out braid, fold back smooth as shown. Trim center conductor.

4. Solder contact on conductor through solder hole. Contact should butt against dielectric. Remove excess solder from outside of contact. Avoid excess heat to prevent swollen dielectric which would interfere with connector body.

5. Push assembly into body. Screw nut into body with wrench until tight. *Don't rotate body on cable to tighten.*

### Improved Clamp

Follow 1, 2, 3 and 4 in BNC connectors (standard clamp) except as noted. Strip cable as shown. Slide gasket on cable with groove facing clamp. Slide clamp on cable with sharp edge facing gasket. Clamp should cut gasket to seal properly.

### C. C. Clamp

- 1) Follow steps 1, 2 and 3 as outlined for the standard-clamp BNC connector.
- 2) Slide on the bushing, rear insulator and contact. The parts must butt securely against each other, as shown.
- 3) Solder the center conductor to the contact. Remove flux and excess solder.
- 4) Slide the front insulator over the contact, making sure it butts against the contact shoulder.
- 5) Insert the prepared cable end into the connector body and tighten the nut. Make sure that the sharp edge of the clamp seats properly in the gasket.

Fig 22.19—BNC connectors are common on VHF and UHF equipment at low power levels. (Courtesy Amphenol Electronic Components, RF Division, Bunker Ramo Corp)

impedance, so the UHF label is a misnomer. PL-259 connectors are designed to fit RG-8 and RG-11 size cable (0.405-inch OD). Adapters are available for use with smaller RG-58, RG-59 and RG-8X size

cable. UHF connectors are not weather-proof.

Fig 22.17 shows how to install the solder type of PL-259 on RG-8 cable. Proper preparation of the cable end is the key to

success. Follow these simple steps. Measure back about  $\frac{3}{4}$ -inch from the cable end and slightly score the outer jacket around its circumference. With a sharp knife, cut through the outer jacket, through the braid,

**Step 1** Place nut and gasket, with "V" groove toward clamp, over cable and cut off jacket to dim. **a**.

**Step 2** Comb out braid and fold out. Cut off cable dielectric to dim. **c** as shown.

**Step 3** Pull braid wires forward and taper toward center conductor. Place clamp over braid and push back against cable jacket.

**Step 4** Fold back braid wires as shown, trim braid to proper length and form over clamp as shown. Solder contact to center conductor.

**Step 5** Insert cable and parts into connector body. Make sure sharp edge of clamp seats properly in gasket. Tighten nut.

Fig 22.20—Type N connectors are a must for high-power VHF and UHF operation. (Courtesy Amphenol Electronic Components, RF Microwave Operations)

**Fig 22.21—Various computer connectors.**

**Fig 22.22—The two most common implementations of EIA-232-D serial connections on personal computers use 9- and 25-pin connectors.**

and through the dielectric, right down to the center conductor. Be careful not to score the center conductor. Cutting through all outer layers at once keeps the braid from separating. Pull the severed outer jacket, braid and dielectric off the end of the cable as one piece. Inspect the area around the cut, looking for any strands of braid hanging loose and snip

them off. There won't be any if your knife was sharp enough. Next, score the outer jacket about  $\frac{5}{16}$ -inch back from the first cut. Cut through the jacket lightly; do not score the braid. This step takes practice. If you score the braid, start again. Remove the outer jacket.

Tin the exposed braid and center conductor, but apply the solder sparingly and avoid melting the dielectric. Slide the coupling ring onto the cable. Screw the connector body onto the cable. If you prepared the cable to the right dimensions, the center conductor will protrude through the center pin, the braid will show through the solder holes, and the body will actually thread onto the outer cable jacket.

Solder the braid through the solder holes. Solder through all four holes; poor connection to the braid is the most common form of PL-259 failure. A good connection between connector and braid is just as important as that between the center conductor and connector. Use a large soldering iron for this job. With practice, you'll learn how much heat to use. If you use too little heat, the solder will bead up, not really flowing onto the connector body. If you use too much heat, the dielectric will melt, letting the braid and center conductor touch. Most PL-259s are nickel plated, but silver-plated connectors are much easier to solder and only slightly more expensive.

Solder the center conductor to the center pin. The solder should flow on the inside, not the outside, of the center pin. If you wait until the connector body cools off from soldering the braid, you'll have less trouble with the dielectric melting. Trim the center conductor to be even with the end of the center pin. Use a small file to round the end, removing any solder that built up on the outer surface of the center pin. Use a sharp knife, very fine sandpaper or steel wool to remove any solder flux from the outer surface of the center pin. Screw the coupling ring onto the body, and you're finished.

Fig 22.18 shows two options available if you want to use RG-58 or RG-59 size cable with PL-259 connectors. The crimp-on connectors manufactured specially for the smaller cable work very well if installed correctly. The alternative method involves using adapters for the smaller cable with standard RG-8 size PL-259s. Prepare the cable as shown. Once the braid is prepared, screw the adapter into the PL-259 shell and finish the job as you would a PL-259 on RG-8 cable.

The BNC connectors illustrated in Fig 22.19 are popular for low power levels at VHF and UHF. They accept RG-58 and RG-59 cable, and are available for cable

mounting in both male and female versions. Several different styles are available, so be sure to use the dimensions for the type you have. Follow the installation instructions carefully. If you prepare the cable to the wrong dimensions, the center pin will not seat properly with connectors of the opposite gender. Sharp scissors are a big help for trimming the braid evenly.

The Type N connector, illustrated in Fig 22.20, is a must for high-power VHF and UHF operation. N connectors are available in male and female versions for cable mounting and are designed for RG-8 size cable. Unlike UHF connectors, they are designed to maintain a constant impedance at cable joints. Like BNC connectors, it is important to prepare the cable to the right dimensions. The center pin must be positioned correctly to mate with the center pin of connectors of the opposite gender. Use the right dimensions for the connector style you have.

### Computer Connectors

As if the array of connectors related to amateur gear were not enough, the prevalence of the computer in the shack has brought with it another set of connectors to consider. Most connections between computers and their peripherals are made with some form of multiconductor cable. Examples include shielded, unshielded and ribbon cable. Common connectors used are the 9- and 25-pin D-Subminiature connector, the DIN and Miniature DIN and the 36-pin Amphenol connector. Various edge-card connectors are used internally (and sometimes externally) on many computers. Fig 22.21 shows a variety of computer connectors.

### EIA-232 Serial Connections

The serial port on a computer is arguably the most used, and often most troublesome, connector encountered by the amateur. The serial port is used to connect modems, TNCs, computer mice and some printers to the computer. As the name implies, the data is transmitted serially.

The EIA-232-D (commonly referred to as RS-232) standard defines a system used to send data over relatively long distances. It is commonly used to send data anywhere from a few feet to 50 feet or more. The standard specifies the physical connection and signal lines. The serial ports on most computers comply with the EIA-232-D standard only to the degree necessary to operate with common peripherals. Fig 22.22 shows the two most common connectors used for computer serial ports. A 9-pin connector can be adapted to a 25-pin by connecting like signals. Earth ground is not provided in the 9-pin version.

Equipment connected via EIA-232-D is usually classified in one of two ways: DTE (data terminal equipment) or DCE (data communication equipment). Terminals and computers are examples of DTE, while modems and TNCs are DCE.

The binary data is represented by specific voltage levels on the signal line. The EIA-232-D standard specifies that a binary one is represented by a voltage ranging from -3 to -25 V. A binary zero ranges from 3 to 25 V.  $\pm 12$  V is a common level in many types of equipment, but anything within the specified ranges is just as valid.

The RTS (request to send), CTS (clear to send), DTR (data terminal ready) and DSR (data set ready) lines are used for handshaking signals. These signals are used to coordinate the communication between the DTE and DCE. The RTS and DTR line are used by the DTE to indicate to the DCE that it is ready to receive data from the DCE. The DCE uses the CTS/DSR lines to signal the DTE as to whether or not it is ready to accept data. DCD (data carrier detect) is also sometimes used by the DCE to signal the DTE that an active carrier is present on the communication line. A +12-V signal represents an active handshaking signal. The equipment "drops" the line to -12 V when it is unable to receive data.

You may notice that the name "ready to send" is sort of a misnomer for the DTE since it actually uses it to signal that it is ready to receive. This is a leftover from when communication was mostly one-way—DTE to DCE. Note also that the signal names really only make sense from the DTE point of view. For example, pin 2 is called TD on both sides, even though the DCE is receiving data on that pin. This is another example of this one-way terminology.

It would be much too simple if all serial devices implemented all of the EIA-232-D specifications. Some equipment ignores some or all of the handshaking signals. Other equipment expects handshaking signals to be used as specified. Connecting these two types of equipment together will result in a frustrating situation. One side will blindly send data while the other side blindly ignores all data sent to it!

Fig 22.23 shows the different possible ways to connect equipment. Fig 22.23A shows how to connect a "normal" DTE/DCE combination. This assumes both sides correctly implement all of the handshaking signals. If one or both sides ignore handshaking signals, the connections shown in Fig 22.23B will be necessary. In this scheme, each side is sending the handshaking signals to itself. This little

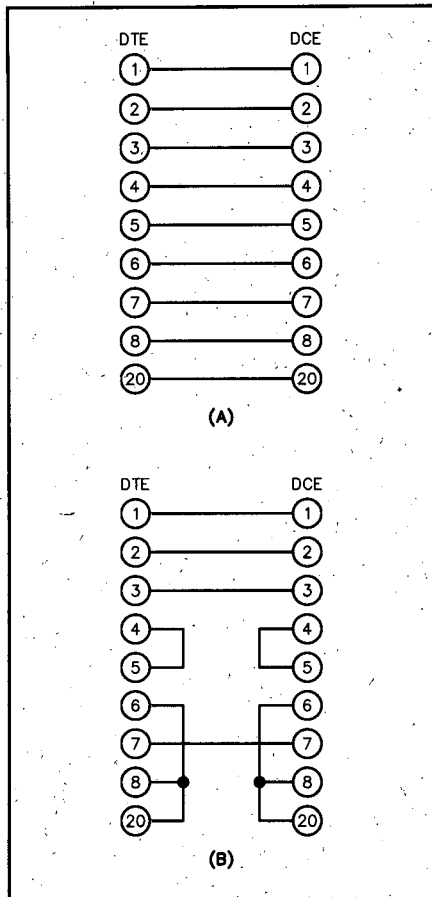

Fig 22.23—EIA-232-D serial connections for normal DTE/DCE (A) and those that ignore handshaking (B).

Fig 22.24—EIA-232-D null modem serial connection.

bit of deceit will almost always work, but handshaking signals that are present will be ineffective.

### Null Modem Connections

Some equipment does not fall completely in the DTE or DCE category. Some serial printers, for example, act as DCE while others act as DTE. Whenever a DTE/DTE or DCE/DCE connection is needed a special connection, known as a *null modem* connection, must be made. An example might be connecting two computers together so they can transmit data back and forth. A null modem connection simply crosses the signal and handshaking lines. Fig 22.24 shows a normal null modem connection (A) and one for equipment that ignores handshaking (B).

### Parallel Connections

Another common computer port is the parallel port. The most popular use for the parallel port by far is for printer connections. As the name implies, data is sent in a parallel fashion. There are eight data lines accompanied by a number of control

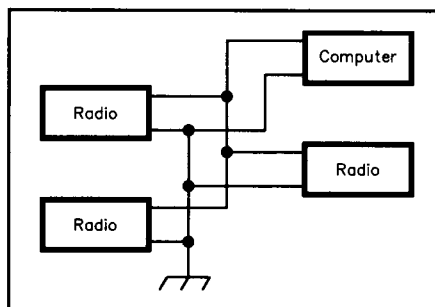

and handshaking lines. A parallel printer connection typically uses a 25-pin D-Subminiature connector at the computer end and a 36-pin Amphenol connector (often called an Epson connector) on the printer.

### Connecting Computers to Amateur Equipment

Most modern transceivers provide a serial connection that allows external control of the rig, typically with a computer. Commands sent over this serial control line can cause the rig to change frequency, mode and other parameters. Logging and contest software running on the computer often takes advantage of this capability.

The serial port of most radios operates with the TTL signal levels of 0 V for a binary 0 and 5 V for a binary 1. This is incompatible with the  $\pm 12$  V of the serial port on the computer. For this reason, level shifting is required to connect the radio to the computer.

A couple of level shifter projects appear in the projects section at the end of this chapter. One of these two examples will work in most rig control situations, al-

**Fig 22.25**—The basic two-wire bus system that ICOM and some Ten-Tec radios share among several radios and computers. In its simplest form, the network would include only one radio and one computer.

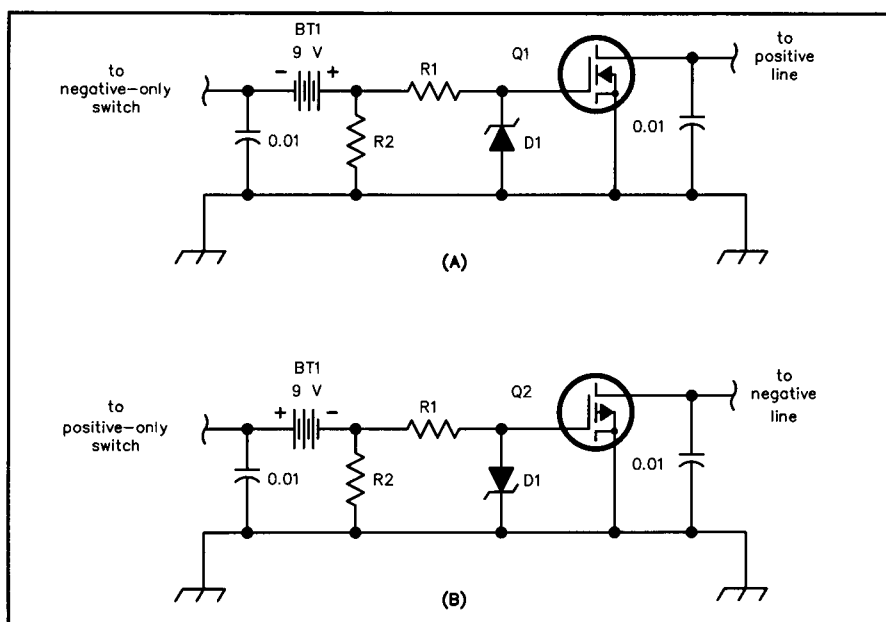

though some minor modifications may be necessary. Use the manual and technical documentation to find out what signals your radio requires and choose the circuit that fits the bill. The important factors to note are whether handshaking is implemented and what polarity the radio expects for the signals. In some cases, a 5-V level represents a logic 1 (active high) and in others a logic 0 (active low).

### CSMA/CD Bus

Some equipment, notably ICOM rigs with the CI-V interface and recent Ten-Tec gear, use a CSMA/CD (carrier-sense multiple access/collision detect) bus that can interconnect a number of radios and computers simultaneously. This bus basically consists of a single wire, on which the devices transmit and receive data, and a ground wire. **Fig 22.25** illustrates the CSMA/CD scheme.

Each device connected to the bus has its own unique digital address. A radio comes from the manufacturer with a default address that can be changed if desired, usually by setting dip switches inside the radio. Information is sent on the bus in the form of packets that include the control data and the address of the device (radio or computer) for which they are intended. A device receives every packet but only acts on the data when its address is embedded in the packet.

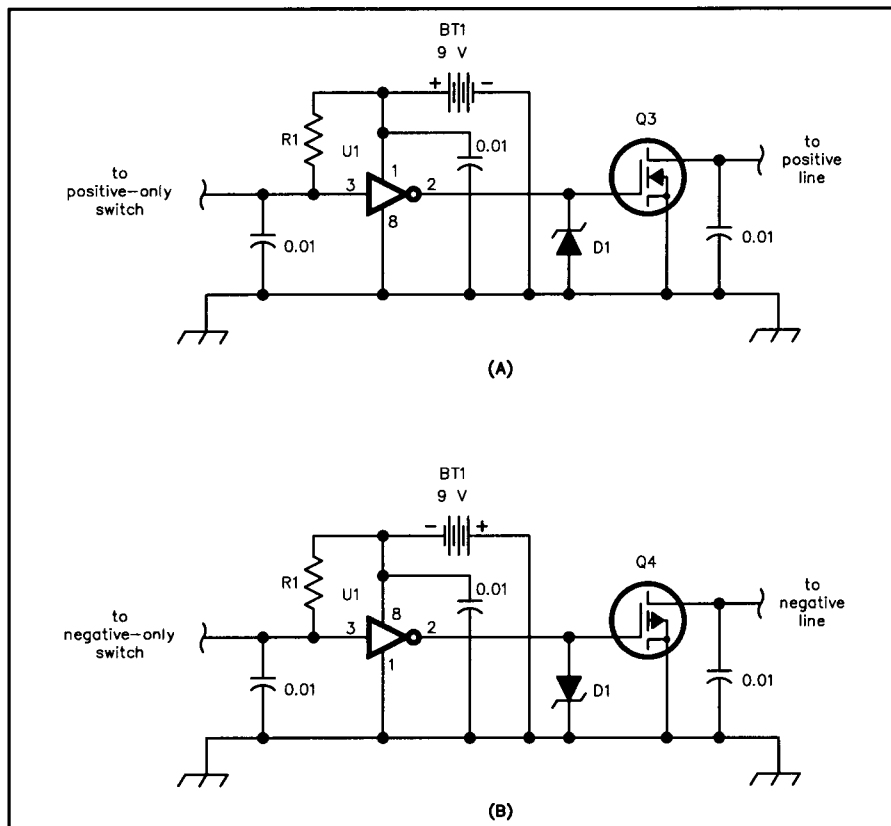

A device listens to the bus before transmitting to make sure it is idle. A problem occurs when both devices transmit on the bus at the same time: They both listen, hear nothing and start to send. When this happens, the packets garble each other. This is known as a collision. That is where the CSMA/CD bus collision-detection feature comes in: The devices detect the collision and each sender waits a random amount of time before resending. The sender waiting the shorter random time will get to send first.

## Computer/TNC Connections

TNCs (terminal node controllers) also connect to the computer (or terminal) via the serial port. A TNC typically implements handshaking signals. Therefore, a connector like the one in Fig 22.23A will be necessary. Connectors at the TNC end vary with manufacturer. The documentation included with the TNC will provide details for hooking the TNC to the computer.

## DOCUMENTING YOUR STATION

An often neglected but very important part of putting together your station is properly documenting your work. Ideally, you should diagram your entire station from the ac power lines to the antenna on paper and keep the information in a special notebook with sections for the various facets of your installation. Having the station well documented is an invaluable aid when tracking down a problem or planning a modification. Rather than having to search your memory for information on what you did a long time ago, you'll have the facts on hand.

Besides recording the interconnections and hardware around your station, you should also keep track of the performance of your equipment. Each time you install a new antenna, measure the SWR at different points in the band and make a table or plot a curve. Later, if you suspect a problem, you'll be able to look in your records and compare your SWR with the original performance.

In your shack, you can measure the power output from your transmitter(s) and amplifier(s) on each band. These measure-

ments will be helpful if you later suspect you have a problem. If you have access to a signal generator, you can measure receiver performance for future reference.

## INTERFACING HIGH-VOLTAGE EQUIPMENT TO SOLID-STATE ACCESSORIES

Many amateurs use a variety of equipment manufactured or home brewed over a considerable time period. For example, a ham might be keying a '60s-era tube rig with a recently built microcontroller-based electronic keyer. Many hams have modern solid-state radios connected to high-power vacuum-tube amplifiers.

Often, there is more involved in connecting HV (high-voltage) vacuum-tube gear to solid-state accessories than a cable and the appropriate connectors. The solid-state switching devices used in some equipment will be destroyed if used to switch the HV load of vacuum tube gear. The polarity involved is important too. Even if the voltage is low enough, a key-line might bias a solid-state device in such a way as to cause it to fail. What is needed is another form of level converter.

## MOSFET Level Converters

While relays can often be rigged to interface the equipment, their noise, slow speed and external power requirement make them an unattractive solution in some cases. An alternative is to use power MOSFETs. Capable of handling substantial voltages and currents, power MOSFETs have become common design items. This has made them inexpensive and readily available.

Nearly all control signals use a common

ground as one side of the control line. This leads to one of four basic level-conversion scenarios when equipment is interconnected:

- 1) A positive line must be actuated by a negative-only control switch.
- 2) A negative line must be actuated by a positive-only control switch.
- 3) A positive line must be actuated by a positive-only control switch.
- 4) A negative line must be actuated by a negative-only control switch.

In cases 3 and 4 the polarity is not the problem. These situations become important when the control-switching device is incapable of handling the required open-circuit voltage or closed-circuit current.

Case 1 can be handled by the circuit in Fig 22.26A. This circuit is ideal for interfacing keyers designed for grid-block keying to positive CW key lines. A circuit suitable for case 2 is shown in Fig 22.26B. This circuit is simply the mirror image of that in Fig 22.26A with respect to circuit polarity. Here, a P-channel device is used to actuate the negative line from a positive-only control switch.

Cases 3 and 4 require the addition of an inverter, as shown in Fig 22.27. The inverter provides the logic reversal needed to drive the gate of the MOSFET high, activating the control line, when the control switch shorts the input to ground.

Almost any power MOSFET can be used in the level converters, provided the voltage and current ratings are sufficient to handle the signal levels to be switched. A wide variety of suitable devices is available from most large mail-order supply houses.

# Mobile and Portable Installations

Time and again, radio amateurs have been pressed into service in times of need. New developments outside of Amateur Radio (cellular phones, for example) often bring with them predictions that amateurs will no longer be needed to provide emergency communications. Just as often, a disaster proves beyond doubt the falseness of that exclamation. When the call for emergency communication is voiced by government and disaster relief organizations, mobile and portable equipment is pressed into service where needed. In addition to the occasional emergency or disaster type of communications, mobile and portable operation under normal conditions can challenge and reward the amateur operator.

Most mobile operation today is carried out by means of narrow-band repeaters. Major repeater frequencies reside in the 146 and 440-MHz bands. As these bands become increasingly congested, the 222 and 1240-MHz bands are being used for this reliable service mode as well. Many amateurs also enjoy mobile and portable HF operation because of the challenge and possibilities of worldwide communication.

## MOBILE STATIONS

Installation and setup of mobile equipment can be considerably more challenging than for a fixed station. Tight quarters, limited placement options and harsher environments require innovation and attention to detail for a successful installation. The equipment should be placed so that operation will not interfere with driving. Driving safely is always the primary

consideration; operating radio equipment is secondary. See **Fig 22.28** for one neat solution. If your vehicle has an airbag, be sure it can deploy unimpeded.

Mobile operation is not confined to lower power levels than in fixed stations. Many modern VHF FM transceivers are capable of 25 to 50 W of output. Compact HF rigs usually have outputs in the 100-W range and run directly from the 13.6-V supply.

If a piece of equipment will draw more than a few amps, it is best to run a heavy cable directly to the battery. Few circuits in an automobile electrical system can safely carry the more than 20 A required for a 100-W HF transceiver. Check the table in the **Component Data** chapter to verify the current handling capabilities of various gauges of wire and cable. Adequate and well-placed fuses are necessary to prevent fire hazards. For maximum safety, fuse both the hot and ground lines near the battery. Automobile fires are costly and dangerous.

The limited space available makes antennas for mobile operation quite different than those for fixed stations. This is especially true for HF antennas. The **Antennas** chapter contains information for building and using mobile antennas.

## Interference

In the past, interference in mobile installations almost always concerned interference to the radio equipment. Examples include ignition noise and charging-system noise. Modern automobiles—packed with arrays of sensors and one or more on-

board computers—have made interference a two-way street. The original type of interference (to the radio) has also increased with the proliferation of these devices. An entire chapter in the ARRL publication *Radio Frequency Interference: How to Find It and Fix It*, is devoted to ways to prevent and cure this problem.

## PORTABLE STATIONS

Many amateurs experience the joys of portable operation once each year in the annual emergency exercise known as Field Day. Setting up an effective portable station requires organization, planning and some experience. For example, some knowledge of propagation is essential to picking the right band or bands for the intended communications link(s). Portable operation is difficult enough without dragging along excess equipment and antennas that will never be used.

Some problems encountered in portable operation that are not normally experienced in fixed-station operation include finding an appropriate power source and erecting an effective antenna. The equipment used should be as compact and lightweight as possible. A good portable setup is simple. Although you may bring gobs of gear to Field Day and set it up the day before, during a real emergency speed is of the essence. The less equipment to set up, the faster it will be operational.

## Portable AC Power Sources

There are two popular sources of ac power for use in the field. One is referred to as a dc-to-ac converter, or more commonly, an inverter. The ac output of an inverter is a square wave. Therefore, some types of equipment cannot be operated from the inverter. Certain types of motors are among those devices that require a

**Fig 22.28**—N8KDY removed the ashtray for his mobile installation. The old faceplate for the ashtray is used as a cover for the rig when not in use. This may help reduce the temptation for would-be thieves. (Photo courtesy AA8DX)

**Fig 22.34**—Photograph of a commercial dc-to-ac inverter that operates from 6 to 12 V dc and delivers 120 V ac (square wave) at 175 W.

sine-wave output. **Fig 22.34** shows a typical commercial inverter. This model delivers 120 V of ac at 175 W continuous power rating. It requires 6 or 12 V dc input.

Besides having a square-wave output, inverters have some other traits that make them less than desirable for field use. Commonly available models do not provide a great deal of power. The 175-W model shown in **Fig 22.34** could barely power a few light bulbs, let alone a number of transceivers. Higher-power models are available but are quite expensive. Another problem is that the batteries supplying the inverter with primary power are discharged as power is drawn from the inverter.

Popularity and a number of competing manufacturers have caused gasoline generators to come down considerably in price. For a reliable, adequate source of ac (with sine-wave output), the gasoline-engine-driven generator is the best choice. (While still referred to as generators, practically all modern units actually use alternators to generate ac power.) Generators have become smaller and lighter as manufacturers have used aluminum and other lightweight materials in their construction. **Fig 22.35** shows the type of generator often used during Field Day.

Generators in the 3 to 5-kW range are easily handled by two people and can provide power for a relatively large multioperator field site. Most generators provide 12 V dc output in addition to 120/240 V ac.

### Generator Maintenance

Proper maintenance is necessary to obtain rated output and a decent service life from a gasoline generator. A number of simple measures will prolong the life of the equipment and help maintain reliability.

It is a good idea to log the dates the unit is used and the operating time in hours. Many generators have hour-meters to make this simple. Include dates of maintenance and the type of service performed. The manufacturer's manual should be the primary source of maintenance information and the final word on operating procedures and safety. The manual should be thoroughly covered by all persons who will operate and maintain the unit.

Particular attention should be paid to fuel quality and lubricating oil. A typical gasoline generator is often used at or near its rated capacity. The engine driving the alternator is under a heavy load that varies with the operation of connected electrical equipment. For these reasons, the demands on the lubricating oil are usually greater than for most gasoline-engine powered equipment such as lawn mowers,

tractors and even automobiles. Only the grades and types of oil specified in the manual should be used. The oil should be changed at the specified intervals usually given as a number of operating hours.

Fuel should be clean, fresh and of good quality. Many problems with gasoline generators are caused by fuel problems. Examples include dirt or water in the fuel and old, stale fuel. Gasoline stored for any length of time changes as the more volatile components evaporate. This leaves excess amounts of varnish-like substances that will clog carburetor passages. If the generator will be stored for a long period, it is a good idea to run it until all of the fuel is burned. Another option is the use of fuel stabilizers added to the gasoline before storage.

Spark plugs should be changed as specified. Faulty spark plugs are a common cause of ignition problems. A couple of spare spark plugs should always be kept with the unit, along with tools needed to change them. Always use the type of spark plug recommended by the manufacturer.

### Generator Ground

A proper ground for the generator is absolutely necessary for both safety reasons and to ensure proper operation of equipment powered from the unit. Most generators are supplied with a three-wire outlet, and the ground should connect to the plug as shown in **Fig 22.36**. Some generators require that the frame be grounded also. An adequate pipe or rod should be driven into the ground near the generator and connected to the provided clamp or lug. If no connection is provided, a clamp can be used to connect the ground lead to the frame of the generator. As always, follow the manufacturer's recommendations.

### Portable Antennas

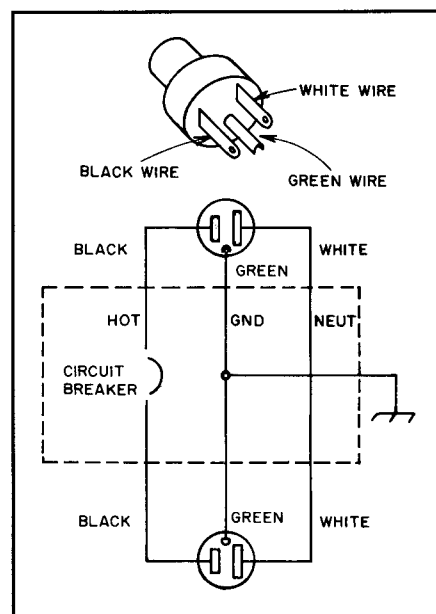

An effective antenna system is essential to all types of operation. Effective portable antennas, however, are more difficult to devise than their fixed-station counterparts. A portable antenna must be light, compact and easy to assemble. It is also important to remember that the portable antenna may be erected at a variety of sites, not all of which will offer ready-made supports. Strive for the best antenna system possible because operations in the field are often restricted to low power by power supply and equipment considerations. Some antennas suitable for portable operation are described in the **Antennas** chapter.

### Antenna Supports

While some amateurs have access to a

**Fig 22.35—Modern gasoline engine-powered generators offer considerable ac power output in a relatively compact and lightweight package.**

**Fig 22.36—A simple accessory that provides overload protection for generators that do not have such provisions built in.**

truck or trailer with a portable tower, most are limited to what nature supplies, along with simple push-up masts. Select a portable site that is as high and clear as possible. Elevation is especially important if your operation involves VHF. Trees, buildings, flagpoles, telephone poles and the like can be pressed into service to support wire antennas. Drooping dipoles are often chosen over horizontal dipoles because they require only one support.

**Fig 22.38—An aluminum extension ladder makes a simple but sturdy portable antenna support. Attach the antenna and feed lines to the top ladder section while it is nested and laying on the ground. Push the ladder vertical, attach the bottom guys and extend the ladder. Attach the top guys. Do not attempt to climb this type of antenna support.**

An aluminum extension ladder makes an effective antenna support, as shown in Fig 22.38. In this installation, a mast, rotator and beam are attached to the top of the second ladder section with the ladder near the ground. The ladder is then pushed vertical and the lower set of guy wires attached to the guy anchors. When the first set of guy wires is secured, the ladder may be extended and the top guy wires attached to the anchors. Do not attempt to climb a guyed ladder.

Figs 22.39 and 22.40 illustrate two methods for mounting portable antennas described by Terry Wilkinson, WA7LYI. Although the antennas shown are used for

VHF work, the same principles can be applied to small HF beams as well.

In Fig 22.39, a 3-ft section of Rohn 25 tower is welded to a pair of large hinges, which in turn are welded to a steel plate measuring approximately 18×30 inches. One of the rear wheels of a pickup truck is "parked" on the plate, ensuring that it will not move. In Fig 22.39, quad array antennas for 144 and 222 MHz are mounted on a Rohn 25 top section, complete with rotator and feed lines. The tower is then pushed up into place using the hinges, and guy ropes anchored to heavy-duty stakes driven into the ground complete the installation. This method of

(A)

(B)

**Fig 22.39—The portable tower mounting system by WA7LYI. At A, a truck is "parked" on the homemade base plate to weigh it down. At B, the antennas, mast and rotator are mounted before the tower is pushed up. Do not attempt to climb a temporary tower installation.**

portable tower installation offers an exceptionally easy-to-erect, yet sturdy, antenna support. Towers installed in this manner may be 30 or 40 ft high; the limiting factor is the number of "pushers" and "rope pullers" needed to get into the air. A portable station located in the bed of the pickup truck completes the installation.

The second method of mounting portable beams described by WA7LYI is shown in Fig 22.40. This support is intended for use with small or medium-sized VHF and UHF arrays. The tripod is available from any dealer selling television antennas; tripods of this type are usually mounted on the roof of a house. Open the tripod to its full size and drive a pipe into the ground at each leg. Use a hose clamp or small U-bolt to anchor each leg to its pipe.

The rotator mount is made from a 6-inch-long section of 1½-inch-diameter pipe welded to the center of an "X" made from two 2-ft-long pieces of concrete reinforcing rod (rebar). The rotator clamps onto the pipe, and the whole assembly is placed in the center of the tripod. Large rocks placed on the rebar hold the rotator in place, and the antennas are mounted on a 10 or 15-ft mast section. This system is easy to make and set up.

(A)

(B)

(C)

**Fig 22.40**—The portable mast and tripod by WA7LYI. At A, the tripod is clamped to stakes driven into the ground. The rotator is attached to a homemade pipe mount. At B, rocks piled on the rotator must keep the rotator from twisting and add weight to stabilize the mast. At C, a 10-ft mast is inserted into the tripod/rotator base assembly. Four 432-MHz Quagis are mounted at the top.

### *Tips for Portable Antennas*

Any of the antennas described in the **Antennas** chapter or available from commercial manufacturers may be used for portable operation. Generally, though, big or heavy antennas should be passed over in favor of smaller arrays. The couple of decibels of gain a 5-element, 20-m beam may have over a 3-element version is insignificant compared to the mechanical considerations. Stick with arrays

of reasonable size that are easily assembled.

Wire antennas should be cut to size and tuned prior to their use in the field. Be careful when coiling these antennas for transport, or you may end up with a tangled mess when you need an antenna in a hurry. The coaxial cable should be attached to the center insulator with a connector for speed in assembly. Use RG-58 for the low bands and RG-8X for higher-band anten-

nas. Although these cables exhibit higher loss than standard RG-8, they are far more compact and weigh much less for a given length.

Beam antennas should be assembled and tested before taking them afield. Break the beam into as few pieces as necessary for transportation and mark each joint for speed in reassembly. Hex nuts can be replaced with wing nuts to reduce the number of tools necessary.

## A KEYSER FOR YOUR RIG OR SHACK

This single-IC electronic keyer will fill just about any need you have for a keyer. Build "The Simplest Possible Keyer Circuit" version into your next QRP project or add it to your rig. Select the features you want. You can have a sidetone with variable pitch and volume, variable weighting, A or B-type iambic keying (more about this later) and even a meter to read the keying speed! The result is a quality, flexible keying system with a minimum of additional components. This project was built by Larry Wolfgang, WR1B.

### The Curtis Chip

This project uses the latest Curtis keyer IC, the 8044ABM. This CMOS IC is a complete keyer in a 20-pin DIP package. Internal circuitry provides a keyer sending-speed signal for display with a meter and a few external components. The IC features contact debouncing, RF immunity and self-completing character generation. A weight control, sidetone output and dot memory are also available. The memory function helps to prevent dot loss if the operator *leads* the keyer. With a quiescent current drain of about 50  $\mu$ A, an on/off switch is not required for the simplest keyer version.

You can select either A- or B-type iambic — squeeze — keying. (Of course you can also use single-lever — nonsqueeze — keying.) With A-type keying, a dot or dash being sent when the paddles are released is completed, and nothing else is sent. With B-type keying, the IC completes the dot or dash being sent upon paddle release, and then sends an opposite element; that is, a dot after a dash and a dash after a dot.

Suppose you wanted to send the letter N. If you select A-type keying you will squeeze first on the dash side and then on the dot side. When you release the paddles nothing will be sent after the dot. B-Type keying is slightly less work. Squeeze the dash side, and if you release the paddle *while the dash is being sent* the following dot will automatically be sent. To send a single dash you must release the paddle *after the dash has been completed*.

Your choice of iambic keying type will probably depend on the method you first learned to use. Some operators find that the B-type keying requires less effort to produce certain characters, such as a period or the letter C. The proper timing for release of the paddles is only half the window for A-type keying, however. If you've learned to send with a keyer that uses type B, stick with it. If you've never used an electronic keyer, it is probably easier to learn to send with A-type keying.

### Planning Your Keyer

Fig 22.41 shows the schematic diagram

of a keyer with all options included. You may find it helpful to redraw the diagram, showing only those components necessary for the features you wish to include in your keyer. For example, if you are not interested in the speed meter, then omit the circuitry associated with pin 12 of the IC. If you want only A-type keying, wire pin 8 to ground instead of including S8. For only B-type keying, wire pin 8 to the positive supply voltage.

The 8044ABM IC is available from several sources. Mouser Electronics and Ocean State Electronics both carry the chip. The resistors, capacitors, switches and other components required to complete the project are available from these and other sources. In addition, Jade Products has a complete kit of parts and a circuit board.<sup>1</sup> You can select the options you need with the Jade kit. For example, you can add positive or negative keying options and weight control with an options kit. The meter option includes a small 200  $\mu$ A meter and the necessary resistors and capacitors, along with a computer program for MS Word and MS Paint on disk that will print a new meter face if you are building the kit for a different speed range than the original design.

The schematic diagram shows a rather complex switching scheme to select either positive or negative keying output. If you want to build your keyer for only one or the other type of keying, you can simplify the construction by omitting the four-pole, double-throw switch, S1, and either Q3 or Q4 with their accompanying resistors.

There are a number of construction options. FAR Circuits sells a circuit board for the "Simplest Possible Keyer Circuit."<sup>2</sup> If you want to search your junkbox for most of the parts, Jade Products offers just the circuit board for the complete keyer. A template package of etching patterns and parts-placement diagrams is available from the ARRL Technical Secretary.<sup>3</sup> The circuit board for the complete keyer is double sided.

Curtis Electro Devices once offered circuit boards and parts kits for the complete keyer project. These are no longer available, but the template package includes a copy of the artwork for that circuit board.

<sup>1</sup>All addresses are given in the **References** chapter Address List.

<sup>2</sup>Circuit boards for the "Simplest Possible Keyer Circuit" are available from FAR Circuits. Ask for the Handbook Mechanical-Paddle-Input circuit board. Price is \$4.25 + \$1.50 shipping at publication time.

<sup>3</sup>Part-placement guides and etching patterns are available from the ARRL Technical Secretary. Enclose a large (8 1/2 x 11) SASE with two First Class units of postage and request the 96 Handbook Curtis Keyer Template package.

Fig 22.41 (see facing page)— The complete keyer circuit, with all options included. The diagram at B shows how to wire a 16-pin header plug either for a switch or as a jumper to select the output keying polarity. The square boxes with numbers refer to the pin numbers for this polarity switch, S1. A 26-pin header is used for connections to the controls and jacks mounted off the circuit board. A mating 26-pin insulation-displacement connector and 26-conductor ribbon cable make these connections. The pin numbers for J5 (inside the dotted line, on the circuit-board side) refer to the header. The number and color sequence on these pins outside the dotted line refer to the order and color of the suggested ribbon cable. (1BRN refers to the first brown wire in the sequence, 2GRN refers to the second green wire and so on. The ribbon cable color sequence is given in the text.) If you use a ribbon cable with a different color scheme, just follow the pin numbers and keep the colors in order. Use either R22 (PC-mount trimmer) or R23 (chassis-mount potentiometer) for the volume control, but not both. Likewise, use either R28 or R2 for the pitch control, but not both.

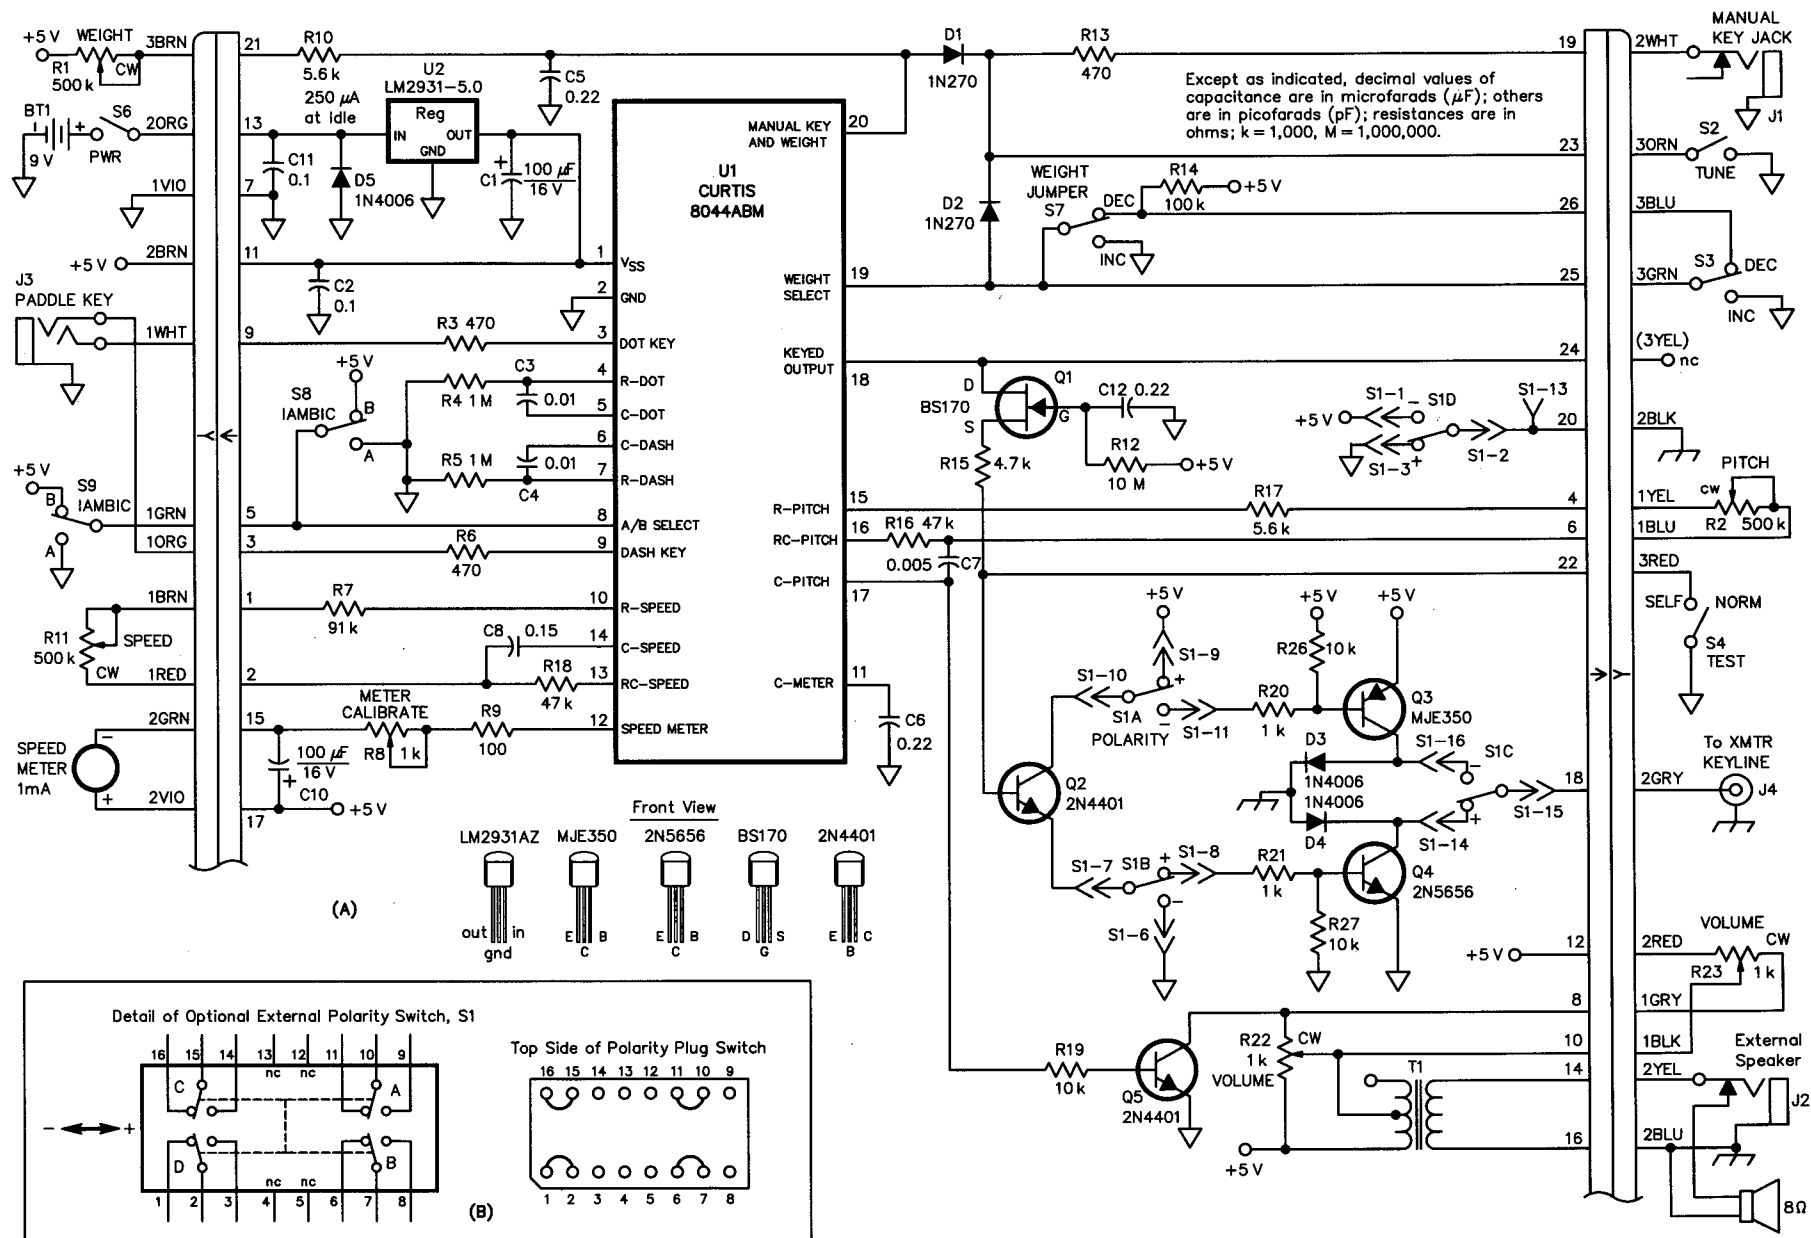

Fig 22.42 — This photo shows the construction details of a keyer built from the Jade Products kit. It is shown without packaging for clarity.

The diagram shown in Fig 22.41 includes a 5-V regulator (U2) for the  $V_{SS}$  supply. The 8044ABM will operate on any voltage from 4 to 12 V, so you can connect a 6, 9 or 12-V supply directly to the chip. The 5-V regulated supply is necessary for the speed meter.

### Assembly

Fig 22.42 shows construction details of the Jade Products keyer version, and Fig 22.43 shows a keyer built from parts collected from Mouser and other sources. Depending on your packaging choices, you may want to use PC-mount controls for features like the keyer speed, weighting, sidetone pitch and volume, or you may want to use panel-mount components.

**Fig 22.43** — This photo shows the construction details of a keyer, partially assembled, using a circuit board from the Curtis PC board pattern. Notice the 26-pin header and matching receptacle that uses insulation-displacement connectors. These connectors are commonly found in computer-parts stores. This one provides a convenient way to make the connections to switches and controls mounted off the circuit board.

The keyer shown in Fig 22.42 uses circuit-board-mounted potentiometers that will fit through holes in the project case for the sidetone volume and keyer speed controls. The version shown in Fig 22.43, built using a board from the Curtis pattern, uses case-mounted potentiometers wired with ribbon cable from a 26-pin connector on the circuit board. This method simplifies the control connections to the circuit board, but it helps to follow the wire numbering and color sequencing shown on the schematic diagram to avoid confusion. (Use a length of 26-conductor ribbon cable with brown, red, orange, yellow, green, blue, violet, gray, white and black wires, with the pattern repeated 2½ times.)

Use a 20-pin socket for the IC. Install the IC only *after* you have soldered all the other components to the board, and measured the voltages to the IC socket pins. Make sure to orient the IC correctly when installing it.

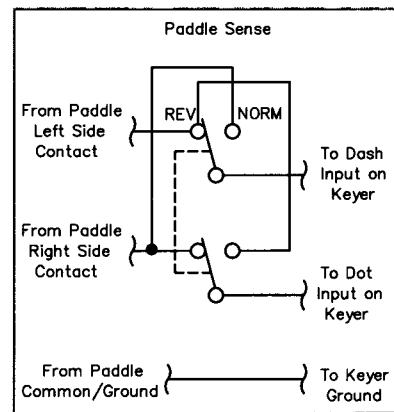

The Curtis circuit board is designed to use a 16-pin DIP socket for the keying polarity selection. Fig 22.41B shows how to wire the four-pole, double-throw switch or a header plug that plugs into the socket. When you insert the header plug in one direction the keyer gives positive keyed output. Turn the plug 180° for negative keyed output! If you use the Jade Products circuit board, the positive power supply and ground connections to Q2 change for the two keying methods. You will have to decide which type of keying you want to use, or adapt a switching method similar to that shown for the Curtis board.

Note that there are different power supply ground and chassis ground connections shown on the schematic diagram. These two grounds must be isolated. This means the paddle-input jack, J3, and manual key input, J1 must be isolated from chassis and case ground. You can use fiber shoulder washers on each side of these jacks for this

## Hooking up Keyer Paddles

It's always nice when you can go to a friend's house or a Field Day setup, and operate without rewiring the keyer. Unfortunately, this does not always happen. The standard, at least for right-handed people, is a left press generates dashes and a right press generates dots. Some left handed operators have wired their paddles with the same connections and others have reversed the connections, so they can operate most right-handed stations.

If you are just learning to use paddles, or operate in CW contests, you may want to learn to send with the opposite hand. A right-handed operator, sending with the left hand, has the right hand free for logging. Larry Wolfgang, WR1B, learned to send this way. He suggests you wire a DPDT switch into the paddle lines, as shown in Fig A, so visitors who prefer

**Fig A**—A DPDT switch wired like this permits quick selection of right- or left-handed keying.

the opposite wiring also can use your station. This is a particularly good idea for CW positions at Field Day.

purpose, or use an insulated jack.

The keyer shown in Fig 22.43 includes a switch to reverse the paddle connections on the back panel. With this switch you can set the keyer for right or left-hand operation no matter how the paddles are wired. This can be especially helpful when you take your keyer for Field Day or similar operation where several operators may be using it. See the sidebar for details.

## Calibrating the Speed Control

One way you can estimate sending speed is to count the number of dashes sent in five seconds. This number is the code speed in words per minute. A more refined measurement method uses an oscilloscope or a frequency counter connected to pin 12 of U1. The formula is  $\text{speed} = f / 1.2$ , where speed is in WPM and  $f$  is the dot frequency measured at pin 18 of U1. For speeds of 10, 25 and 50 WPM, the frequency counter should display dot frequencies of 8.33, 20.8 and 41.6 Hz, respectively.

Carefully adjust R8 until the meter reading agrees with the calculated or measured keying speed. Since this is a "set it and forget it" adjustment, you needn't worry about access to the control once the keyer is packaged.

## Packaging

The Jade Products circuit board is about 2×3 ½ inches. The Curtis board (in the ARRL template package) is about the same size. The FAR Circuits board for the "Simplest Possible Keyer Circuit" is about 2×2 inches. Any of these boards could be easily

built into all but the smallest or most crowded radios. You can even build the keyer with its own enclosure, and have a fairly small package. Just leave enough room for the controls and jacks.

The keyer shown in Fig 22.43 was built into a Hammond Manufacturing 1458B4B project case measuring approximately 6×4×4 inches outside. These boxes are easy to work with because the top and bottom pieces form the sides. Separate front and rear panels have channels on the inside that allow the attachment of mounting rails (available separately from Hammond) that are used to hold the circuit board and other internal components.

Lay out the positions of the controls and switches, as well as the meter location (if you are including that feature). Keep in mind the location of the circuit board inside the case, to avoid space conflicts. Drill all the holes to size and make a cut-out for the meter. When you are sure you've included mounting holes for all the controls, and they are the proper size, you are ready to paint the enclosure if desired, and label the panels. Dry transfer letters can produce a professional job if you carefully align them. It is helpful to start with the letters in the middle of the word, and work toward both ends for each label. Finish the job with a few coats of clear acrylic spray to protect the finish and seal the letters.

After the acrylic is dry you are ready to install the controls and switches, connect the wiring to the circuit board and connect power.

Enjoy your keyer!

## THE NEW AND IMPROVED UNCLE ALBERT'S KEYS

This unique keyer can help you improve your CW sending and receiving, whether you use a straight key, bug or keyer. Sam Ulbing, N4UAU, described an earlier version in the January 1994 *QST*. A 87C51 microcontroller and a two-row, dot-matrix liquid-crystal display (LCD) are at the heart of that keyer. The program stored in the 87C51 provides an iambic keyer with memory, a code-speed calculator, a CW reader that displays what you send, and a random-character code-practice generator. This new version includes a received code display as well as several other features. Two versions of the keyer are shown in Fig 22.44A and the internal layout in Fig 22.44B.

### What Can It Do?

The stored program includes the features that are commonly found in today's keyers. Unique is its ability to display both the transmitted and received code. Most often, this capability is found only in communications processors and CW software for personal computers. This keyer:

- Displays the code you send and receive on an LCD screen.
- Contains an iambic keyer—the speed

- can be set digitally from 2 to 40 WPM.
- Has an internal 47 character memory.
- Lets you set any character speed and any space speed in the internal random character code practice generator.
- Includes a sidetone oscillator with selectable frequency and an audio amplifier to drive a small speaker.
- Has a tuning indicator to help you zero beat the other station.
- Can be set to a reduced power mode for portable or backpack operation.
- Allows paddles, straight key or bug input.
- Does not need an on/off switch because the keyer can go into a sleep mode when you are finished transmitting.
- Can be split into two parts. Use the keyer and transmitting display in a battery power mode for portable and backpack operation. Plug in the code reader and power supply for fixed operation.

When you press a dot or dash paddle, the 87C51 microcontroller acts as an iambic keyer and sends the appropriate dot or dash to the transmitter. It then determines what character you sent by looking it up in a table, and sends that character to the LCD display. Thus you see exactly what you are sending as you send it—mistakes and all. As an example, if you don't leave long enough pauses between words you **Will**

**seethisonyourscreenandyouwillknowyouarerunningwordstogether.**

The demodulator circuit converts the incoming audio dots and dashes to digital signals. The 87C51 then processes them, and sends the decoded characters to the display.

The paddles, with buttons R and S, set sending and receiving speeds: Pressing the dot or dash side increases and decreases the speed by the number of dot or dash closures. Do this while pressing the S button to control the transmit speed, or the R button to set receive speed. The receive speed need only be set close ( $\pm 30\%$ ) to the actual incoming speed, for the decoder to work.

### Circuit Description

Fig 22.45 shows the circuit schematic. Two PC boards are used. The microprocessor is located on the keyer board and the decoder chip, an LM567 (U3), on the decoder board.

In the iambic keyer modes, the microprocessor samples the paddle input lines at pins 10 and 11. The voltage on these pins is normally 5-V. When a paddle is closed, the voltage goes to zero, starting a timer in the micro. The timer will cause the appropriate dots or dashes to appear on pin 39. This pin is connected to keying transistors Q1 and Q2. The dots and dashes

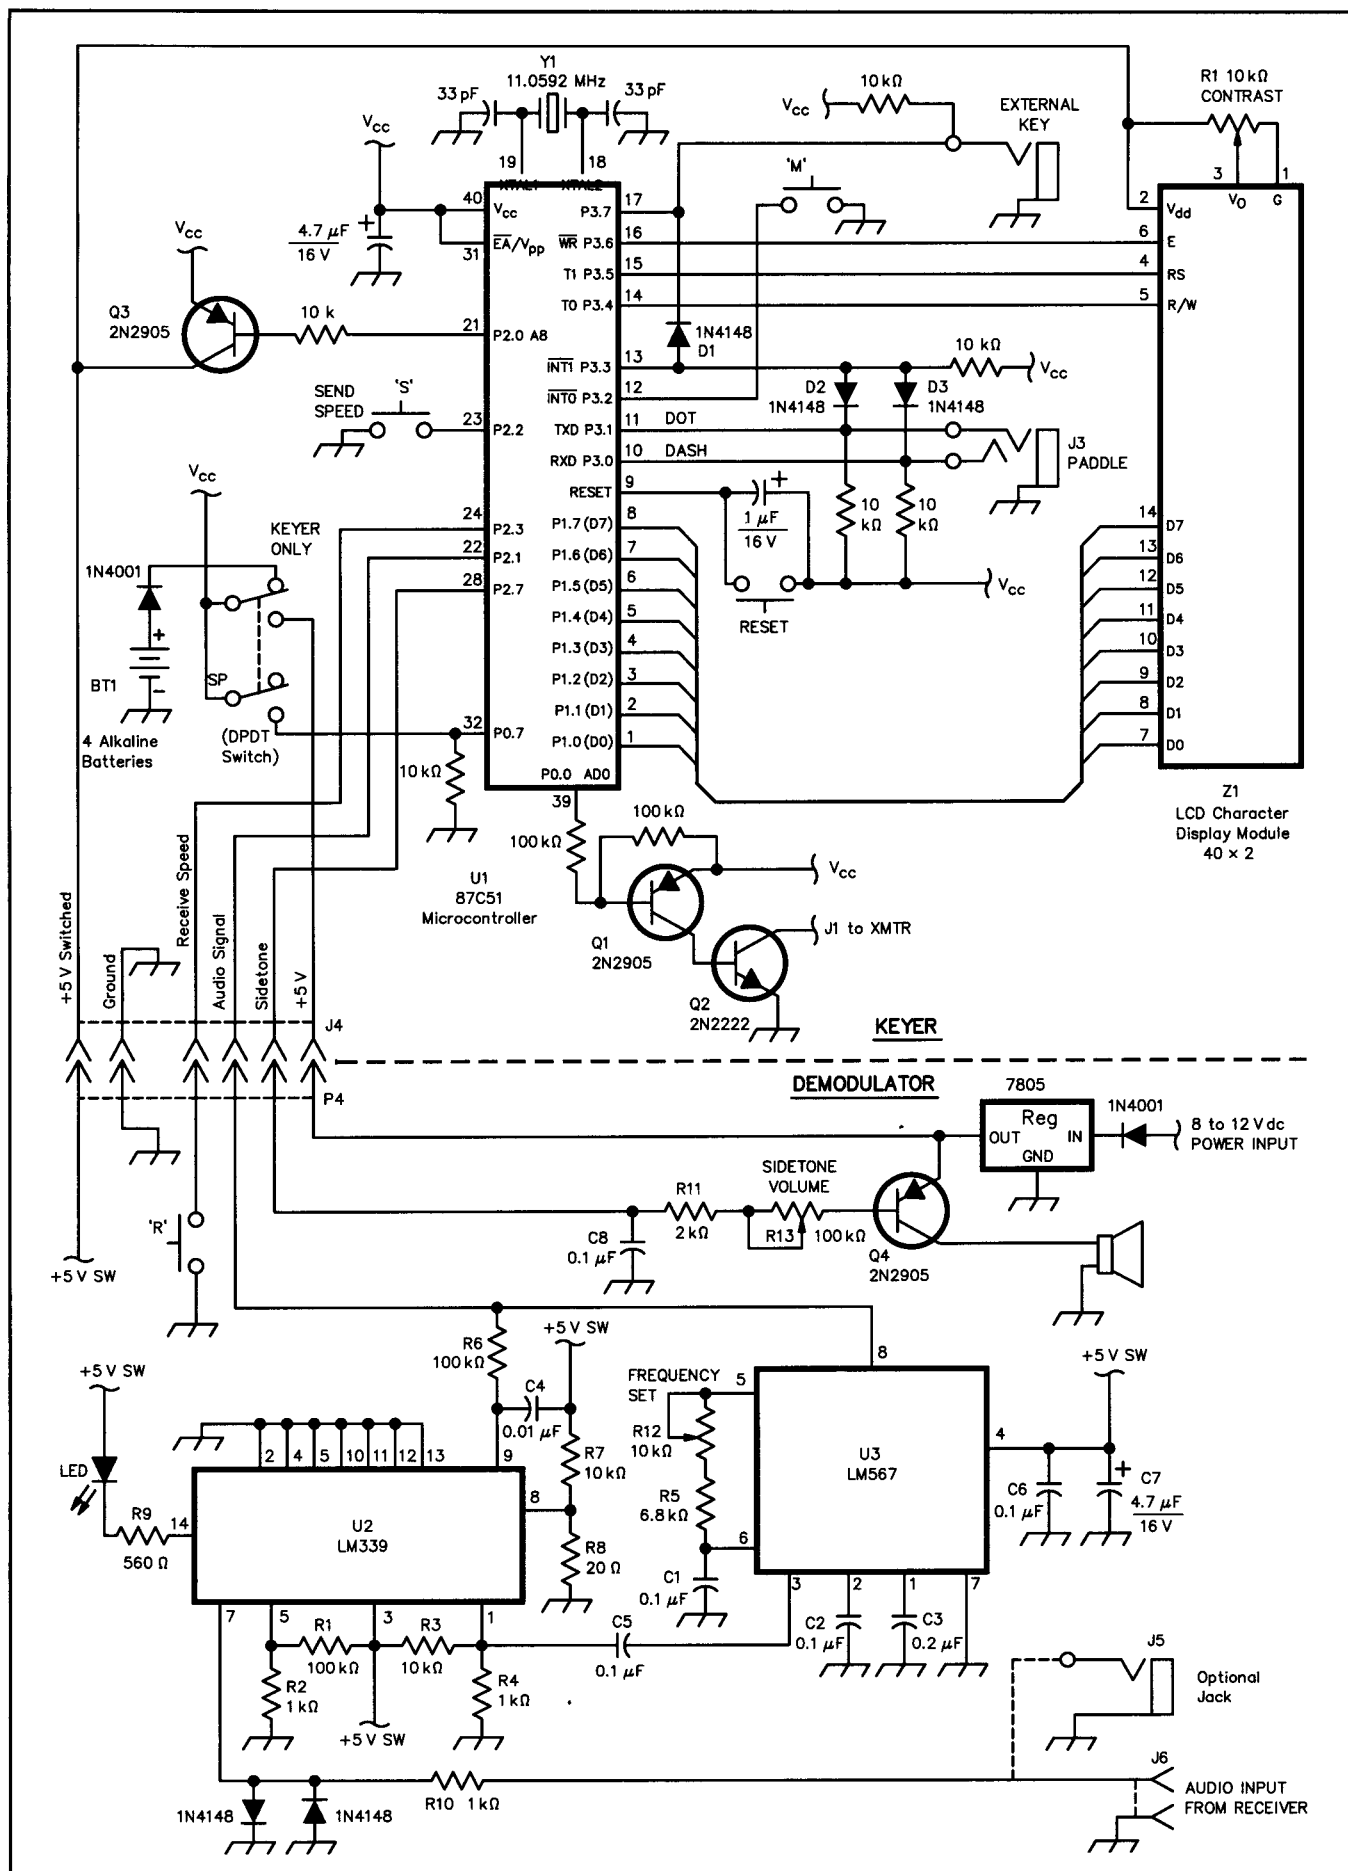

Fig 22.44—Two versions of this keyer are stacked in the photograph (A). Delmar Stone, AC4NO, built the larger unit and Chuck Grey, ND7K, built the smaller unit. The inside of Philip Kirby, N6ZAT's unit, is in (B). It is powered by 4 D cells.

### The 87C51 Microcontroller

The 87C51 is a member of the 8051 family, manufactured by both Signetics and Intel. These are 8 bit microprocessors, optimized for control applications. They are found in a wide range of applications, from medical instrumentation to automobile control systems and Amateur Radio applications. All microprocessors take data from memory, process it in a CPU and take action based on the results. Most computer systems—such as your home PC—have a CPU chip (a 486 for example), other chips for memory, more chips for input and output and still more chips to control the communications between all these chips.

The 8751 has all these components in a single chip: 128 bytes of RAM, 4k bytes of ROM, up to 32 ports for I/O, 2 timers, 5 interrupt sources, a serial I/O port and of course the CPU. For projects like this one, these features mean greatly simplified design and construction as well as much smaller size. The feature that makes the 8751 well suited for control applications is its ability to process only one bit of an 8 bit word (called Boolean processing). In an 8 bit processor, data is normally processed 8 bits (1 byte) at a time. Programmers have to consider the state of all 8 bits, even though they only want to control one of those bits. With the 8751 a single bit can be controlled and the other bits ignored. In this project, the paddle and the control lines for the LCD display are both connected to port 3. Because of the Boolean processing capabilities, the system program can check the state of the paddle without having to worry about the LCD control lines.

The 87C51 is a CMOS device, so it draws very little current—only around 9 mA when it is running. In addition it has two power reduction modes. This project uses both modes. In the idle mode current draw is reduced to around 4 mA. The second power reduction mode—the power down or sleep mode—reduces current draw to just micro amps.

←  
**Fig 22.45—The microcontroller and LCD display module are at the heart of this keyer. All polarized capacitors are electrolytic and the others are disc ceramics. A voltage rating of 16-V is sufficient for all capacitors. The fixed resistors are 1/4-W units.**

are also stored in memory, until an entire character is sent. Then the character is displayed on the LCD.

The sidetone signal appears on pin 28. It goes to the audio amp, Q4, on the demod board. The program controls the frequency of the sidetone, and it can vary from about 600 to 900-Hz.

If you are using an external key, bug or keyer, it controls the voltage on pin 17. The microprocessor repeats this input on pin 39.

Pin 32 controls the keyer's minimum power mode. The demod circuit with 2 chips and tuning LED draw about 15 mA, and must be on constantly to monitor the incoming signal. If you want to use the keyer in a portable situation from small batteries, and are willing to operate without the incoming signal decoding, this feature minimizes the current draw.

When the voltage at pin 32 is 5 V, the micro will shift to the receive mode as soon as sending stops. It then will begin to copy incoming code. In this mode the normal current draw is about 25 mA. If the voltage on pin 32 is 0, the micro will go into an idle mode every time sending stops. It will shut down many of its power consuming functions and wait for an interrupt signal. The three diodes, D1-D3, will cause an interrupt at pin 13 if you press either the paddle or an external key. Pressing the message send switch, M, will cause an interrupt at pin 12. These interrupts put the micro back into the sending mode again until the next pause in keying. This option reduces the average current draw to around 6 mA.

Momentary contact SPST switches S and R are used together with paddles bug, or a key to set the sending and receiving speeds. These speeds can be changed at any time during sending or receiving. When you are done, you can put the 87C51 into a sleep mode by pressing S and RESET together. The microprocessor will turn off power to the rest of the circuit through Q3, and the LCD will go blank. In this mode all settings and memory content are saved, but current draw is reduced to micro amps. To return to normal operation push the RESET button.

The second circuit board contains the

demodulator circuit.<sup>1</sup> It decodes signals from a receiver and sends them to the microcontroller. Audio from the receiver comes in through J6. It is compared against a dc threshold on pin 6. The resulting output signal of 500 mV (at pin 1 of U2) goes to the input of U3 on pin 3.

U2 serves two purposes: first, it rejects noise levels that are not as strong as the desired signal. Second, it keeps the voltage to U3 independent of the signal strength. It is either 0 V when no signal is recognized or 500 mV (P-P) if a signal is present. Thus U3 always receives a constant amplitude input signal. This is important for U3 to work properly.

U3 is an LM567 PLL that was designed to decode DTMF signals. R5, the 10-k $\Omega$  pot (R12) and C1 set the lock frequency. C2 and C3 set the bandwidth. The maximum possible bandwidth of 14% of the center frequency (105-Hz at 750-Hz) makes a narrow filter, but it is ideal for our purposes. When the 500-mV signal from U2 is in the passband of the LM567, the output at pin 8 goes to 0 V from its normal value of 5 V.

Since the PLL bandwidth is about 100 Hz, tuning can be tricky. Therefore a second comparator on the LM339 drives an

LED from pin 14. The LED lights when a signal is detected in this bandwidth.

The demod board also contains a 5-V regulator to allow running the circuit from an external source, such as a 12-V battery or wall transformer. Q4 amplifies the sidetone signal from the keyer board to drive a small speaker.

Switch SP selects the power source for fixed or backpack operation. When used in a fixed location, powered by an external power supply, SP is toggled to the lower contacts on the schematic. J4 and P4 connect the demodulator section, including the 5-V power supply, to the keyer. If you want to use the keyer in a low-power mode, unplug P4 and set SP to the upper contacts. This disconnects the demodulator section, the keyer is powered by the alkaline batteries, and the microcontroller automatically goes into a low power mode when you stop transmitting.

## Construction

The keyer is built on two PC boards. The larger board (Fig 22.44B) is the keyer board. It contains the microprocessor chip and the LCD display. The demod board has the tone decoder IC and the quad comparator IC. With relatively few parts the keyer is easy to build. After wiring the unit only three adjustments are necessary—set the LCD contrast with R1, sidetone level with R13 and the passband of the demod circuit with R12.

<sup>1</sup>This demod circuit was first described by the author in "The N4UAU Super CW Station," *73 Amateur Radio Today*, June 1995, pp10-16.

## The LCD Dot Matrix Display

The screen of an LCD dot matrix display is really only one of several components used to produce the display. If you look on the reverse side of the component you will see two LSI chips. These chips have software that perform many of the tedious functions necessary to use an LCD dot matrix display.

This display is different from and more sophisticated than its simpler cousin, the 7 segment LCD display. The LCD dot matrix display does not have just 7 segments. Instead it has a matrix of dot elements—usually 35 dots per character in a 5  $\times$  7 pattern. Nearly any conceivable shape can be displayed on this device by lighting the appropriate dots. As you can imagine, the housekeeping for such a display is substantial. For a 16 character by 2 line (16  $\times$  2) display, there are 35  $\times$  16  $\times$  2 = 1120 dots to control.

One of the chips on the LCD module does the character display housekeeping for the programmer. This is done with a device called a character generator. The character generator takes an 8 bit code sent from the microcomputer and transforms it into the proper dot pattern. Other instruction registers take different bytes of data, and determine the display position for the character. An onboard RAM stores the data sent to the LCD. This permits the current information to be displayed while the microprocessor does other work.

A total of 192 different characters are in the character generator ROM library. These include both capital and small letters, all the numbers and a variety of other common symbols. LCD dot matrix displays come in many different styles and sizes. Common are 16 characters by 1 line up to 40 characters by 4 lines. Some are back lit. Unlit LCDs draw only about 2 mA in use while the backlit ones can draw nearly 1 A.

If you want to take advantage of the battery-powered backpack mode, build the demodulator, 5-V regulator, and momentary contact switch R into one enclosure. Put the keyer board, DPDT switch SP and batteries into a second enclosure.

Construction and layout are not critical. N6ZAT built the unit shown in Fig 22.44B. He does not use the power reduction mode but still uses batteries—D cells because of the current draw.

The keyer will work with 40 by 2, 32 by 2, 24 by 2, 20 by 2 and 16 by 2 displays. The ND7K keyer shown was built to be small. He used a unique 20 by 2 display with very large letters that he found in a piece of old telephone gear at a hamfest. The cost was \$1! This display is mounted

on a piece of Plexiglas bent at an angle. The angle mounting greatly improves readability when the keyer is at table level.

N1OKL built a version using a backlit display, because he keeps the lighting low in his shack. The letters are visible across the room. He got his display from Digi-Key.

All the parts except the programmed microcontroller and PC boards are available from suppliers such as Digi-Key, Mouser and JDR. All Electronics sells wired six conductor telephone connectors that work well for J4 and P4. The preprogrammed 87C51, two PC boards and complete building instructions are available from the author for \$40, which includes shipping (add sales tax if you live

in Florida). The author also has available a package of parts that includes nearly all the items you need. Prices range from about \$70 to \$100 depending on the kit. Send an SASE for latest information.<sup>2</sup>

### Acknowledgments

Thanks to the many users of the original keyer, who provided suggestions and ideas to improve it, and the photos that accompany this write-up. Tim Glennon, KQ4TQ, was of particular help. He provided much-needed technical data about the LM567.

<sup>2</sup>The addresses of the author, Digi-Key, Mouser, All Electronics and JDR are in the Address List in the **References** chapter.

## QUICK AND EASY CW WITH YOUR PC

A couple of chips and a few hours work will yield this CW only terminal for a PC. Designed by Ralph Taggart, WB8DQT, the software transforms a computer into a Morse machine that's a full-function CW keyboard and a receive display terminal.

The circuit works with IBM-compatible PCs and uses the printer port to communicate with the computer. Parts cost is generally less than \$50, and a printed-circuit board is available to make construction easier.

### Circuit Description

Each stage of the circuit in Fig 22.46A is labeled with its function. Ferrite beads are used to keep RF from entering the unit. K1 provides isolation, so any transmitter may be keyed without worrying about polarity. Fig 22.46B shows the power and computer interconnections for the circuit board.

### Power Supply Options

Three voltage sources are required (+12 V, +5 V and -9 V) at relatively low current. The simplest approach is to use a wall-mount power transformer/supply (200 mA minimum) to provide the +12 V. A 7805 voltage regulator chip (U6) produces +5 V from the +12 V bus for the 74LS TTL ICs. Since the -9 V current requirements are very low, a 9 V alkaline transistor battery was used in WB8DQT's unit. This battery is switched in and out using one set of contacts on the POWER switch and will last a long time—unless you forget to turn the unit off between operating sessions!

### The Computer Connection

The circuit connects to the PC parallel

printer port, which is usually a DB-25F (female) connector on the rear of the computer. A standard cable with a mating DB-25M (male) connector on one end and DB-25F on the other end could be used. This cable is available at any computer store, but it would require a DB-25M to be mounted on your project box.

Unfortunately, DB-25 connectors need an odd-shaped mounting hole, which is difficult to make with standard shop tools. Since only four conductors are needed (ground, printer data bits 0 and 1,

and the strobe data bit), it's easier to make a cable. Use a 4-pin microphone connector at one end and a DB-25M at the other end. Wire the cable as follows:

Function	Microphone Plug	DB-25M Connector
Ground	1	25
Printer data 0	2	2
Printer data 1	3	3
Printer strobe	4	1

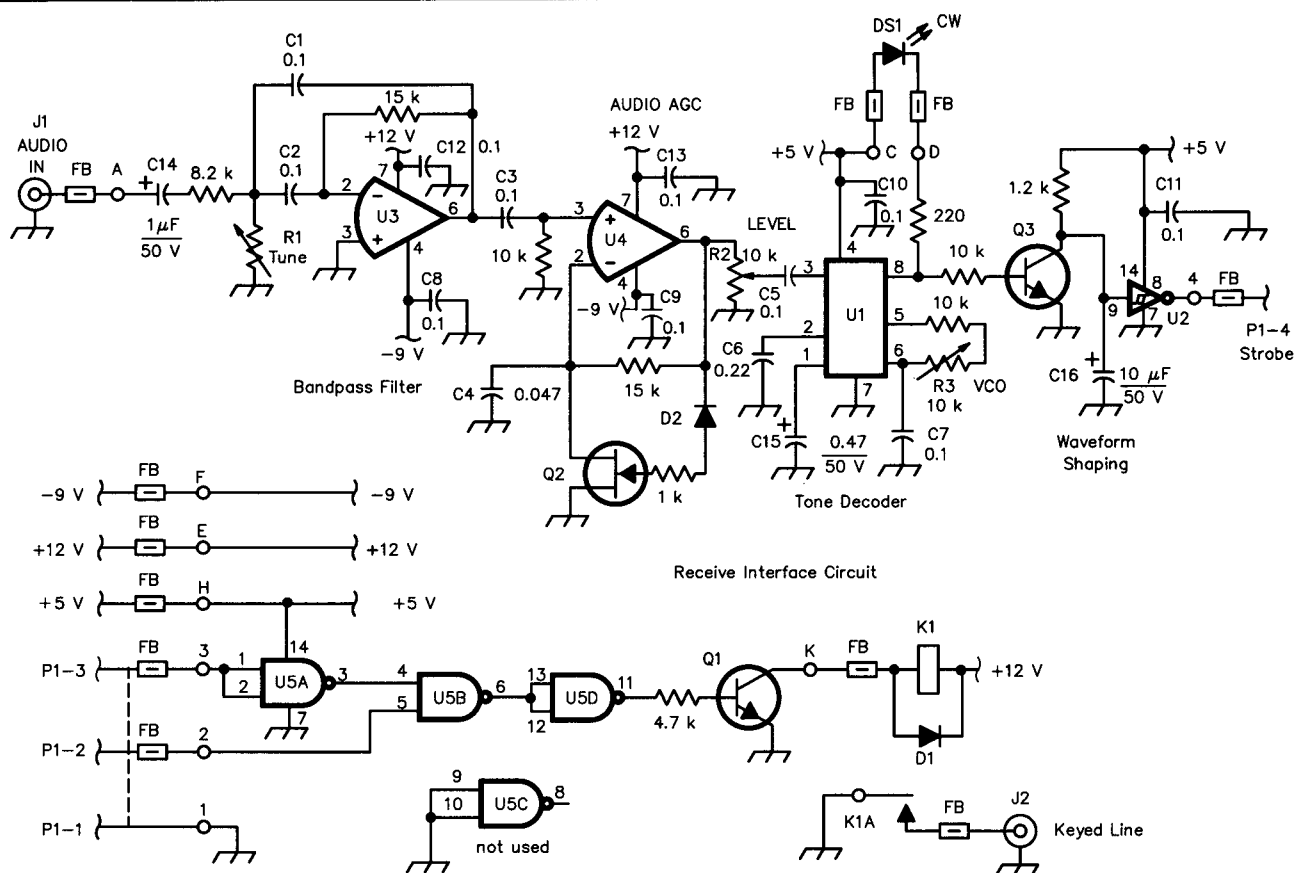

Drill a  $\frac{5}{8}$ -inch round hole on the rear

14-pin DIP IC sockets.  
DPDT miniature toggle switch.  
J3 is a panel-mounting coaxial power jack to match your wall-mount/transformer power supply. BT1 is a 9-V alkaline battery. See text. C17 and C18 are 0.1  $\mu$ F, 50 V monolithic or disc ceramic bypass capacitors. The +5 V regulator chip should be mounted to the grounded wall of the cabinet. Off-board components are duplicated in section B of this drawing (J1, J2, P1, the CW LED indicator, and K1). The CW and POWER indicators are panel-mounting LED indicators (red for POWER and green for CW). FB indicates optional ferrite beads used to prevent RF interference with the interface circuits.

Except as indicated, decimal values of capacitance are in microfarads ( $\mu\text{F}$ ); others are in picofarads (pF); resistances are in ohms; k=1,000, M=1,000,000. Labeled circles (A-K, 1-4) indicate PC board connections.

apron of the project enclosure for the mating chassis-mount 4-pin microphone socket.

## Keying Options

For equipment with a positive, low-voltage keying line, point K on the board can be connected directly to the keying jack. In this case, omit K1 and its 1N4004 diode. For a wider range of transmitting equipment, use the keying relay. Mount it anywhere in the cabinet using a dab of silicone adhesive or a piece of double-sided foam mounting tape.

## Construction

The simplest way to construct this circuit is on a single PC board. The PC-board pattern and parts overlay are available from the ARRL.<sup>1</sup> Make a PC board, or use the overlay to wire the circuit using perf-board. An etched and drilled PC board, with a silk-screened parts layout, is available from FAR Circuits.<sup>2</sup>

Any cabinet or enclosure that can accommodate the circuit board can be used. The POWER switch and POWER and CW LED indicators are the only front-panel items. J2 (KEYED LINE), J1 (AUDIO IN), J3 (+12 V DC POWER) and P1 (COMPUTER) are on the rear apron of the enclosure.

## Alignment

There are three alignment adjustments, all of which are for the receive mode. Start by loading (and running) the software and turning the unit on. Switch the receiver to a dummy antenna to eliminate any interfering signals, and tune the receiver to a strong signal from a frequency calibrator or any

other stable signal source. Carefully adjust the receiver for peak audio output. You may need a Y connector so the receiver can feed the interface and a speaker.

Connect a pair of headphones to the junction of the 0.1- $\mu$ F capacitor and 10-k $\Omega$  resistor at pin 3 of U4. Adjust the Tune (R1) control on the PC board for the loudest signal. The filter is sharp, so make the adjustment carefully.

Set the PC board Level pot (R2) to midrange and adjust the VCO pot (R3) until the CW LED (DS1) comes on. Decrease the Level setting slightly (adjust the control in a counterclockwise direction) and readjust the VCO pot, if required, to cause the CW LED to light. Continue to reduce the Level setting in small steps, each time readjusting the VCO setting, until you reach the point where operation of the CW indicator becomes erratic.

Now turn the Level control back (clockwise) to just past the point where the LED comes on with no sign of erratic operation. The Level threshold setting is critical for best operation of the receive demodulator. If the control is advanced too far, the LED will trigger on background noise and copy will be difficult. If you reduce the setting too far, the interface will trigger erratically, even with a clean beat note. If you have a reasonably good CW receiver (CW bandwidth crystal filters and/or good audio filtering), you can back down the Level control until the LED stops flickering on all but the strongest noise pulses, but where it will still key reliably on a properly tuned CW signal.

## Software Installation

The software for this project is included on the disk supplied with this book. The distribution files include MORSE.EXE, a sample set-up file (CW.DAT), a sample logging file (LOG.DAT), the HELP text file (CWHELP.DAT) and the program Quick-BASIC source code (MORSE.BAS). To run the program log into the directory holding these files and type *MORSE* <CR>. The symbol <CR> stands for *Return* or *Enter*, depending on

your keyboard.

The program menu permits you to enter or change the following items:

**SPEED**—Select a transmitting speed from 5 to 60 WPM. The program autocalibrates to your computer clock speed, and transmitting speeds are accurate to within 1%. On receive, the system automatically tracks the speed of the station you are copying up to 50 or 60 WPM.

**YOUR CALL**—You can enter your call sign so you never have to type it in routine exchanges. The call can be changed at any time if you want to use the program for contests, special events, or any other situation where you will be using another call.

**OTHER CALL**—If you enter the call of the station you are working (or would like to work), you can send all standard call exchanges at the beginning and end of a transmission with a single keystroke.

**CQ OPTIONS**—Select one of two CQ formats. The "standard" format is a 3x3 call using your call sign. The program also lets you store a custom CQ format, which is useful for contests.

**MESSAGE BUFFERS**—There are two message buffers. Either can be used for transmitting.

**SIDETONE**—Select on or off and a frequency of 400 to 1200 Hz.

**WEIGHTING**—Variable from 0.50 through 1.50.

**DEFAULT SETUP**—All the information discussed up to this point can be saved into a default disk file (CW.DAT). These choices will then be selected whenever you boot the program. Any setup can be saved at anytime.

**LOGGING**—The program supports a range of logging functions. It even includes the ability to check the log and let you know if you have worked that station before. If you have fully implemented the logging options, it will tell you the operator's name and QTH.

**HELP FILES**—If you forget how to use a function or are using the program for the first time, you can call up on-screen HELP files that explain every function.

<sup>1</sup>A PC-board template package is available free from the ARRL Technical Secretary. Enclose a business-size SASE and request the '96 *Handbook* Taggart CW Interface Template.

<sup>2</sup>A circuit board is available for \$5 (plus \$1.50) from FAR Circuits (see the Address List in the **References** chapter).

## THE CONTEST CARD

This project, by Gary Sutcliffe, W9XT, was originally published in September 1993 *QST*. It describes a PC-compatible plug-in card that contains a voice recorder and CW interface. The Contest Card is software-compatible with the most popular contest logging programs and can be built for less than the cost of most standalone voice recorders.

### DESIGN CONSIDERATIONS

After hearing some voice keyers on the air, the author decided it was very important for such devices to reproduce the operator's voice accurately. It's confusing to answer a CQ and hear a different voice coming back. Many use inexpensive electret microphones for recording. To minimize the difference between live and recorded audio, the Contest Card uses the mike normally used with the transmitter.

The design must also be compatible with K8CC's *NA* and K1EA's *CT* contest programs. These programs use the same technique to key external voice keyers via one of the computer's LPT (parallel) ports.

It soon became obvious that the whole unit could mount inside the computer. The card's hardware would "look like" an LPT port to the software. Since *NA* and *CT* can also key a transmitter on CW with a suitable interface, the author also included this feature in his design. Fig 22.47 is a photo of the completed unit, and Fig 22.48 shows the Contest Card in block-diagram form.

Putting the entire unit on a PC plug-in card offers several advantages. The first is price. A plug-in computer card is more expensive than a box-mounted board because of the card's complex shape and gold-plated contact fingers. This higher cost, however, is more than offset by the savings gained from the lack of packaging and power-supply requirements. Since the card is controlled by software, fewer buttons and switches are needed, further reducing cost. Putting the card inside the computer also frees up desk space and eliminates the need to share an LPT port between a printer and voice keyer—important for PCs with only one parallel port.

### THE ISD-1016A INTEGRATED CIRCUIT

The heart of the card is the ISD-1016A. The ISD-1016A can store 16 seconds of audio. It samples the audio signal at its microphone input at an 8-kHz rate. The chip's EEPROM stores the sampled values in analog form. The main advantage of this technique is that the message is not lost when power is removed, as it is in traditional RAM-based voice recorders.

Fig 22.47—The Contest Card combines a voice keyer and CW interface in a single PC-compatible plug-in card.

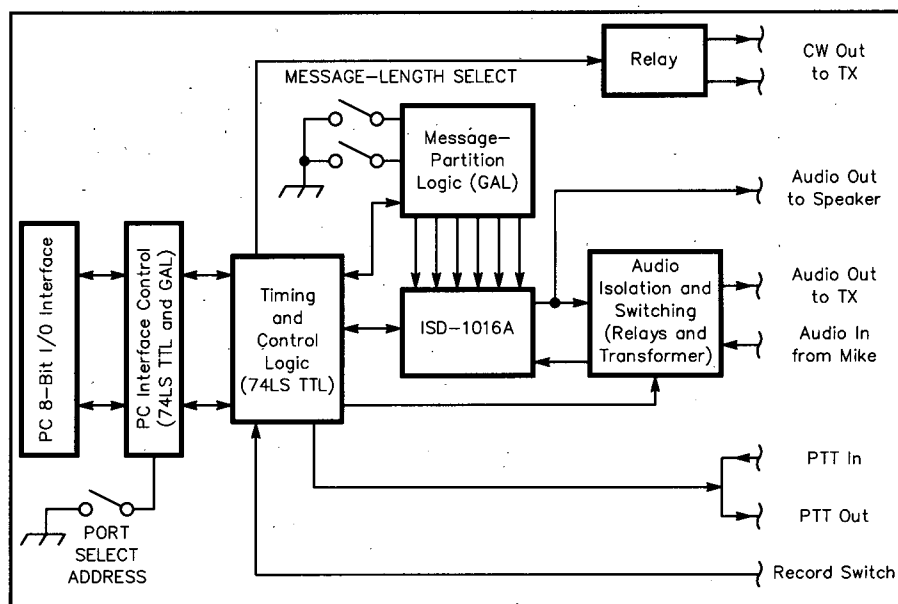

Fig 22.48—Block diagram of the Contest Card

The Contest Card supports up to four messages. These correspond to the messages started by pressing the F1, F2, F3 and F4 keys on the keyboard while running *NA* or *CT*. Each key is assigned a specific type of message by the software, such as CQ, contest report, QRZ message and your call sign. The chip's 16 seconds of recording time must be divided between the messages. You select how this time is divided by setting two switches.

During playback, a message continues until it reaches the end of the message. You can interrupt playback in the middle of a message by pressing ESC in *CT* or *NA*.

Recording resembles playback, except that it requires a record-control signal that

can be generated by two sources: an external switch or software control. The transmitter's PTT line is not activated during recording.

Audio to and from the ISD-1016A is switched by a pair of DPDT relays. When the Contest Card is not recording or playing back a message, the microphone audio input and microphone ground are switched directly to the transmitter. This provides complete isolation from the computer, which is required to prevent hum on live audio. You can leave your microphone connected through the Contest Card even when the computer is powered off.

The card's audio output is isolated by a transformer. Without this isolation, volt-

age differences between the computer and the transmitter cause current to flow on the ground connection. This current generates hum on the transmit audio.

On CW, the card uses a relay to key the transmitter. Relay keying was chosen to allow operation with positive- and negative-keyed rigs with a single circuit.

## CONSTRUCTION

Detailed construction information, including schematics for the Contest Card and interface cable, are available from the ARRL.<sup>1</sup> The card uses entirely off-the-shelf parts, with the exception of two generic-array logic (GAL) ICs that manage some of the ISD-1016A's functions. As a result, you can build a Contest Card yourself from scratch, if you have GAL-programming capabilities. If you don't, programmed GALs are available.<sup>2</sup> A PC board, kits of parts and the completed Contest Card are available through Unified Microsystems.

In order for the Contest Card circuit board to be offered for sale, FCC Class B certification was required. The testing procedure revealed that unacceptably high levels of RF emissions were being picked up and radiated through the cable. To eliminate this problem, a special DB25 connector is needed. Each pin of this connector contains a 470-pF bypass capacitor to ground. Such connectors are very expensive in small quantities, so they're included in the kits and assembled version.

If you decide to wire-wrap or design your own Contest Card PC board, you should either use the specified connector or install 470-pF bypass capacitors on every signal line leaving the connector. Place the capacitors as close to the connector as possible and ground the connector shell. Under FCC regulations, home-built electronics for personal use do not require certification, but must use "good engineering practice." Aside from the FCC regulations, you don't want computer-generated noises covering up weak DX stations answering your CQs!

To use the Contest Card, you'll need to construct an interface cable. All connections to the card are made through a single DB25 connector. The circuit uses only 14 of this connector's pins, but a 25-pin con-

nectector provides a bit of extra space to ease construction. Use only shielded cable for all connections. The PTT ground and microphone ground *must* be separate shields or severe hum is likely to appear on the transmitted audio. Small coaxial cable, such as RG-174, works well for this application.

Some transmitters (notably ICOMs) place +8 V on their microphone-audio lines. If you have such a rig, put a dc-blocking capacitor in series with the audio line to the transmitter. A 0.22- $\mu$ F or larger cap should work fine and can be mounted in the cable's DB25 shell. Interface cables for most popular transceivers are available from LTA Industries.<sup>3</sup>

## USING THE CONTEST CARD

You'll need to decide how to partition the card's memory space. This is handled by two switches on the card, accessible through the card's mounting bracket. **Table 22.2** shows how the messages can be divided. The simplest way to divide the time between four messages is to give each one 4 seconds. This is fine for some uses, but poor for others. Your contest exchange for the ARRL Sweepstakes, for example, may be too long to fit comfortably in 4 seconds. You can set the switches so that one of the messages is zero seconds long, giving the extra time to the remaining messages.

You can record messages in two ways. Perhaps the easiest method is to use your logging program and an external switch (normally open, momentary) connected to pins 8 and 9 of the DB25 connector. To record with the external switch, bring up *CT* or *NA*. In the set-up screen be sure to set the Contest Card to use the correct parallel port. In *CT* and *NA*, function keys F1-F4 correspond to messages 1 through 4, respectively. Pressing a function key starts playing back the appropriate message. If the record switch is held closed before the function key is pressed, the corresponding message can be recorded. Recording continues until the record button is released. This method of recording messages was chosen so it would not be necessary to quit the logging program to record new messages. (*NA* Version 8 also supports recording without the switch and *CT* may soon do so as well.)

The other way to store messages is to use a program that supports software-controlled recording. Such a program can be easily written in most common computer languages. The card's documentation (and the information package available from

**Table 22.2**

### Contest Card Message Partitioning

Switch Selection	Message #1	Message Length #2	Length #3	(Seconds) #4
1	6.4	2.4	4.0	3.2
2	5.6	7.2	3.2	0.0
3	8.0	0.0	4.8	3.2
4	4.0	4.0	4.0	4.0

ARRL<sup>4</sup>) explains the requirements. A standalone program for Contest Card control, DVRC.EXE, is also available from Unified Microsystems.<sup>2</sup> It controls record and playback of voice messages on the Contest Card. It also controls playback on other voice keyers that follow the same interface standards.

It is important that you not record messages longer than the length of time specified for each message (see Table 22.2). A message that's too long will overrun part of the next message's space, recording over anything already stored there. Also, if you change the switch settings, you will usually need to record each message again.

Last, you'll need to adjust the card's audio-output level. First, record a long test message. Then adjust your transmitter's microphone gain to the appropriate level while speaking into the microphone. Next, play back the test message and adjust the potentiometer accessible through the card-edge bracket for the proper level for your transmitter. The ISD-1016A has an excellent AGC circuit, so it should not be necessary to adjust this pot again unless you switch to a significantly different microphone.

## SUMMARY

The Contest Card offers a low-cost solution for integrating your computer, transceiver, digital voice recorder and CW-keying interface. It does this while maintaining software compatibility with the standards set by *NA* and *CT*. Other applications for the Contest Card abound. For example, a PC-based repeater controller could use the Contest Card for IDs and special messages. VHF operators can also use it for their transmit sequences during meteor-scatter schedules.

Thanks to Bruce Herrick, WW1M, for laying out the Contest Card circuit board. Additional thanks to Paul Hellenberg, KS9K, and Scott Ellington, K9MA, for their help and suggestions.

<sup>1</sup>A package of information including GAL program listings, detailed construction information, circuit theory and schematics for the Contest Card is available from the ARRL Technical Department Secretary. Request the *September 1993 QST Sutcliffe Information Package*. Include a large SASE with your request.

<sup>2</sup>For a list of available kits, send an SASE to Unified Microsystems (see the Address List in the **References** chapter).

<sup>3</sup>For information about ordering these cables, contact LTA Industries (see the Address List in the **References** chapter).

<sup>4</sup>See Note 1.

## AN INEXPENSIVE AMPLIFIED BOOM/HEADSET MIKE

The microphone project presented here is a combination of two separate projects that appeared in *QST*.<sup>1,2</sup> Shown are ways to construct both a headset and a boom microphone using the same readily-available electret element. In addition, an amplifier with high- and low-frequency boost adjustments can be added to either design.

### HEADSET MIKE CONSTRUCTION

The headset mike is about as simple as you can ask for. The electret element is simply held in place by a slightly rigid piece of copper wire (#18 or so). A claw test clip is used to connect the assembly to your headphones. See Fig 22.49 for detail.

First, attach a 6-inch piece of the wire to the claw test clip. Put your headphones on and attach the clip to a convenient spot. You might need a mirror to find the best place.

Next, trim the support wire to length. The best place for the mike to be is at the corner of your mouth. This location helps minimize the popping noises you get when you speak and breathe directly into the mike.

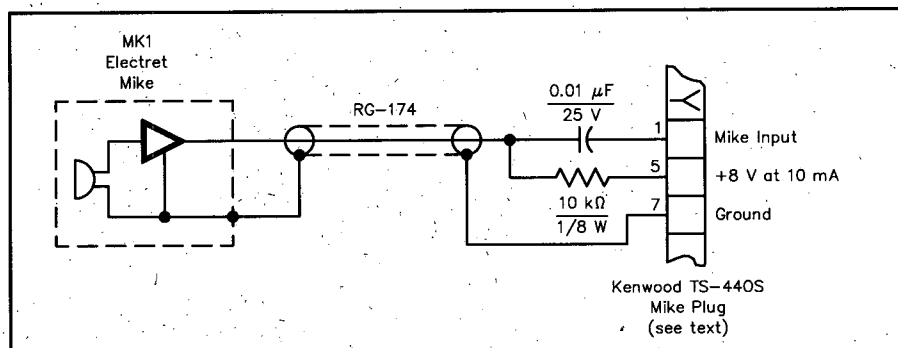

Slide the support wire and a length of miniature coax (such as RG-174) through a 6-inch piece of heat-shrink tubing. Solder the cable to the two mike-element connectors and carefully solder the

<sup>1</sup>D. Brede, "A \$5 Headset Mike," Jan 1993 *QST*.

<sup>2</sup>D. DeMaw, "Build a Low-Cost Booster Microphone," Aug 1989 *QST*.

**Fig 22.49**—To form the headset-mike boom, slide the support wire and the end of a length of miniature coax through a 6-inch piece of heat-shrink tubing. Solder the coaxial cable to the two connectors on the mike element and carefully solder the support wire onto the mike's case. If your mike element has an aluminum case, solder the support wire to the mike's ground connector.

**Fig 22.50**—Schematic of the \$5 Headset Mike circuit. Part numbers in parentheses are Radio Shack; equivalent parts can be substituted.

**MK1**—Miniature electret microphone element (270-090 or 270-02).

**Misc:** Claw clip (270-345), 4 to 5 ft of RG-174 miniature coaxial cable, 6

inches of heat-shrink tubing, a 6-inch piece of semi-rigid bare #18 copper wire, an 8-pin microphone connector (274-025A), or other connector required to match your rig's mike jack.

support wire to the mike's case. See Fig 22.50 for connection details. If your mike element has an aluminum case, solder the support wire to the ground connector instead. After verifying that the mike element is positioned correctly, heat the shrink tubing.

The tiny electret mike element contains a small amplifier that requires a dc power source to operate. Fig 22.50 shows how to take power from the microphone connector of a Kenwood TS-440S. Most rigs will have a similar source available. If not, a 9-V battery works well. The element only draws about 1 mA, so battery life should not be a problem.

### BOOM MIKE AND AMPLIFIER CONSTRUCTION

The same electret element can be used to build a boom microphone. Also detailed is a boost circuit that can be housed in the base of the boom mike or added to a separate housing for the headset mike. Fig 22.51 is a photograph of the boom mike made from PVC pipe. Other ideas may be tried that have a little more esthetic appeal. The PVC solution is inexpensive and easy to construct, however.

The boom is made from 1/2-inch PVC pipe. The vertical post is fashioned from 3/4-inch PVC pipe. The boom is approximately 6 1/2 inches long, including the pipe cap at the back end. The vertical post is 5 1/2 inches long, including the pipe cap on the top.

A hollow base for housing the boost circuit can be made from pieces of single-sided PC board. The dimensions (HWD) are 1 3/8 × 4 × 5 1/8 inches. The PC sections are soldered at the seams (copper surfaces inside the box). A piece of PC-board stock

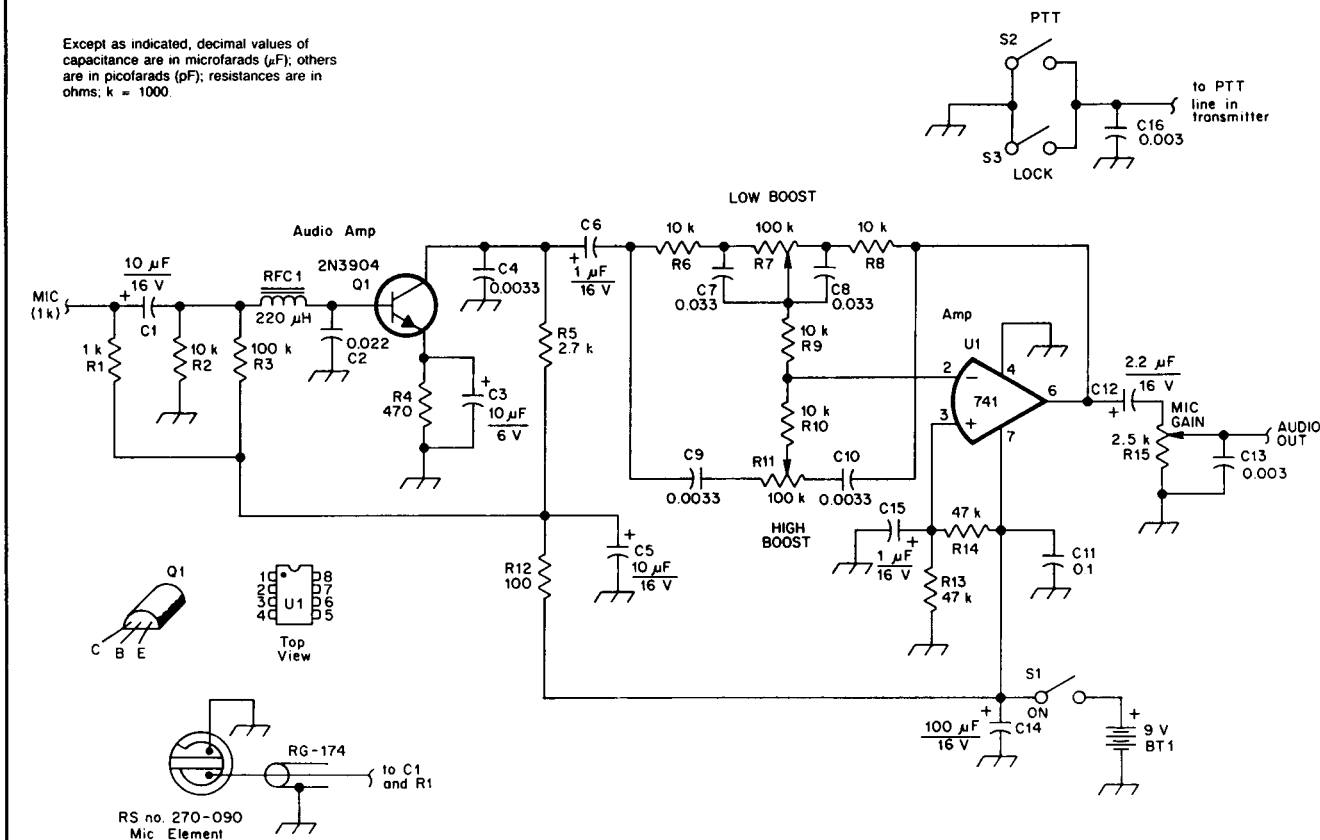

**Fig 22.51**—Photograph of the boom mike made from PVC pipe. Other ideas may be tried that have a little more esthetic appeal (aren't as ugly). The PVC solution is inexpensive and easy to construct, however.

**Fig 22.52**—Internal view of the mike. The PC board is elevated above the base plate by means of short metal spacers. Shielded leads (RG-174) are used for the audio lines. The shield braid is grounded at each end of these leads. Shielded two-conductor mike cord is recommended between the mike and the transmitter.

Except as indicated, decimal values of capacitance are in microfarads ( $\mu\text{F}$ ); others are in picofarads (pF); resistances are in ohms; k = 1000

**Fig 22.53—Schematic diagram of the mike amplifier/booster. Capacitors are disc ceramic unless otherwise noted. Polarized capacitors are electrolytic or tantalum. Fixed-value resistors are  $\frac{1}{4}$ -W carbon composition.**

**BT**—Standard 9-V transistor-radio battery.

**C7-C10, incl**—Mylar or disc ceramic (match values within 5%).

**R7, R9, R15**—Miniature PC-mount control with triangular lead layout.  
**RFC1**—Miniature RF choke, 220  $\mu\text{H}$  to 1 mH (value not critical). Do not substitute a ferrite bead.

**S1, S3**—Miniature SPST toggle.  
**S2**—Momentary push-button switch, normally open.  
**U1**—8-pin DIP 741 op amp.

serves as the bottom plate. The circuit board for the boost circuit, BT1 and a  $\frac{3}{4}$ -inch PVC pipe cap are attached to the bottom plate (Fig 22.52). A  $\frac{7}{8}$ -inch hole is bored in the top surface of the base directly over the  $\frac{3}{4}$ -inch pipe cap inside the box. The vertical post for the mike fits snugly into the pipe cap.

The electret element is inserted into one end of the PVC boom. It must be mounted flush. If it is recessed, it will adversely affect audio quality. The element will need to be wrapped with a few turns of masking tape to ensure a snug fit. A short 4-40 screw that fits in a threaded hole in the boom can be used to hold the element in place. RG-174 coaxial cable is used between the mike element and the boost circuit in the base. The cable is passed through a hole in the boom at the junction of the boom and vertical post. Another hole is drilled in the vertical post, just below the top surface of the base. This allows the RG-174 cable to be routed to

the PC board above the pipe cap in the base.

The diagonal hole in the vertical post is a bit tricky to drill. One method involves placing the  $\frac{3}{4}$ -inch pipe in a vise at the desired angle. Then drill the hole while holding the drill straight up and down. Start with a  $\frac{1}{8}$ -inch drill bit and work progressively up to a  $\frac{1}{2}$ -inch. A round file is then used to shape the hole for a snug fit between the boom pipe and the vertical post. A drop of PVC cement will lock the two together. PVC cement can also be used to secure the pipe cap at the back of the boom.

The circuit of Fig 22.53 fits on a PC board that measures  $1\frac{1}{2} \times 3\frac{3}{4}$  inches. Drilled and plated PC boards are available for this project from FAR Circuits.<sup>3</sup>

<sup>3</sup>A parts-placement guide and etching pattern are available from the ARRL Technical Secretary. Enclose a business-size return envelope and request the 95 Handbook Boom/Headset package.

## PROPER ADJUSTMENT

Be aware of the gain of this mike! Adjust the audio level of your rig using the stock or existing non-amplified mike. Do this in accordance with the operator's manual and on-the-air checks. After replacing that mike with this one, adjust R15 for the same peak meter readings as before. Do not exceed this output level. Too much audio from the mike will overdrive the input circuit and cause distortion. Experiment with the settings for R7 and R11.

Operate your rig into a dummy load and monitor the signal with a receiver (AGC disabled and RF gain setting reduced). Tweak the boost controls until you feel the audio response is suitable for your voice. Final adjustments may be carried out on the air. Try to obtain reports from amateurs that have heard you speak in person. Do not use a speech processor when you make your preliminary tests, as you won't get an accurate picture of your voice range and quality.

## AN EXPANDABLE HEADPHONE MIXER

From time to time, active amateurs find themselves wanting to listen to two or more rigs simultaneously with one set of headphones. For example, a DXer might want to comb the bands looking for new ones while keeping an ear on the local 2-m DX repeater. Or, a contestor might want to work 20 m in the morning while keeping another receiver tuned to 15 m waiting for that band to open. There are a number of possible uses for a headphone mixer in the ham shack.

The mixer shown in Figs 22.54 and 22.55 will allow simultaneous monitoring of up to three rigs. Level controls for each channel allow the audio in one channel to be prominent, while the others are kept in the background. Although this project was built for operation with three different rigs, the builder may vary the number of input sections to suit particular station requirements. This mixer was built in the ARRL Lab by Mark Wilson, AA2Z.

Fig 22.54—The 3-channel headphone mixer is built on a small PC board. Lead length was kept to a minimum to aid stability.

### CIRCUIT DETAILS

The heart of the mixer is an LM386 low-power audio amplifier IC. This 8-pin device is capable of up to 400-mW output at 8  $\Omega$ —more than enough for headphone listening. The LM386 will operate from 4- to 12-V dc, so almost any station power supply, or even a battery, will power it.

As shown in Fig 22.55, the input circuitry for each channel consists of an 8.2- $\Omega$  resistor (R1-R3) to provide proper termination for the audio stage of each transceiver, a 5000- $\Omega$  level control (R4-R6) and a 5600- $\Omega$  resistor (R7-R9) for isolation between channels. C1 sets the gain of the LM386 to 46 dB. With pins 1 and 8 open, the gain would be 26 dB. Feedback resistor R10 was chosen experimentally for minimum amplifier total harmonic distortion (THD). C2 and R11 form a “snubber” to prevent high-frequency oscillation, adding to amplifier stability. None of the parts values are particularly critical, except R1-R3, which should be as close to 8  $\Omega$  as possible.

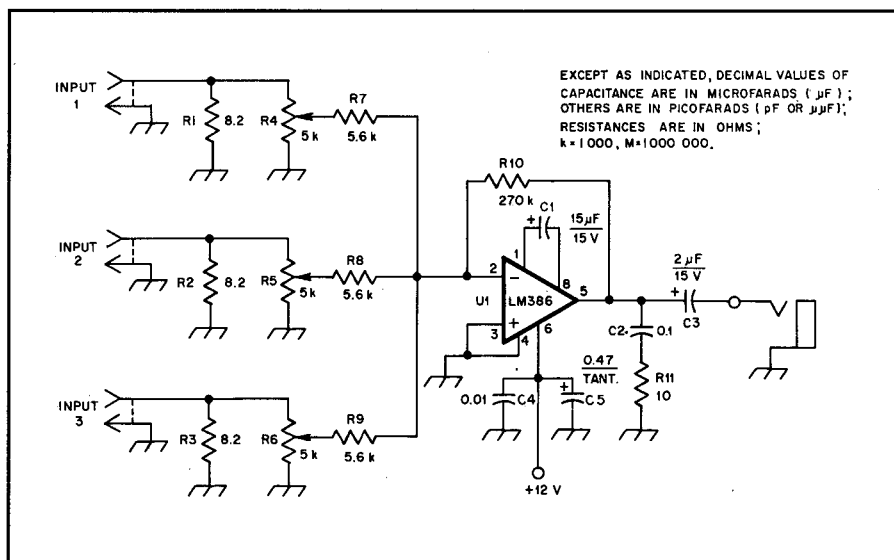

Fig 22.55—Schematic diagram of the LM386 headphone mixer. All resistors are 1/4 W. Capacitors are disc ceramic unless noted.

### CONSTRUCTION

Most of the components are arranged on a small PC board.<sup>1</sup> Perfboard will work fine also, but some attention to detail is

<sup>1</sup>A parts placement diagram and full-size etching pattern are available from the ARRL Technical Secretary. Enclose a business-size SASE and request the 95 Handbook Headphone Mixer package.

necessary because of the high gain of the LM386. Liberal use of ground connections, short lead lengths and a bypass capacitor on the power-supply line all add to amplifier stability.

The mixer was built in a small diecast box. Tantalum capacitors and 1/4-W resistors were used to keep size to a minimum. The '386 IC is available from Radio Shack (cat. no. 276-1731). A 0.01- $\mu$ F capacitor

and a ferrite bead on the power lead help keep RF out of the circuit. In addition, shielded cable is highly recommended for all connections to the mixer. The output jack is wired to accept stereo headphones.

Output power is about 250 mW at 5% THD into an 8- $\Omega$  load. The output waveform faithfully reproduces the input waveform, and no signs of oscillation or instability are apparent.

## AUDIO BREAK-OUT BOX

Two integrated circuits and a small PC board are all you need to solve the problem of feeding one receiver into several add-ons, such as a TNC, a PC interface or a speaker. Ben Spencer, G4YNM, described this project in March 1995 *QST*. It takes the audio output from a receiver and applies it to the inputs of four identical, independent, low-level AF amplifiers and one high-level (1-W output) AF amplifier.

Each low-level output channel can provide up to 20 dB of gain that's independently adjustable. You can apply audio to each of your accessories at a selected level without changing the level to the other accessories. In addition you can set the level to the speaker independently. Turn the speaker volume up to tune in the signal, and then turn the speaker volume down once tuning is finished and the mode is operating.

### Circuit Description

Four identical low-level channels, each feeding an amplifier (U1A, B, C and D), are shown in **Fig 22.56**. Using the top channel as an example, C1 connects the input jack J1 to the noninverting input of U1A. R3 and R4 set U1A's voltage gain. R4 is the gain control, and when set fully clockwise (maximum resistance), the amplifier's gain is 10 (20 dB). At a counterclockwise (minimum resistance) setting, the amplifier's gain is 1 (0 dB).

The lower cut-off frequency (set by C2 and R3) is 16 Hz. The upper cut-off frequency of each channel is well beyond the audio frequency range. Each channel's output is dc isolated from its load; for example, U1A's output is dc isolated by C3.

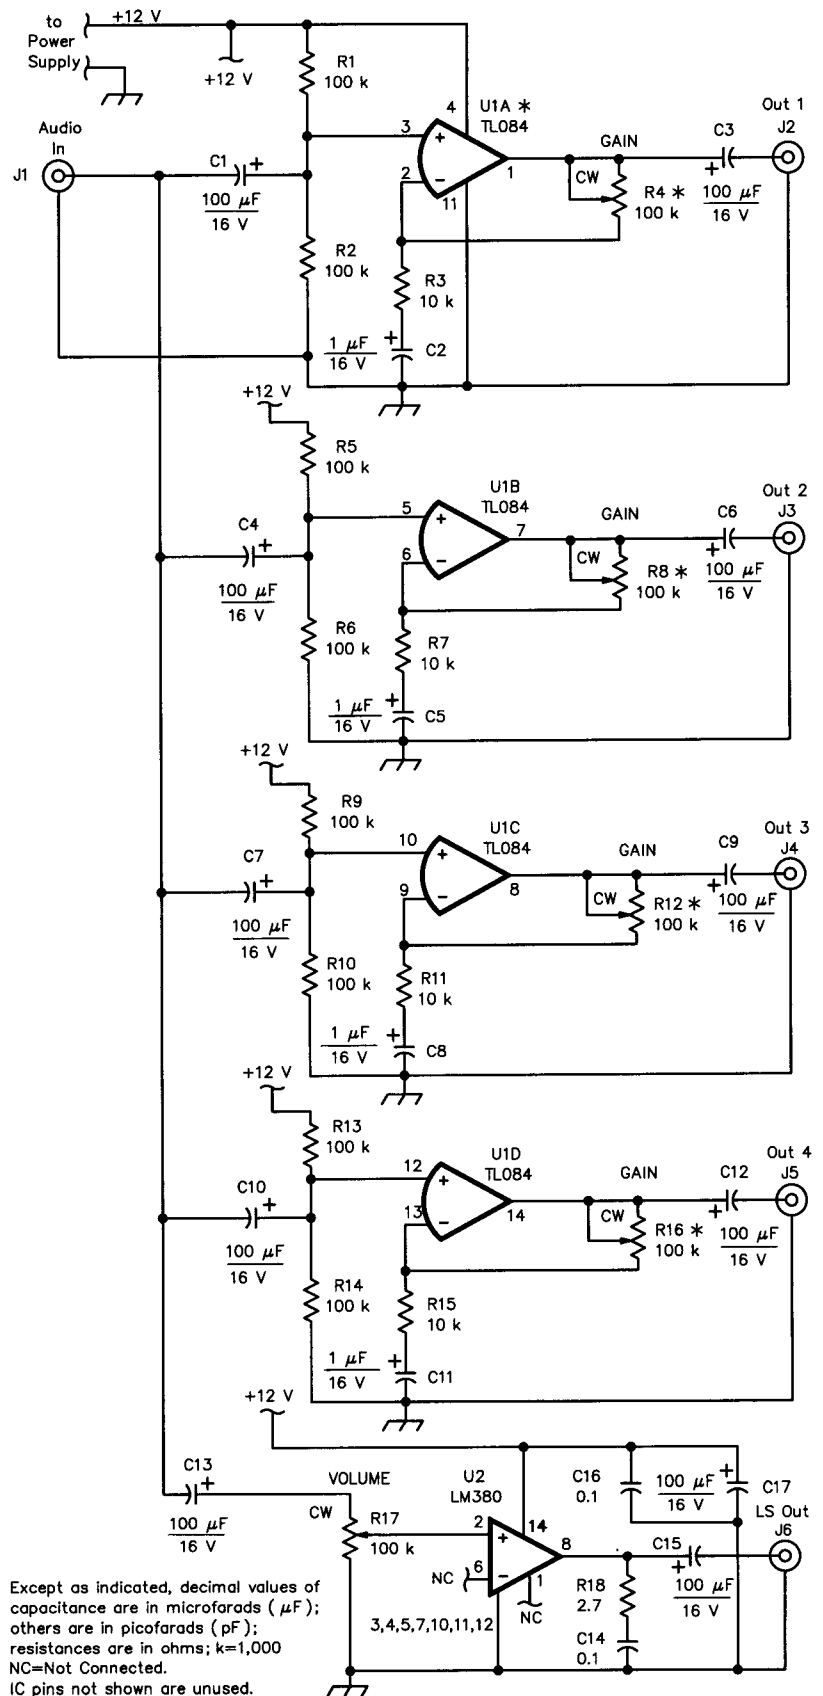

R17 is the volume control for AF power amplifier U2. This stage will drive a low-impedance load such as a loudspeaker (4 to 16  $\Omega$ ) at a level up to 1 W.

### Construction

A single-sided PC board is available,<sup>1</sup> but the unit will work equally well built on perf-board. A template available from the ARRL<sup>2</sup> includes a PC board layout and a parts layout. This parts layout also can be used as a guide for construction on perf-board. The PC board directly accepts vertical and horizontal-mount single-turn potentiometers, but you can run wires from the mounting holes to front-panel-mount

<sup>1</sup> PC boards are available for \$6, plus \$1.50 shipping, from FAR Circuits (see the Address List in the **References** chapter).

<sup>2</sup> A PC-template is available from the ARRL Technical Secretary. Enclose a business size (#10) SASE and ask for the 96 *Handbook* Spencer Audio Break-Out Box Template.

**Fig 22.56**—This audio break-out box requires less than 500-mA from a 12-VDC supply. All resistors are  $\frac{1}{4}$ -W, 5%-tolerance carbon-composition or film units unless otherwise specified. RS numbers in parentheses are Radio Shack stock numbers.

C1, C3, C4, C6, C7, C9, C10, C12, C13, C15, C17—100  $\mu$ F, 16-V radial electrolytic or tantalum (RS 272-1028).

C2, C5, C8, C11—1  $\mu$ F, 16-V radial electrolytic or tantalum (RS 272-1434).

C14, C16—0.1  $\mu$ F, 50 V disc ceramic (RS 272-135).

R1, R2, R5, R6, R9, R10, R13, R14—100 kW.

R3, R7, R11, R15—10 kW.

R4, R8, R12, R16, R17—100-kW log or audio taper, panel-mount potentiometer (RS 271-1722) or PC-board vertical-mount trimmer potentiometer; see text.

R18—2.7  $\Omega$ ,  $\frac{1}{2}$  W.

U1—TL084, TL074, or LM324 quad op amp (RS 276-1711).

U2—LM380N 2-W audio power amplifier. The LM380 is available in several packages. Be sure to use the 14-pin DIP if you are going to build this project on the PC board from FAR or from the ARRL template.

Misc: Single-sided PC board (see Note 1), enclosure, knobs, IC sockets, input and output connectors of choice, hook-up wire.

potentiometers. Since the project uses high-gain audio circuits, enclose it in a metal box. Place the input and output jacks on the rear panel to keep the interconnecting leads out of the way.

### Checkout

After rechecking your wiring and soldering, connect the circuit to a 12-V power supply. The current drawn should be less than 50 mA when no audio is applied. Connect J1 to the AF output of your receiver and a speaker to J6. Adjust R17, VOLUME, for a comfortable listening level. Next check the operation of the low-power outputs by connecting J2, J3, J4 and J5 to a small earplug. Vary the four gain controls to check their operation. Each gain control can now be set to provide the audio level needed for each add-on.

## AN SWR DETECTOR AUDIO ADAPTER

This SWR detector audio adapter is designed specifically for blind or vision-impaired amateurs, but anyone can use it. The basic circuit can be adapted to any application where you want to use an audio tone rather than a meter to give an indication of the value of a dc voltage.

Usually a meter (or meters) is used to display SWR by measuring the feed line forward and reflected voltages. This adapter generates two tones with frequencies that are proportional to these voltages. The tones are fed to a pair of stereo headphones (the miniature types are ideal) so one ear hears the forward-voltage tone and the other ear hears the reflected-voltage tone. Ben Spencer, G4YNM, described this system in the July 1994 *QST*. He connected the forward voltage tone to his left earphone and reverse voltage tone to his right earphone. Thus, tuning up a transmitter is simply a matter of tuning for the highest pitched tone in the left ear, and the lowest pitched tone in the right ear.

The PC board can be installed in existing SWR detectors, and the forward and reflected voltages obtained by tapping into the lines that currently connect the voltage

sensors to the existing meters or meter selector switch.

### Circuit Description

The audio-adapter circuit is shown in Fig 22.57. Each half of the adapter circuit operates identically. Most SWR detectors consist of two RF voltage sensors, one for forward voltage and one for reverse. These voltages are diode-rectified. The resulting dc voltages are fed to meters that indicate relative forward and reflected power. With this circuit, the forward and reflected voltages are applied to the audio adapter board and drive voltage-controlled oscillators (VCOs).

The forward dc voltage from the SWR detector is routed to R1, buffered by U1B, fed to Sensitivity control R5A and applied to VCO U2B. As the voltage on pin 1 of U2B increases, so does the frequency of the tone output at U2B pin 10.

Adjusting the Sensitivity control sets the range of audio tones produced by the audio adapter. This signal is fed via VOLUME control R6A to the audio amplifier (U3A) to drive the left headphone. Zener diode D1 limits the maximum input voltage, partly to protect U1B, but also to limit the upper VCO frequency to about 3 kHz.

Without any dc input, each VCO runs at a low frequency (approximately 380 Hz) to tell you the unit is operating. Increased voltage on the transmission line—even from a low-power transmitter—is sufficient to cause the tone frequency to increase noticeably. As the voltage decreases, so does the frequency of the tone.

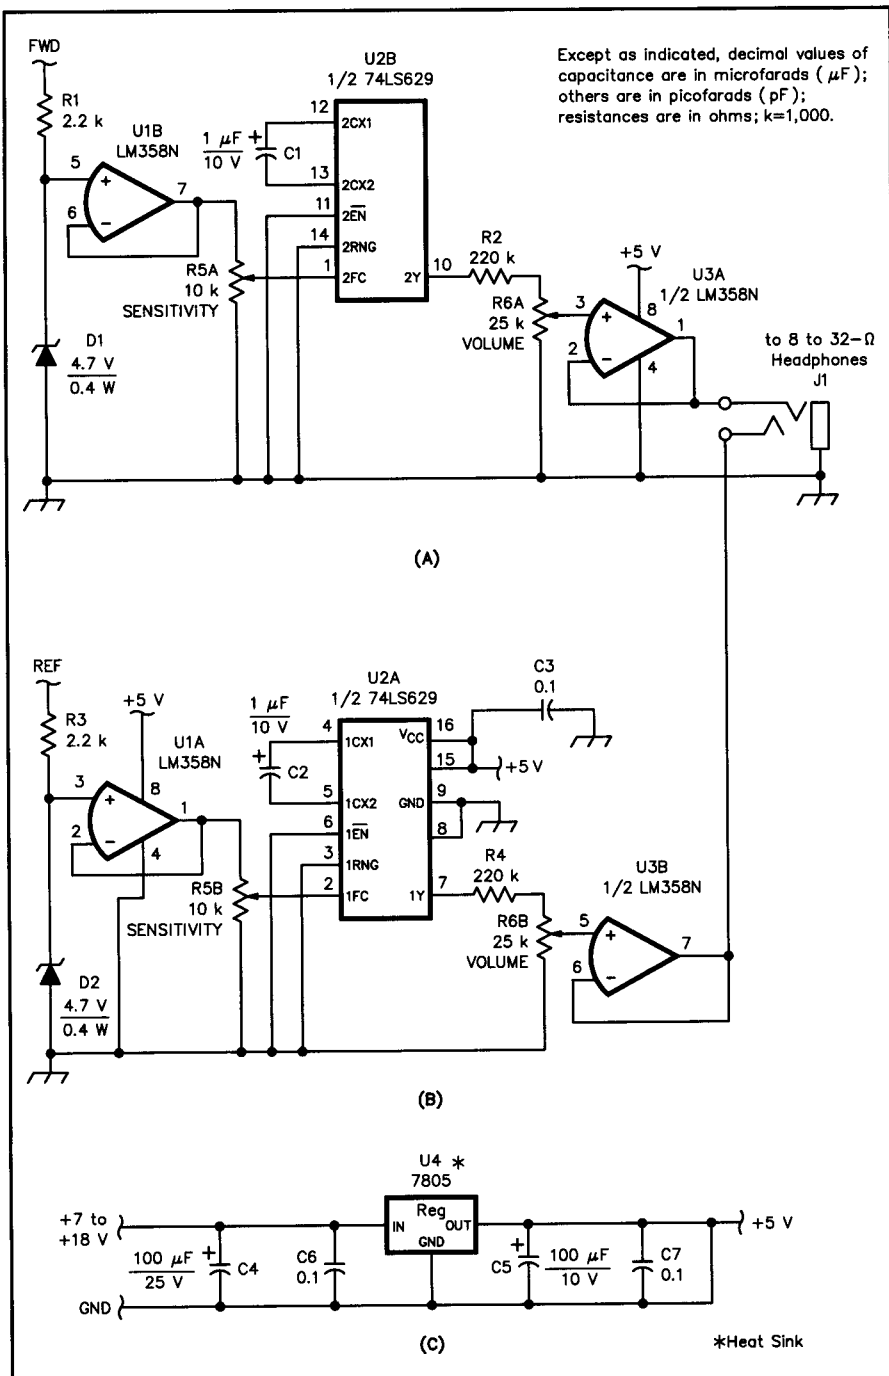

### Construction

A single-sided PC board and template package are available.<sup>1,2</sup> The PC board is small enough to fit inside most existing SWR detectors and the circuit can be battery operated if required. Mount a stereo headphone jack on the SWR detector's front panel to accept the headphone plug.

R6A and R6B are parts of a dual-section, panel-mount potentiometer. R5A and R5B are PC-board mounted trimmer potentiometers. For those who want a

<sup>1</sup> PC boards are available for \$2.50, plus \$1.50 shipping, from FAR Circuits (see the address list in the **References** chapter).

<sup>2</sup> A PC-template is available free from the ARRL Technical Secretary. Enclose a business size (#10) SASE and ask for the '96 *Handbook* Spencer Audible SWR Adapter Template.

**Fig 22.57—Schematic of the SWR detector audio-adaptor circuit. Unless otherwise specified, resistors are 1/4-W, 5%-tolerance carbon-composition or film units. All capacitors are disc ceramic unless otherwise stated. The circuits of A and B are identical, each driving one earphone of an 8- to 32-Ω stereo headset. At A, the forward-voltage circuit; at B, the reflected-voltage circuit. A voltage regulator that provides 5-V dc is shown at C.**

**R5A, R5B**—10-kΩ horizontal-mount trimmer potentiometer; optionally, a 25-kΩ dual-gang, panel-mount potentiometer can be used.

**R6**—25-kΩ dual-gang, panel-mount potentiometer.

**U1, U3**—LM358N dual op amp (available from Jameco. See the Address List in the References chapter) or substitute an NTE928M (available from Hosfelt Electronics).

**U2**—74LS629 dual VCO (available from Jameco) or a NTE74LS629 (available from Hosfelt Electronics).

**Misc:** PC board, stereo headphone jack, 8 to 32-Ω stereo headphones, mounting hardware.

panel-mounted Sensitivity control, a dual-gang potentiometer can be substituted for R5A and R5B.

## Testing and Calibration

Once the unit is installed in an SWR detector, connect a 5-V power supply to the audio adapter board. When power is applied, you should hear two identical low frequency tones in the headphones. Adjust the VOLUME controls to provide a comfortable listening level.

Next, connect your transmitter to a dummy load via the SWR detector. When you key your transmitter, the tone in the left earpiece should increase in frequency quite dramatically, representing increasing forward power. Theoretically, with a matched line and load, there should be no reflected voltage and therefore, the right-headphone tone shouldn't change. In all probability, however, the tone frequency will increase, but only slightly.

If you use an antenna tuner for matching your antenna system, you'll hear the two tones change frequency according to the degree of mismatch. The best match is indicated by the forward headphone tone reaching its maximum frequency while the reflected (right) headphone tone frequency decreases to its minimum.

## PC VOLTMETER AND SWR BRIDGE

Personal computers are very good at doing arithmetic. To use this capability around the shack, the first thing to do is convert whatever you want to measure (voltage, power, SWR) to numbers. Next you have to find a way to put these numbers into your computer. Paul Danzer, N1II, took a single chip A/D (analog to digital converter) and built this unit to connect to a computer printer port. Construction and test is just a few evenings' work, and the software to run the chip is on the disk enclosed with this book.

### Circuit Description

The circuit consists of a single-chip A/D converter, U2, and a DB-25 male plug (Fig 22.58). Pins 2 and 3 are identical voltage inputs, with a range from 0 to slightly less than the supply voltage  $V_{CC}$  (+5 V). R1, R2, C3 and C4 provide some input isolation and RF bypass. There are four signal leads on U2—DO is the converted data from the A/D out to the computer, DI and CS are control signals from the computer and CLK is a computer generated clock signal sent to pin 7 of U2.

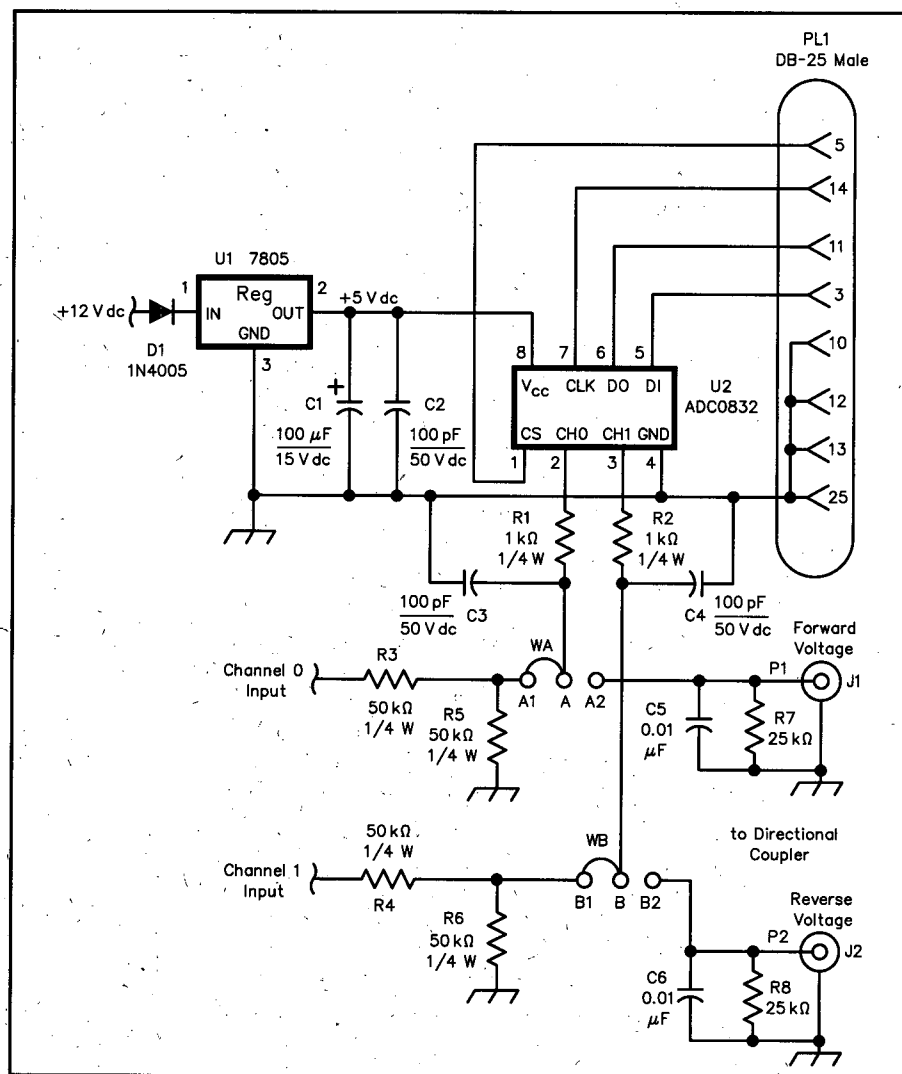

The +5 V supply is obtained from a +12 V source and regulator U1. One favorite accident, common in many ham shacks, is to connect power supply leads backwards. Diode D1 prevents any damage from this action. Current drain is usually less than 20-mA, so any 5-V regulator may be used for U1. The power supply ground, circuit ground and computer ground are all tied together.

In this form the circuit gives two identical dc voltmeters. To extend the range, a 2:1 divider, using 50-k $\Omega$  resistors, is shown. Resistor accuracy is not important, since the circuit is calibrated in the accompanying software.

The breadboard circuit, built on a universal PC board (Radio Shack 276-150), is shown in Fig 22.59. The voltage regulator is on the top left and the converter chip, U2, in an 8-pin socket. Power is brought in through a MOLEX plug which follows the standard suggested earlier in this chapter. Signal input and ground are on the wire stubs. Two strips of soft aluminum, bent into L-shapes, hold the male DB-25 connector (Radio Shack 276-1547) to the PC board.

### Use It As An SWR Bridge

Most analog SWR measuring devices use a meter, which has a nonlinear scale calibration. An SWR of 3:1 is usually close to center scale, and values above this are rarely printed. To use the PC voltmeter as an SWR bridge indicator, move jumpers WA and WB from the A1 and B1 posi-

**Fig 22.58**—Only two chips are used to provide a dual-channel voltmeter. PL1 is connected through a standard 25-pin cable to a computer printer port. U2 requires an 8-pin IC socket. All resistors are 1/4 W. You can use the A/D as an SWR bridge by connecting it to a sensor such as the one used in the Tandem Match described in this chapter (see text). A few more resistors are all that are needed to change the voltmeter scale. The 50 k $\Omega$  resistors form 2:1 voltage dividers, extending the voltmeter scale (on both channels) to almost 10-V dc.

tions to the A2 and B2 positions. Disconnect the cathodes (banded end) of the diode detectors in your SWR bridge and connect them to J1 and J2.

The current that flows out of these diodes, and into J1 and J2, goes through the 25 k $\Omega$  resistors R7 and R8, to provide voltages of less than 5 V. These voltages are proportional to the forward and reverse voltages developed in the directional coupler. The software in the PC takes the sum and difference of these forward and reverse voltages, and calculates the SWR.

### Software

The software, including a voltmeter function and an SWR function, is written in

GW-BASIC and saved as an ASCII file. Therefore you can read it on any word processor, but if you modify it make sure you resave it as an ASCII file. It can be imported into QBasic and most other BASIC dialects.

It was written to be understandable rather than to be most efficient. Each line of basic code has a comment or explanation. It can be modified for most computers. The printer port used is LPT1, which is at a hex address of 378, 379 and 37A. If you wish to use LPT2 (printer port 2) try changing these addresses to 278, 279 and 27A.

Gary Sutcliffe, W9XT, wrote a small BASIC program to help you find the addresses of your printer ports. Run

**Fig 22.59—Construction of this model took only one evening. No special tools are required. All parts except U2 are available from most suppliers as well as Radio Shack. The A/D converter chip can be purchased from any National Semiconductor dealer such as Digi-Key. See the Address List in the References chapter.**

FINDLPT.BAS, which is included on the *Handbook* disk.

The A2D program was written to run on computers as slow as 4.7-MHz PC/XTs. If you get erratic results with a much faster computer, set line 1020 (CD=1) to a higher value to increase the width of the computer generated clock pulses.

The A2D program operates by first reading the value of voltage at point A into the computer, followed by the voltage at point B. It then prints on the screen these two values, and computes their sum and difference to derive the SWR. If you use the project as a voltmeter, simply ignore the SWR reading on the screen or suppress it by deleting lines 2150, 2160 and 2170. If the two voltages are very close to each other (within 1 mV) the program declares a bad reading for SWR.

### Calibration

Lines 120 and 130 in the program independently set the calibration for the two voltage inputs. To calibrate a channel, apply a known voltage to the input point A. Read the value on the PC screen. Now multiply the constant in line 120 by the correct value and divide the result by the value you previously saw on the screen. Repeat the procedure for input point B and line 130.

## THE TANDEM MATCH—AN ACCURATE DIRECTIONAL WATTMETER

Most SWR meters are not very accurate at low power levels because the detector diodes do not respond to low voltage in a linear fashion. This design uses a compensating circuit to cancel diode nonlinearity. It also provides peak detection for SSB operation and direct SWR readout that does not vary with power level. **Fig 22.65** is a photo of the completed project. The following information is condensed from an article by John Grebenkemper, KI6WX, in January 1987 *QST*. Some modifications by KI6WX were detailed in the "Technical Correspondence" column of July 1993 *QST*. The minor ones have been included here. More extensive changes are included with a PC Board available from FAR Circuits.<sup>1</sup>

### CIRCUIT DESCRIPTION

A directional coupler consists of an in-

<sup>1</sup>A PC board is available from FAR Circuits. See the Address List in the **References** chapter. PC board template packages are also available from FAR Circuits.

**Fig 22.65—The Tandem Match uses a pair of meters to display net forward power and true SWR simultaneously.**

put port, an output port and a coupled port. Ideally, a portion of the power flowing from the input to the output appears at the coupled port, but *none* of the power flowing from the output to the input appears at the coupled port.

The coupler used in the Tandem Match consists of a pair of toroidal transformers connected in tandem. The configuration was patented by Carl G. Sontheimer and Raymond E. Fredrick (US Patent no. 3,426,298, issued February 4, 1969). It has been described by Perras, Spaulding (see

**Table 22.4**

### Performance Specifications for the Tandem Match

Power range:	1.5 to 1500 W
Frequency range:	1.8 to 54 MHz
Power accuracy:	Better than $\pm 10\%$ ( $\pm 0.4$ dB)
SWR accuracy:	Better than $\pm 5\%$
Minimum SWR:	Less than 1.05:1
Power display:	Linear, suitable for use with either analog or digital meters
SWR display:	Linear, suitable for use with either analog or digital meters
Calibration:	Requires only an accurate voltmeter

**Fig 22.71** —Construction details for the directional coupler. A metal case is required.

**Fig 22.72**—The parallel load resistors mounted on an SO-239 connector. Four 200-Ω resistors are mounted in parallel to provide a 50-Ω detector load.

bibliography) and others. With coupling factors of 20 dB greater, this coupler is suitable to sample both forward and reflected power.

The configuration used in the Tandem Match works well over the frequency range of 1.8 to 54 MHz, with a nominal coupling factor of 30 dB. Over this range, insertion loss is less than 0.1 dB. The coupling factor is flat to within  $\pm 0.1$  dB from 1.8 to 30 MHz, and increases to only  $\pm 0.3$  dB at 50 MHz. Directivity exceeds 35 dB from 1.8 to 30 MHz and exceeds 26 dB at 50 MHz.

The low-frequency limit of this directional coupler is determined by the inductance of the transformer secondary windings. The inductive reactance should be greater than 150  $\Omega$  (three times the line characteristic impedance) to reduce insertion loss. The high-frequency limit of this

directional coupler is determined by the length of the transformer windings. When the winding length approaches a significant fraction of a wavelength, coupler performance deteriorates.

The coupler described here may overheat at 1500 W on 160 m (because of the high circulating current in the secondary of T2). The problem could be corrected by using a larger core or one with greater permeability. A larger core would require longer windings; that option would decrease the high-frequency limit.

Most amateur directional wattmeters use a germanium-diode detector to minimize the forward voltage drop. Detector voltage drop is still significant, however, and an uncompensated diode detector does not respond to small signals in a linear fashion. Many directional wattmeters compensate for diode nonlinearity by ad-

**Table 22.5**

**Range-Switch Resistor Values**

Full-Scale Power Level (W)	Range Resistor (1% Precision) (k $\Omega$ )
1	2.32

justing the meter scale.

The effect of underestimating detected power worsens at low power levels. Under these conditions, the ratio of the forward power to the reflected power is overestimated because the reflected power is always less than the forward power. This results in an instrument that underestimates SWR, particularly as power is reduced. A directional wattmeter can be checked for this effect by measuring SWR at several power levels. The SWR should be independent of power level.

The Tandem Match uses a feedback circuit to compensate for diode nonlinearity. Transmission-line SWR is displayed on a linear scale. Since the displayed SWR is not affected by changes in transmitter power, a matching network can be simply adjusted to minimize SWR. Transmatch adjustment requires only a few watts.

## CONSTRUCTION

The schematic diagram for the Tandem Match is shown in **Fig 22.70**. The circuit is designed to operate from batteries and draws very little power. Much of the circuitry is of high impedance, so take care to isolate it from RF fields. House the circuit in a metal case. Most problems in the prototype were caused by stray RF in the op-amp circuitry.

## DIRECTIONAL COUPLER

The directional coupler is constructed in its own small ( $2\frac{3}{4} \times 2\frac{3}{4} \times 2\frac{1}{4}$ -inch) aluminum box (see **Fig 22.71**). Two pairs of SO-239 connectors are mounted on opposite sides of the box. A piece of PC board is run diagonally across the box to

improve coupler directivity. The pieces of RG-8X coaxial cable pass through holes in the PC board. (Note: Some brands of "mini 8" cable have extremely low breakdown voltage ratings and are unsuitable to carry even 100 W when the SWR exceeds 1:1. See "High-Power Operation" for details of a coupler made with RG-8 cable.)

Begin by constructing T1 and T2, which are identical except for their end connections. (Refer to Fig 22.71.) The primary for each transformer is the center conductor of a length of RG-8X coaxial cable. Cut two cable lengths sufficient for mounting as shown in the figure. Strip the cable jacket, braid and dielectric as shown. The cable braid is used as a Faraday shield between the transformer windings, so it is only grounded at one end. *Important—connect the braid only at one end or the directional-coupler circuit will not work properly!* Wind two transformer secondaries, each 31 turns of #24 enameled wire on a T-50-3 iron-powder core. Slip each core over one of the prepared cable pieces (including both the shield and the outer insulation). Mount and connect the transformers as shown in Fig 22.71, with the wires running through separate holes in the copper-clad PC board.

The directional coupler can be mounted separately from the rest of the circuitry if desired. If so, use two coaxial cables to carry the forward- and reflected-power signals from the directional coupler to the detector inputs. Be aware, however, that any losses in the cables will affect power readings.

This directional coupler has not been used at power levels in excess of 100 W. For more information about using Tandem Match at high power levels, see "High-Power Operation."

## DETECTOR AND SIGNAL-PROCESSING CIRCUITS

The detector and signal-processing circuits were constructed on a perforated, copper-clad circuit board. These circuits use two separate grounds—it is *extremely important to isolate the grounds as shown in the circuit diagram*. Failure to do so may result in faulty circuit operation. Separate grounds prevent RF currents on the cable shield from affecting the op-amp circuitry.

The directional coupler requires good 50- $\Omega$  loads. They are constructed on the back of the female UHF chassis connectors where the cables from the directional coupler enter the wattmeter housing. Each load consists of four 200- $\Omega$  resistors connected from the center conductor of the UHF connector to the four holes on the mounting flange, as shown in Fig 22.72.

The detector diode is then mounted from the center conductor of the connector to the 100-pF and 1000-pF bypass capacitors, which are located next to the connector. The response of this load and detector combination measures flat to beyond 500 MHz.

Schottky-barrier diodes (type 1N5711) were used in this design because they were readily available. Any RF-detector diode with a low forward voltage drop (less than 300 mV) and reverse breakdown voltage greater than 30 V could be used. (Germanium diodes could be used in this circuit, but performance will suffer. If germanium diodes are used, reduce the values of the detector-diode and feedback-diode load resistors by a factor of 10.)

The rest of the circuit layout is not critical, but keep the lead lengths of 0.001- and 0.01- $\mu$ F bypass capacitors short. The capacitors provide additional bypass paths for the op-amp circuitry.

D6 and D7 form a voltage doubler to detect the presence of a carrier. When the forward power exceeds 1.5 W, Q3 switches on and stays on until about 10 seconds after the carrier drops. (A connection from TP7 to TP9 forces the unit on, even with no carrier present.) The regulated references of +2.5 V and -2.5 V generated by the LM334 and LM336 are critical. Zener-diode substitutes would significantly degrade performance.

The four op amps in U1 compensate for nonlinearity of the detector diodes. D1-D2 and D3-D4 are the matched diode pairs discussed above. A RANGE switch selects the meter range. (A six-position switch was used here because it was handy.) The resistor values for the RANGE switch are shown in Table 22.5 Full-scale input power gives an output at U1C or U1D of 7.07 V. The forward- and reflected-power detectors are zeroed with R1 and R2.

The forward- and reflected-detector voltages are squared by U2, U5 and U6 so that the output voltages are proportional to forward and reflected power. The gain constants are adjusted using R3 and R4 so that an input of 7.07 V to the squaring circuit gives an output of 5 V. The difference between these two voltages is used by U4B to yield an output that is proportional to the power delivered to the transmission line. This voltage is peak detected (by an RC circuit connected to the OPERATE position of the MODE switch) to indicate and hold the maximum power measurement during CW or SSB transmissions.

SWR is computed from the forward and reflected voltages by U3, U4 and U7. When no carrier is present, Q4 forces the SWR reading to be zero (that is, when the

forward power is less than 2% of the full-scale setting of the RANGE switch). The SWR computation circuit gain is adjusted by R5. The output is peak detected in the OPERATE mode to steady the SWR reading during CW or SSB transmissions.

Transistor arrays (U5, U6 and U7) are used for the log and antilog circuits to guarantee that the transistors will be well matched. Discrete transistors may be used, but accuracy may suffer.

A three-position toggle switch selects the three operating modes. In the OPERATE mode, the power and SWR outputs are peak detected and held for a few seconds to allow meter reading during actual transmissions. In the TUNE mode, the meters display instantaneous output power and SWR.

A digital voltmeter is used to obtain more precise readings than are possible with analog meters. The output power range is 0 to 5 V (0 V = 0 W and 5 V = full scale). SWR output varies from 1 V (SWR = 1:1) to 5 V (SWR = 5:1). Voltages above 5 V are unreliable because of voltage limiting in some of the op amp circuits.

## CALIBRATION

The directional wattmeter can be calibrated with an accurate voltmeter. All calibration is done with dc voltages. The directional-coupler and detector circuits are inherently accurate if correctly built. To calibrate the wattmeter, use the following procedure:

- 1) Set the MODE switch to TUNE and the RANGE switch to 100 W or less.
- 2) Jumper TP7 to TP8. This turns the unit on.
- 3) Jumper TP1 to TP2. Adjust R1 for 0 V at TP3.
- 4) Jumper TP4 to TP5. Adjust R2 for 0 V at TP6.
- 5) Adjust R1 for 7.07 V at TP3.
- 6) Adjust R3 for 5.00 V at TP9, or a full-scale reading on M1.
- 7) Adjust R2 for 7.07 V at TP6.
- 8) Adjust R4 for 0 V at TP9, or a zero reading on M1.
- 9) Adjust R2 for 4.71 V at TP6.
- 10) Adjust R5 for 5.00 V at TP10, or a full-scale reading on M2.
- 11) Set the RANGE switch to its most sensitive scale.
- 12) Remove jumpers from TP1 to TP2 and TP4 to TP5.
- 13) Adjust R1 for 0 V at TP3.
- 14) Adjust R2 for 0 V at TP6.
- 15) Remove jumper from TP7 to TP8.

This completes the calibration procedure. This procedure has been found to equal calibration with expensive laboratory equipment. The directional wattmeter should now be ready for use.

## ACCURACY

Performance of the Tandem Match has been compared to other well-known directional couplers and laboratory test equipment, and it equals any amateur directional wattmeter tested. Power measurement accuracy of the Tandem Match compares well to a Hewlett-Packard HP-436A power meter. The HP meter has a specified measurement error of less than  $\pm 0.05$  dB. The Tandem Match tracked the 436A within  $\pm 0.5$  dB from 10 mW to 100 W and within  $\pm 0.1$  dB from 1 W to 100 W. The unit was not tested above 1200 W because a transmitter with a higher power rating was not available.

SWR performance was equally good when compared to the SWR calculated from measurements made with 436A and a calibrated directional coupler. The Tandem Match tracked the calculated SWR within  $\pm 5\%$  for SWR values from 1:1 to 5:1. SWR measurements were made at 8 W and 100 W.

## OPERATION

Connect the Tandem Match in the 50- $\Omega$  line between the transmitter and the antenna matching network (or antenna if no matching network is used). Set the RANGE switch to a range greater than the transmitter output rating and the MODE switch to TUNE. When the transmitter is keyed, the Tandem Match automatically switches on and indicates both power delivered to the antenna and SWR on the transmission line. When no carrier is present, the output power and SWR meters indicate zero.

The OPERATE mode includes RC circuitry to momentarily hold the peak-power and SWR readings during CW or SSB transmissions. The peak detectors are not ideal, so there could be about 10% variation from the actual power peaks and the SWR reading. The SWR $\times 10$  mode increases the maximum readable SWR to 50:1. This range should be sufficient to cover any SWR value that occurs in amateur use. (A 50-ft open stub of RG-8

yields a measured SWR of only 43:1, or less, at 2.4 MHz because of cable loss. Higher frequencies and longer cables exhibit a smaller maximum SWR.)

It is easy to use the Tandem Match to adjust an antenna-matching network. Adjust the transmitter for minimum output power (at least 1.5 W). With the carrier on and the MODE switch set to TUNE or SWR $\times 10$ , adjust the matching network for minimum SWR. Once minimum SWR is obtained, set the transmitter to the proper operating mode and output power. Place the Tandem Match in the OPERATE mode.

## PARTS

Few parts suppliers carry all the components needed for these couplers. Each may stock different parts. Good sources include Digi-Key, Surplus Sales of Nebraska, Newark Electronics and Anchor Electronics. See the Address List in the **References** Chapter.

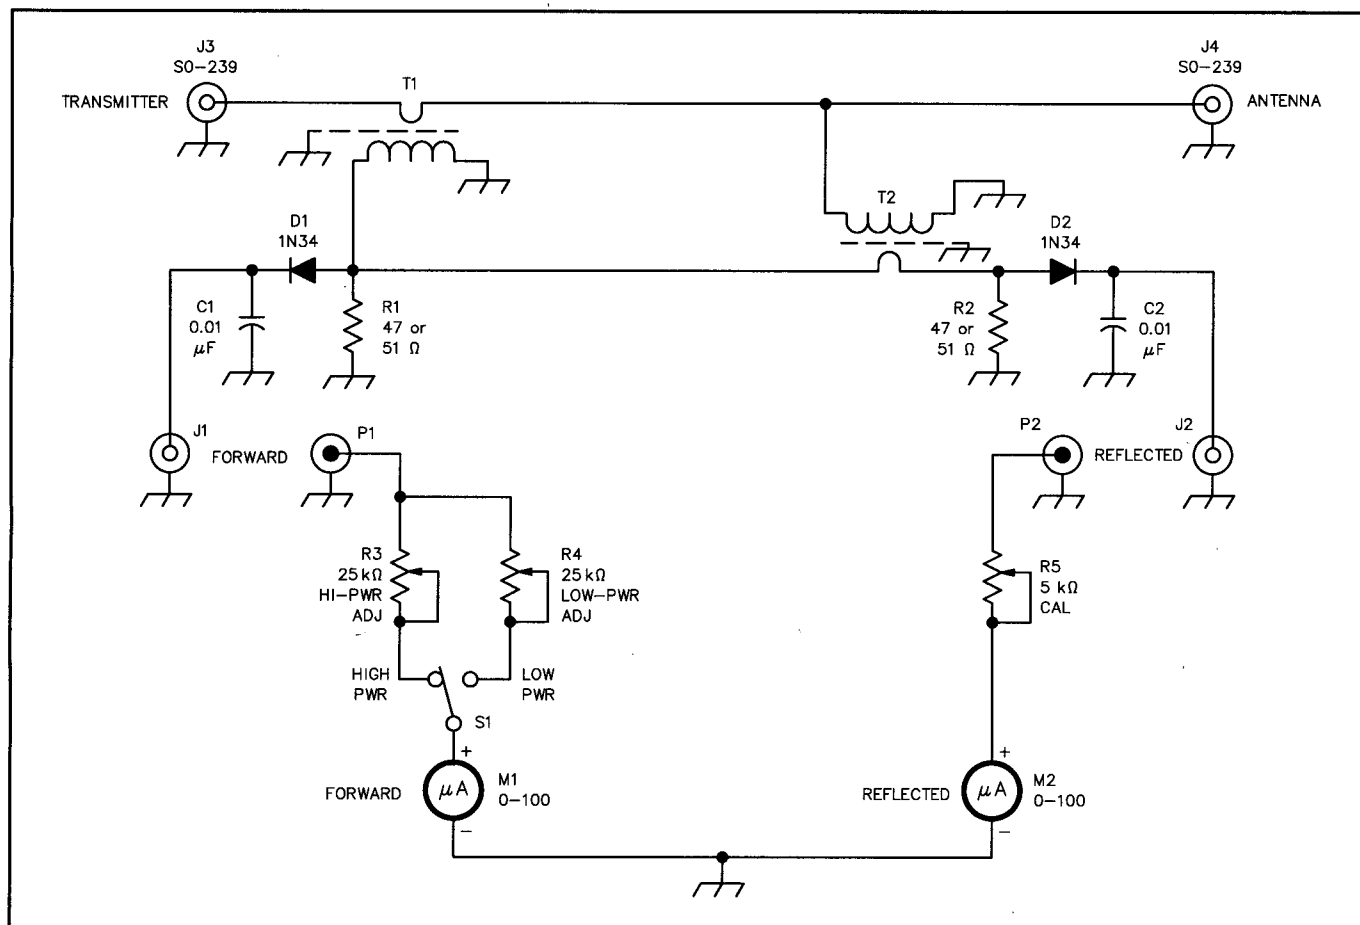

Fig 22.73—Schematic diagram of the high-power directional coupler. D1 and D2 are germanium diodes (1N34 or equiv). R1 and R2 are 47- or 51- $\Omega$   $\frac{1}{2}$ -W resistors. C1 and C2 have 500-V ratings. The secondary windings of T1 and T2 each consist of 40 turns of #26 to 30 enameled wire on T-68-2 powdered-iron toroid cores. If the coupler is built into an existing antenna tuner, the primary of T1 can be part of the tuner coaxial output line. The remotely located meters (M1 and M2) are connected to the coupler box at J1 and J2 via P1 and P2.

**Fig 22.74—Directional-coupler construction details. Grommets or standoff insulators can be used to route the secondary windings of T1 and T2 through the PC-board shield. A 3½×3½×4-inch metal box serves as the enclosure.**

## HIGH-POWER OPERATION

This material was condensed from a letter by Frank Van Zant, KL7IBA, that appears in July 1989 *QST* (pp 42-43). In April 1988, Zack Lau, KH6CP, described a directional-coupler circuit (based on the same principle as Grebenkemper's circuit) for a QRP transceiver (see the bibliography at the end of this chapter). The main advantage of Lau's circuit is very low parts count.

Grebenkemper uses complex log-antilog amplifiers to provide good measurement accuracy. This application gets away from complex circuitry, but retains reasonable measurement accuracy over the 1 to 1500-W range. It also forfeits the SWR-computation feature.

Lau's coupler uses ferrite toroids. It works great at low power levels, but the ferrite toroids heat excessively with high power, causing erratic meter readings and the potential for burned parts.

## The Revised Design

Powdered-iron toroids are used for the transformers in this version of Lau's basic circuit. The number of turns on the secondaries was increased to compensate for the lower permeability of powdered iron.

Two meters display reflected and forward power (see Fig 22.73). The germanium detector diodes (D1 and D2—1N34) provide fairly accurate meter readings particularly if the meter is

calibrated (using R3, R4 and R5) to place the normal transmitter output at midscale. If the winding sense of the transformers is reversed, the meters are transposed (the forward-power meter becomes the reflected-power meter, and vice versa).

## Construction

Fig 22.74 shows the physical layout of this coupler. The pickup unit is mounted in a 3½×3½×4-inch box. The meters, PC-mount potentiometers and HIGH/LOW power switch are mounted in a separate box or a compartment in an antenna tuner.

The primary windings of T1 and T2 are constructed much as Grebenkemper described, but use RG-8 with its jacket removed so that the core and secondary winding may fit over the cable. The braid is wrapped with fiberglass tape to insulate it from the secondary winding. An excellent alternative to fiberglass tape—with even higher RF voltage-breakdown characteristics—is ordinary plumber's Teflon pipe tape, available at most hardware stores.

The transformer secondaries are wound on T-68-2 powdered-iron toroid cores. They are 40 turns of #26 to 30 enameled wire spread evenly around each core. By using #26 to 30 wire on the cores, the cores slip over the tape-wrapped RG-8 lines. With #26 wire on the toroids, a single layer of tape (slightly more with Teflon tape) over the braid provides an extremely snug

fit for the core. Use care when fitting the cores onto the RG-8 assemblies. After the toroids are mounted on the RG-8 sections, coat the assembly with General Cement Corp Polystyrene Q Dope, or use a spot or two of RTV sealant to hold the windings in place and fix the transformers on the RG-8 primary windings.

Mount a PC-board shield in the center of the box, between T1 and T2, to minimize coupling between transformers. Suspend T1 between SO-239 connectors and T2 between two standoff insulators. The detector circuits (C1, C2, D1, D2, R1 and R2) are mounted inside the coupler box as shown.

## Calibration, Tune up and Operation

The coupler has excellent directivity. Calibrate the meters for various power levels with an RF ammeter and a 50-Ω dummy load. Calculate  $I^2R$  for each power level, and mark the meter faces accordingly. Use R3, R4 and R5 to adjust the meter readings within the ranges. Diode nonlinearities are thus taken into account, and Grebenkemper's signal-processing circuits are not needed for relatively accurate power readings.

Start the tune-up process using about 10 W, adjust the antenna tuner for minimum reflected power, and increase power while adjusting the tuner to minimize reflected power.

This circuit has been built into several antenna tuners with good success. The bridge worked well at 1.5-kW output on 1.8 MHz. It also worked fine from 3.5 to 30 MHz with 1.2- and 1.5-kW output. The antenna is easily tuned for a 1:1 SWR using the null indication provided.

Amplifier settings for a matched antenna, as indicated with the wattmeter, closely agreed with those for a 50-Ω dummy load. Checks with a Palomar noise bridge and a Heath Antenna Scope also verified these findings. This circuit should handle more than 1.5 kW, as long as the SWR on the feed line through the wattmeter is kept at or near 1:1. (On one occasion high power was applied while the antenna tuner was not coupled to a load. Naturally the SWR was extremely high, and the output transformer secondary winding opened like a fuse. This resulted from the excessively high voltage across the secondary. The damage was easily and quickly repaired.)

## A REMOTELY CONTROLLED ANTENNA SWITCH

This project originally appeared in *QST*.<sup>1</sup> This switch can be used to automatically select the correct antenna when used with an ICOM MF/HF rig. Modifications would allow it to be used with other brands as well, or controlled manually. The switch can also be controlled manually.

### DESCRIPTION

Fig 22.75 is a block diagram of the system. The decoder connects to the rig via an accessory connector on the back of the transceiver. Many modern rigs have an accessory connector used for automatic bandswitching of amplifiers and other equipment. They usually use particular voltages on one of the accessory connector pins to indicate the selected band. A single length of coax and a multiconductor control cable run from the rig and the decoder box to the remotely located switch unit. The remote relay box is equipped with seven SO-239 connectors: one for the feed line (COMMON) and one for each antenna.

The details of the ICOM rear-panel accessory connector (ACC2) are provided here. Refer to the documentation for your rig for details if you have another brand. The connector on the ICOM provides the band signal, an 8.0-V reference and a 13.8-V supply tap. Table 22.6 shows the output voltage at the accessory socket when the radio is switched to the various bands.

The ACC2 connector pin assignments for the IC-735 are:

- Pin 1 +8 V reference
- Pin 2 Ground
- Pin 4 Band signal voltage
- Pin 7 +13.8 V supply

### DECODER CIRCUIT

The schematic for the decoder is shown in Fig 22.76. R1 through R7 divide the 8-V reference voltage from the rig to provide midpoints between the band signal levels. Three LM339 quad comparators do the work deciding which band the rig is on.

Two bands (1.8 MHz and 10 MHz) need only a single comparator because they are at the ends of the reference voltage range. All other bands use two comparators. One detects if the band signal is above a specific level while the other determines if it is below a specific level. If the signal is between the two levels, the output-relay

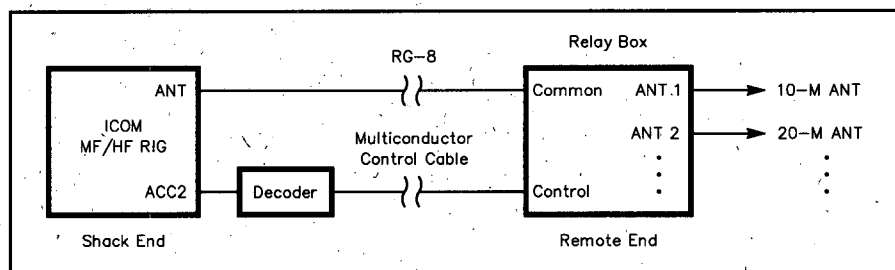

Fig 22.75—Block diagram of the remotely controlled antenna switch.

driver transistor is turned on.

Because the LM339 has open-collector outputs, they can conveniently be connected together to a pull-up resistor so that the output signal goes high only if both LM339 sections are off. This provides a simple AND function without extra components.

LEDs are used to indicate which band is selected. Since they are in the base circuit of the relay-driver transistor they always indicate the correct band even when more than one driver transistor is connected to a single relay. Such a configuration would be used with a tribander; the outputs for 14, 21 and 28 MHz are simply wired to a single relay.

### RELAY BOX

The circuit of Fig 22.77 uses DPDT relays to short the antennas to ground when not selected. This helps prevent static buildup on the antenna which could damage the rig's front end upon connection to the feed line. An additional relay is energized whenever the rig is turned on. Its purpose is to ground the feed line when the rig is turned off.

The relays listed handle 100 W comfortably. Higher power versions of this switch will require relays with much higher voltage and current ratings.

### Alternative Designs

The simplicity of this design invites "hacking." If you have a tribander, you might consider modifying the design so that there is only one output for three bands. Simply change the resistor ladder to have two fewer nodes.

Radios with different signal levels can be accommodated by appropriately changing the values in the resistor ladder. Manual control can be added using a second resistive divider to deliver the signal levels the transceiver would normally provide. See Fig 22.78. This divider and

Table 22.6

### ICOM Accessory Connector Output Voltages by Band

Band (MHz)	Output Voltage
1.8	7 - 8.0
3.5	6 - 6.5
7	5 - 5.5
14	4 - 4.5
18, 21	3 - 3.5
24, 28	2 - 2.5
10	0 - 1.2

Note: The voltage step between bands is not constant, but close to 1.0 V, and the 10-MHz band is not in sequence with the others.

switch are connected between the radio jack and the existing resistive divider in the control box. Use a switch on the decoder input to select automatic or manual control.

### CONSTRUCTION

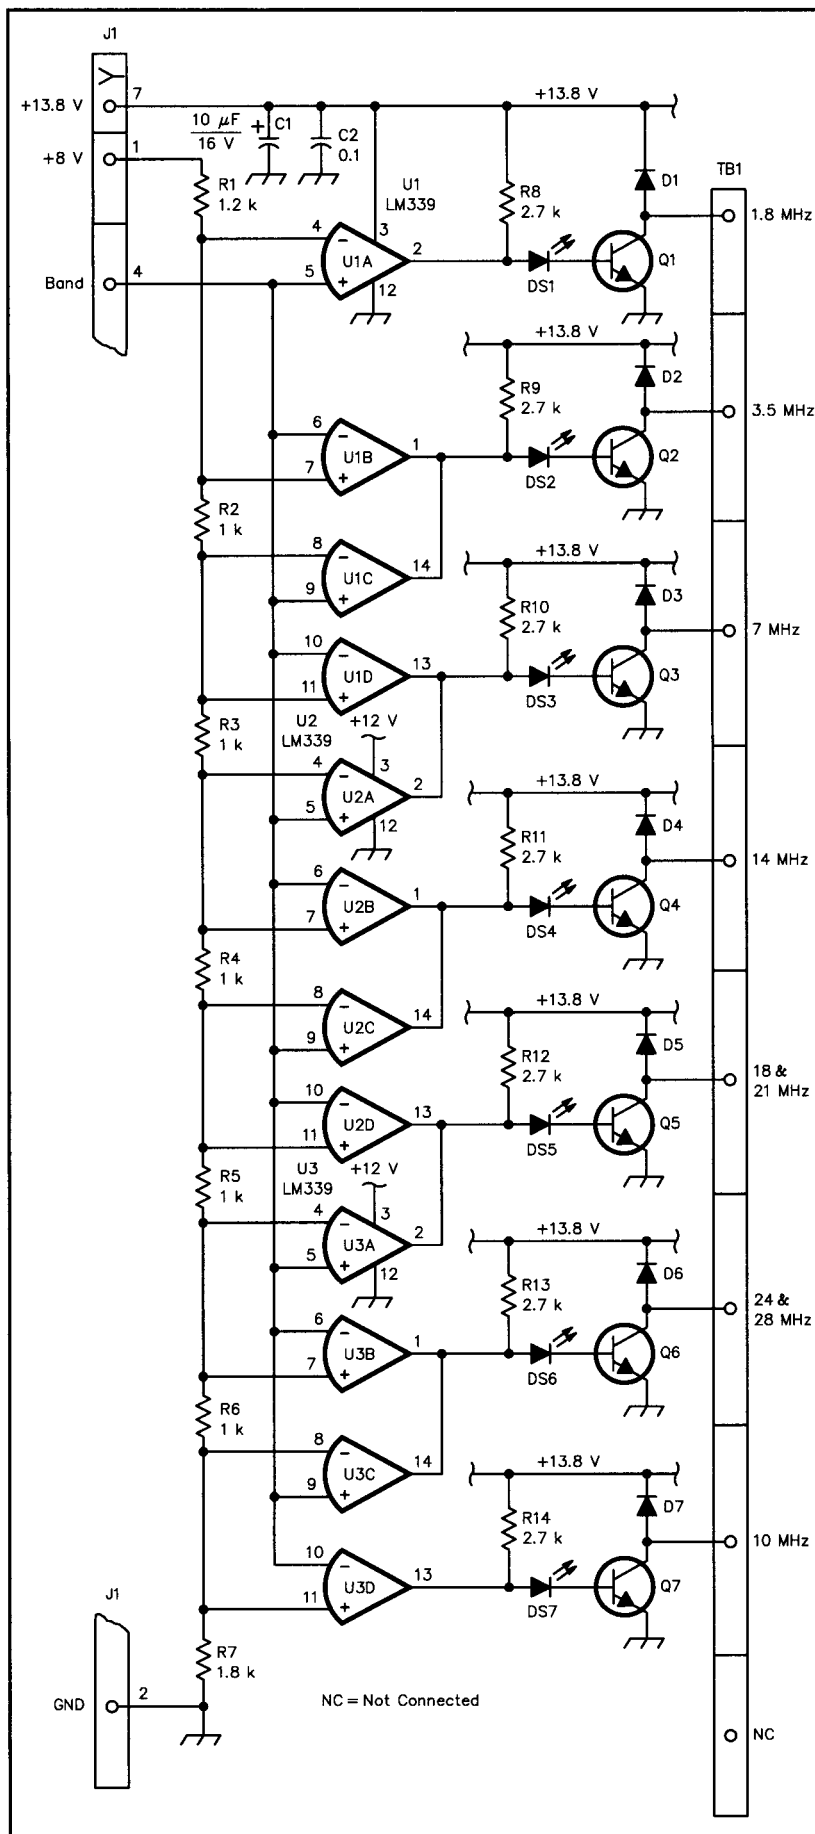

A PC board is available for the control circuit.<sup>2</sup> The controller can be built using a relatively small enclosure. A 7-pin DIN plug is used for the ICOM radios. Other manufacturer's connectors vary.

Because the controller requires no power supply of its own, it takes up very little space on the operating table.

The relay box uses SO-239 connectors for the common feed-line and antenna connections and a 9-pin D-sub connector for the control cable. The relay box can be placed in a weatherproof enclosure to guard against the elements.

<sup>2</sup>A PC board is available from FAR Circuits. See the Address List in the References chapter. An etching pattern is available from the ARRL Technical Secretary for an SASE. Request the 95 Handbook Remote Control Antenna Switch package.

<sup>1</sup>"A Remotely Controlled Antenna Switch," by Nigel Thompson, April 1993 *QST*.

**Fig 22.76**—Schematic of the remotely controlled antenna switch control-box circuit. Part numbers in parentheses are Radio Shack; equivalent parts can be substituted. Unless otherwise specified, resistors are  $\frac{1}{4}$ -W, 5%-tolerance carbon-composition or film units.

**D1-D7**—1N4003 (276-1102).

**DS1-DS7**—LED.

**J1**—7-pin female DIN chassis-mount connector.

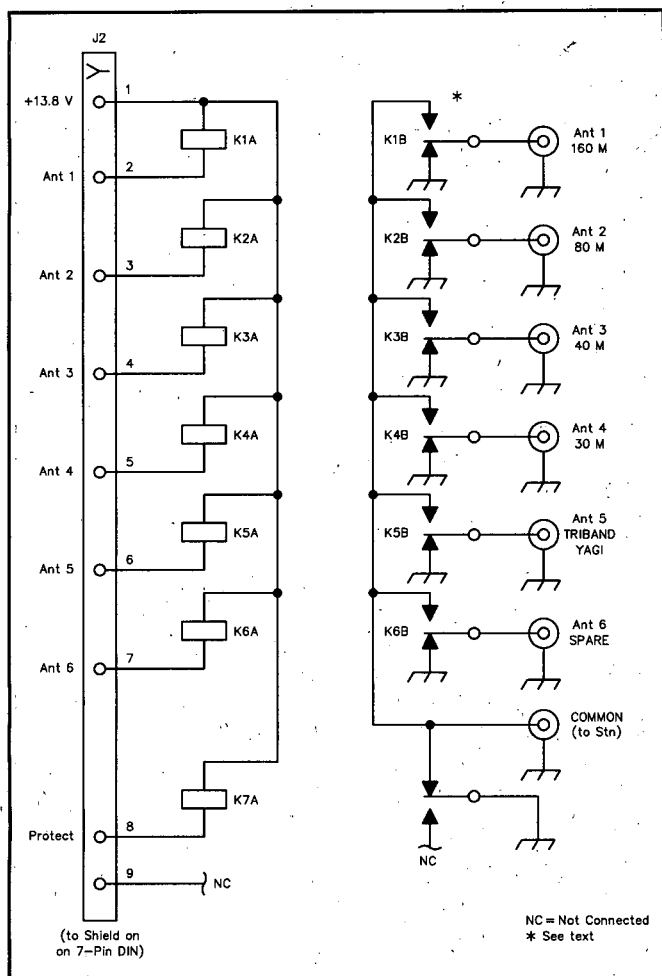

**Q1-Q7**—Almost any NPN transistor capable of sinking 150 mA (for the Radio Shack relays used in this project), ZTX657s or equivalent. Other types include MPSA05, MPSA06 and 2N4401 (276-2058).

**TB1**—9-position screw-terminal strip.

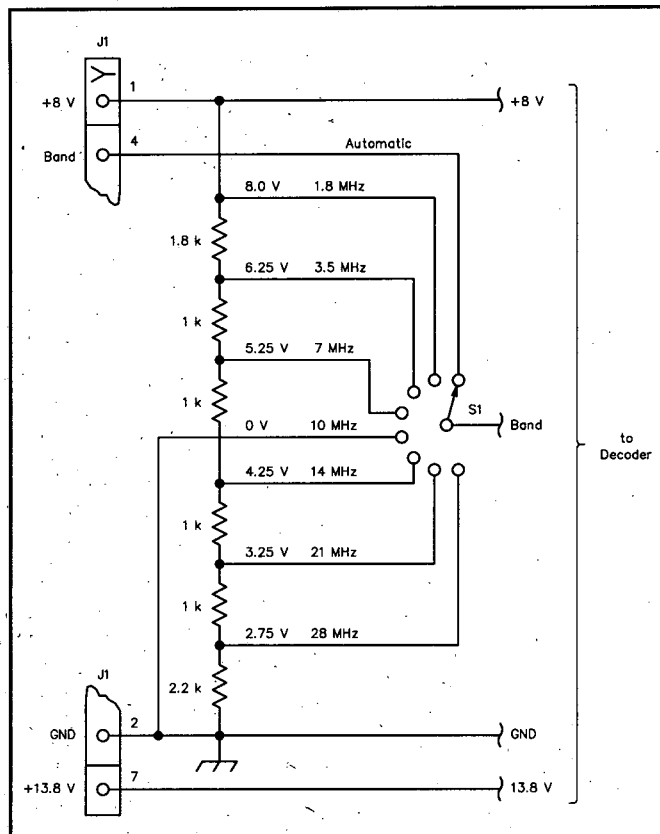

**U1-U3**—LM339N (276-1712).

**K1-K7**—12-V, DPDT relay with 10-A/125-V ac contacts (275-218). (Presently, local Radio Shack stores stock the 275-218c [note suffix] relay, with a contact rating of 15 A.—Ed.)

**Misc:** decoder enclosure (approximately  $2\frac{1}{2} \times 4 \times 3$  inches HWD), relay enclosure (approximately  $3 \times 6 \times 8$  inches HWD). 7 single-hole-mount SO-239 connectors.

**Fig 22.77—Relay box schematic.** The normally open and normally closed contact pairs of the DPDT relays are individually connected in parallel to increase current-handling capability. J2 is a DB9M chassis-mount connector (RS 276-1537).

**Fig 22.78—The addition of a multiposition switch provides a means of selecting automatic or manual control of relay switching with ICOM rigs. Rather neatly, this circuit also furnishes a remotely controlled antenna switch for non-ICOM rigs.**

## A TRIO OF TRANSCEIVER/COMPUTER INTERFACES

Virtually all modern Amateur Radio transceivers (and many general-coverage receivers) have provisions for external computer control. Most hams take advantage of this feature using software specifically developed for control, or primarily intended for some other purpose (such as contest logging), with rig control as a secondary function.

Unfortunately, the serial port on most radios cannot be directly connected to the serial port on most computers. The problem is that most radios use TTL signal levels while most computers use RS-232-D.

The interfaces described here simply convert the TTL levels used by the radio to the RS-232-D levels used by the computer, and vice versa. Interfaces of this type are often referred to as level shifters. Two basic designs, one having a couple of

**Fig 22.79—The basic two-wire bus system that ICOM and newer Ten-Tec radios share among several radios and computers. In its simplest form, the bus would include only one radio and one computer.**

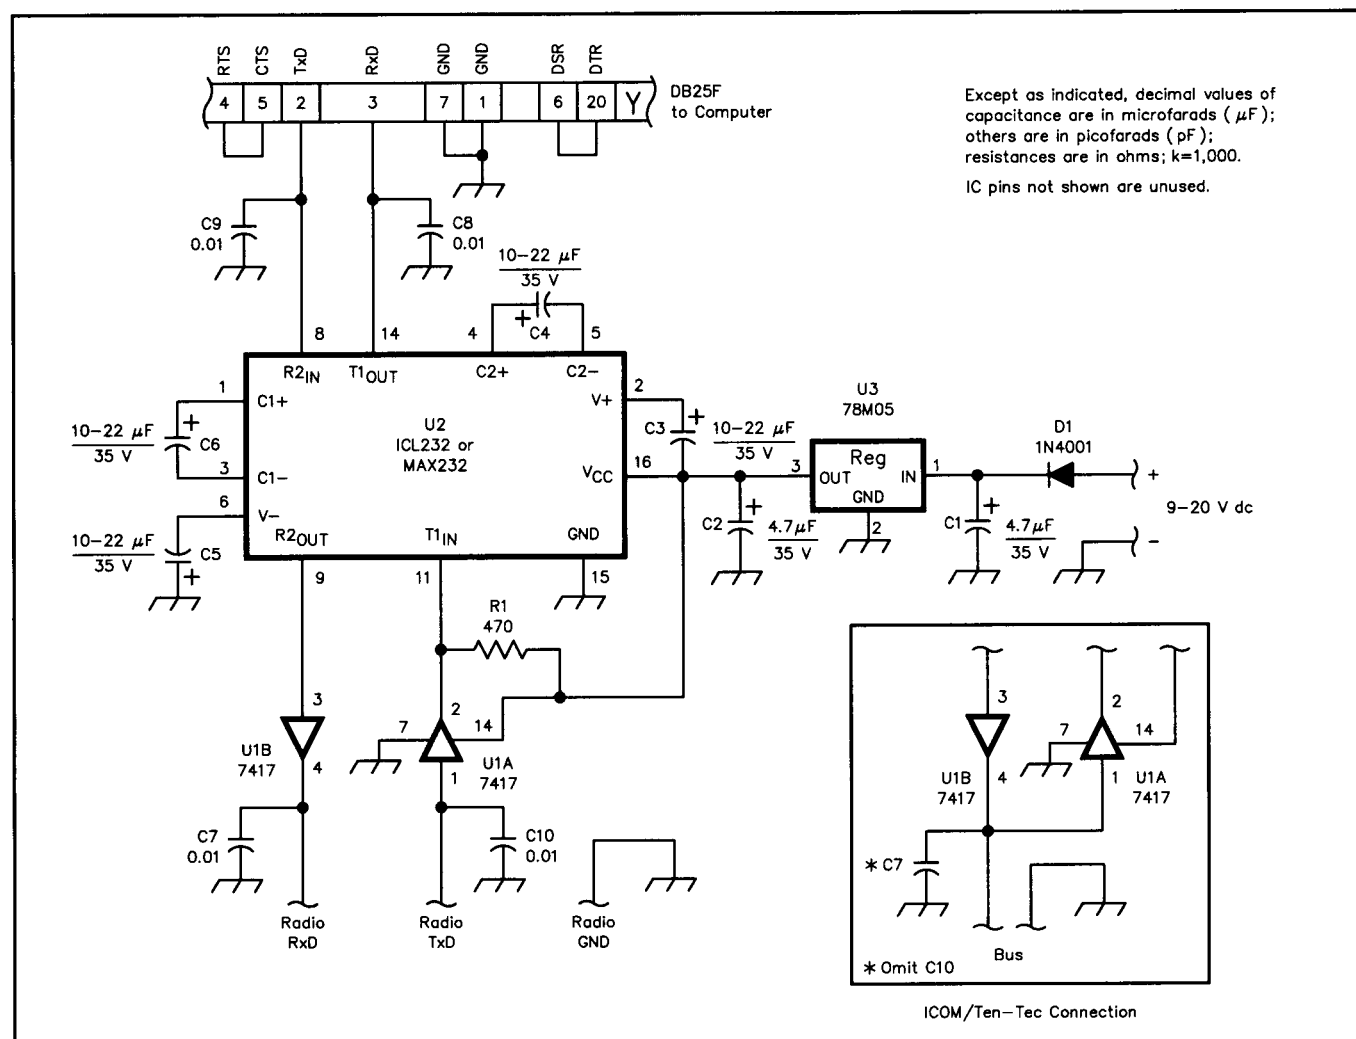

variations, cover the popular brands of radios.

### TYPE ONE: ICOM CI-V

The simplest interface is the one used for the ICOM CI-V system. This interface works with newer ICOM and Ten-Tec rigs. Fig 22.79 shows the two-wire bus system used in these radios.

This arrangement uses a CSMA/CD (carrier-sense multiple access/collision detect) bus. This refers to a bus that a number of stations share to transmit and receive data. In effect, the bus is a single wire and common ground that interconnect a number of radios and computers.

The single wire is used for transmitting and receiving data. Each device has its own unique digital address. Information is transferred on the bus in the form of pack-

**Fig 22.80—ICOM/Ten-Tec/Yaesu interface schematic. The insert shows the ICOM/Ten-Tec bus connection, which simply involves tying two pins together and eliminating a bypass capacitor.**

C7-C10—0.01- $\mu\text{F}$  ceramic disc.

U1—7417 hex buffer/driver.

U2—Harris ICL232 or Maxim MAX232.

ets that include the data and the address of the intended receiving device.

The schematic for the ICOM/Ten-Tec interface is shown in Fig 22.80. It is also the Yaesu interface. The only difference is that the transmit data (TxD) and receive data (RxD) are jumpered together for the ICOM/Ten-Tec version.

The signal lines are active-high TTL. This means that a logical one is represented by a binary one (+5 V). To shift this to RS-232-D it must be converted to -12 V while a binary zero (0 V) must be converted to +12 V. In the other direction, the opposites are needed: -12 V to +5 V and +12 V to 0 V.

U1 is used as a buffer to meet the interface specifications of the radio's circuitry and provide some isolation. U2 is a 5-V-powered RS-232-D transceiver chip that translates between TTL and RS-232-D

levels. This chip uses charge pumps to obtain  $\pm 10$  V from a single +5-V supply. This device is used in all three interfaces.

A DB25 female (DB25F) is typically used at the computer end. Refer to the discussion of RS-232-D earlier in the chapter for 9-pin connector information. The interface connects to the radio via a 1/8-inch phone plug. The sleeve is ground and the tip is the bus connection.

It is worth noting that the ICOM and Ten-Tec radios use identical basic command sets (although the Ten-Tec includes additional commands). Thus, driver software is compatible. The manufacturers are to be commended for working toward standardizing these interfaces somewhat. This allows Ten-Tec radios to be used with all popular software that supports the ICOM CI-V interface. When configuring the software, simply indicate

that an ICOM radio (such as the IC-735) is connected.

## TYPE TWO: YAESU INTERFACE

The interface used for Yaesu rigs is identical to the one described for the ICOM/Ten-Tec, except that RxD and TxD are not jumpered together. Refer to Fig 22.80. This arrangement uses only the RxD and TxD lines; no flow control is used.

The same computer connector is used, but the radio connector varies with model. Refer to the manual for your particular rig to determine the connector type and pin arrangement.

## TYPE THREE: KENWOOD

The interface setup used with Kenwood radios is different in two ways from the previous two: Request-to-Send (RTS) and

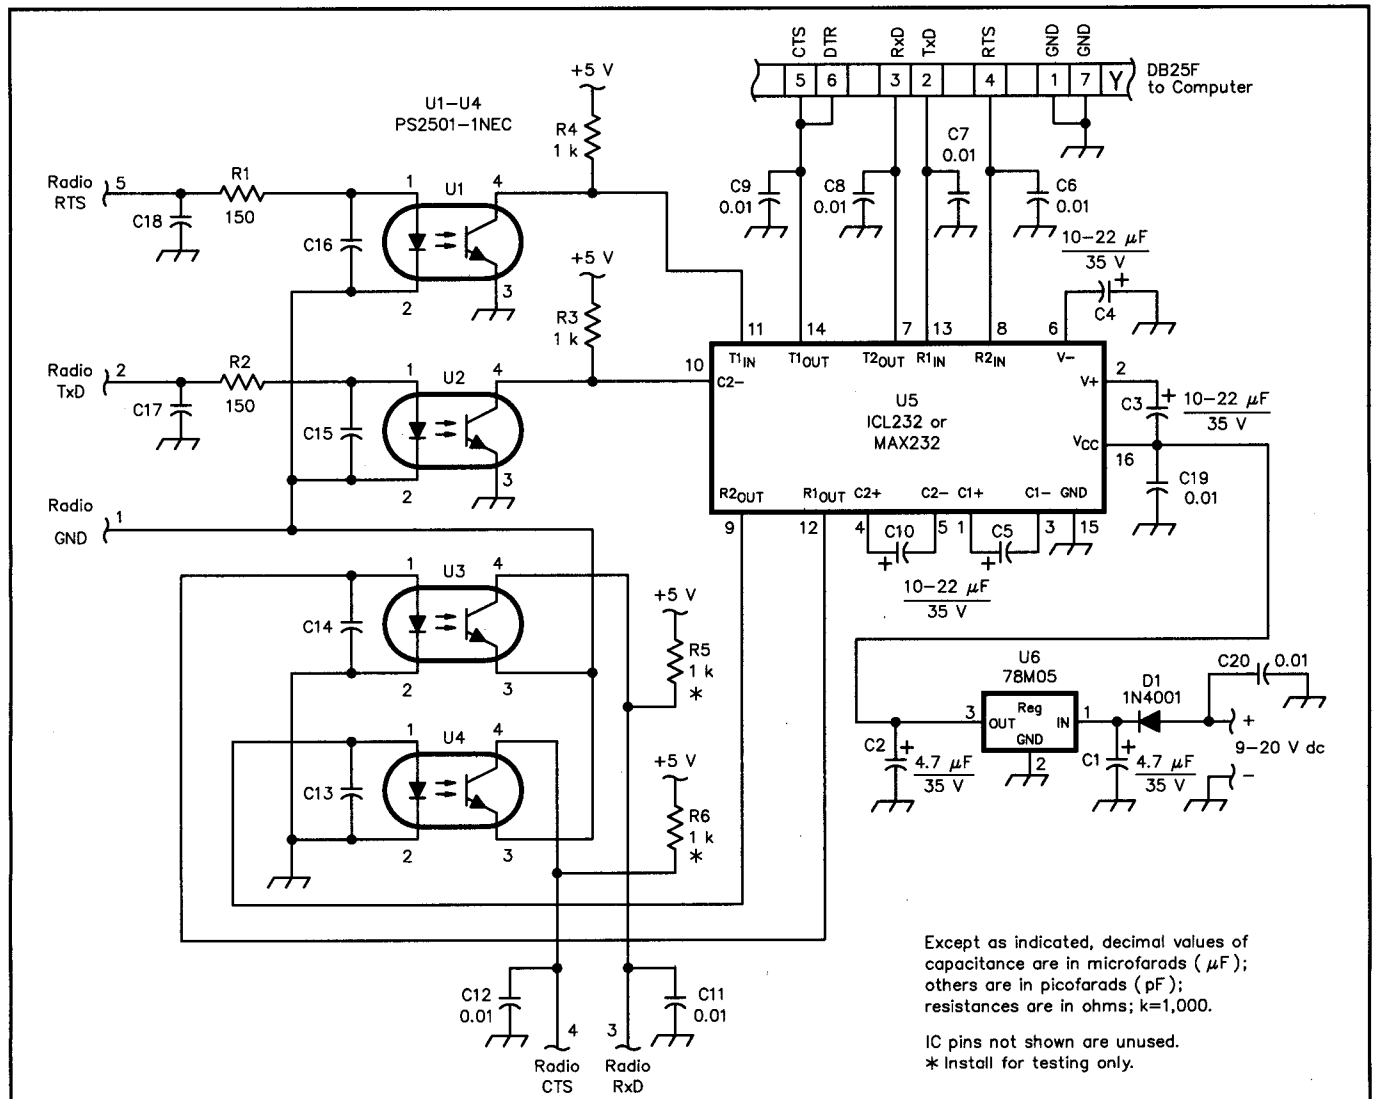

Fig 22.81—Kenwood interface schematic.

C6-C9, C11, C12, C17, C18—0.01- $\mu\text{F}$  ceramic disc.  
C13-C16, C19-C21—0.01  $\mu\text{F}$  ceramic disc.

U1-U4—PS2501-1NEC (available from Digi-Key).

U5—Harris ICL232 or Maxim MAX232.

Clear-to-Send (CTS) handshaking is implemented and the polarity is reversed on the data lines. The signals used on the Kenwood system are active-low. This means that 0 V represents a logic one and +5 V represents a logic zero. This characteristic makes it easy to fully isolate the radio and the computer since a signal line only has to be grounded to assert it. Optoisolators can be used to simply switch the line to ground.

The schematic in **Fig 22.81** shows the Kenwood interface circuit. Note the different grounds for the computer and the radio. This, in conjunction with a separate power supply for the interface, provides excellent isolation.

The radio connector is a 6-pin DIN plug. The manual for the rig details this connector and the pin assignments.

Some of the earlier Kenwood radios require additional parts before their serial connection can be used. The TS-440S and R-5000 require installation of a chipset and some others, such as the TS-940S require an internal circuit board.

## CONSTRUCTION AND TESTING

The interfaces can be built using a PC board, breadboarding, or point-to-point wiring. PC boards and parts kits are available.<sup>1</sup> The PC board template is available from the ARRL Technical Secretary for an SASE. Request the 95 Handbook Interfaces package.

<sup>1</sup>PC boards and parts kits are available from CW Technology. See the Address List in the **References** chapter.

**Table 22.7**

### Kenwood Interface Testing

<i>Apply</i>	<i>Result</i>
GND to Radio-5	-8 to -12 V at PC-5
+5 V to Radio-5	+8 to +12 V at PC-5
+9 V to PC-4	+5 V at Radio-4
-9 V to PC-4	0 V at Radio-4
GND to Radio-2	-8 to -12 at PC-3
+5 V to Radio-2	+8 to +12 V at PC-3
+9 V to PC-2	+5 V to Radio-3
-9 V to PC-2	0 V at Radio-3

**Table 22.8**

### ICOM/Ten-Tec Interface Testing

<i>Apply</i>	<i>Result</i>
GND to Bus	+8 to +12 V at PC-3
+5 V to Bus	-8 to -12 V at PC-3
-9 V to PC-2	+5 V on Bus
+9 V to PC-2	0 V on Bus

**Table 22.9**

### Yaesu Interface Testing

<i>Apply</i>	<i>Result</i>
GND to Radio Tx/D	+8 to +12 V at PC-3
+5 V to Radio Tx/D	-8 to -12 V at PC-3
+9 V to PC-2	0 V at Radio Rx/D
-9 V to PC-2	+5 V at Radio Rx/D

It is a good idea to enclose the interface in a metal case and ground it well. Use of a separate power supply is also a good idea. You may be tempted to take 13.8 V from your radio—and it works well in many cases; but you sacrifice some isolation and may have noise problems. Since these in-

terfaces draw only 10 to 20 mA, a wall transformer is an easy option.

The interface can be tested using the data in **Tables 22.7, 8 and 9**. Remember, all you are doing is shifting voltage levels. You will need a 5-V supply, a 9-V battery and a voltmeter. Simply supply the voltages as described in the corresponding table for your interface and check for the correct voltage on the other side. When an input of -9 V is called for, simply connect the positive terminal of the battery to ground.

During normal operation, the input signals to the radio float to 5 V because of pullup resistors inside the radio. These include Rx/D on the Yaesu interface, the bus on the ICOM/Ten-Tec version, and Rx/D and CTS on the Kenwood interface. To simulate this during testing, these lines must be tied to a 5-V supply through 1-k $\Omega$  resistors. Connecting these to the supply without current-limiting resistors will damage the interface circuitry. R5 and R6 in the Kenwood schematic illustrate this. They are not shown (but are still needed) in the ICOM/Ten-Tec/Yaesu schematic. Also, be sure to note the separate grounds on the Kenwood interface during testing.

Another subject worth discussing is the radio's communication configuration. The serial ports of both the radio and the computer must be set to the same baud rate, parity, and number of start and stop bits. Check your radio's documentation and configure your software or use the PC-DOS/MS-DOS MODE command as described in the computer manual.

## A VERSATILE STATION INTERFACE BOX

Getting new ham equipment is fun, but additional gear usually makes for a more complicated shack. If you acquire a boom mike/headset for contesting or DXing, for example, but prefer to use your desk mike for less-intense activities, changing mikes can be a nuisance. *Frequent* mike changes may even wear or damage your transceiver's mike connector! Adding a second MF/HF transceiver adds further complications, such as different mike-connector pinouts and the need to move your headset from one rig to the other. And then there's digital operation: Adding Pactor or packet can *really* increase the complexity of a station!

This project, by Raymond Bintliff, K1YDG, originally published in September 1989 *QST*, simplifies interconnection of a variety of station equipment. Although designed for a particular set of equipment, the project can be easily adapted for use with other brands and types of gear.

### WHAT THE SWITCHER SWITCHES

As described here, the Switcher allows quick selection between (1) two transceivers, a Yaesu FT-767GX and a Kenwood TS-940S; (2) voice or digital operation; and (3) a desk microphone and separate headset or a boom mike/headset. Fig 22.82 shows this switching in simplified form.

Illuminated push-button switches select the Switcher's functions. Pressing 767, for instance, selects the FT-767GX mike and PTT input and headphone output; pressing 940 selects the TS-940S. Assuming that the FT-767GX has been selected, pressing the VOICE or DIGI switches connects the '767GX's mike and PTT inputs to the Switcher's mike-selection circuitry (VOICE) or to the station TNC (DIGI). Selecting Voice mode allows the further selection of desk and boom mikes by means of DESK and BOOM buttons. These buttons also direct the transceiver's headphone output to the appropriate headset—a pair of headphones in the Desk mode and the boom-mike headset in the Boom mode. As configured the Switcher's default modes are 767, Voice and Desk.

Relays handle the Switcher's audio and control-line switching; the front-panel push buttons control the relay. Figs 22.83 and 22.84 show the complete schematic

**Fig 22.82**—In its basic form, the Switcher allows push-button selection between (1) two transceivers; (2) voice or digital operation and (3) a desk microphone and separate headset or a boom mike/headset. Relays handle the actual switching of audio and control lines; see text.

**Table 22.10**

#### Switcher Parts List

- C1—4700- $\mu$ F, 35-V electrolytic (RS 272-1022).
- C2-C4—0.01- $\mu$ F, 500-V disc ceramic (RS 272-131).
- FB1-3—FB73-101 (Amidon, RADIOKIT) or FB-7-73 (Palomar) ferrite bead.
- K1-K7—4PDT, 12-V dc relay (RS 275-214).
- J1-J5—Eight pin male mike jack, chassis mount (see text and Note 3).
- J6, J7—Four-pin male mike jack, chassis mount (RS 274-002).
- J8—Five-pin female DIN connector, chassis mount (RS 274-005).
- J9, J10—Three-conductor, open-circuit  $\frac{1}{4}$ -inch phone jack (RS 274-312).
- J11, J12—Three-conductor, open-circuit,  $\frac{1}{8}$ -inch phone jack (RS 274-249).
- J13—DC power connector (RS 274-1565).
- S1-S6—Illuminated push-on, push-off SPDT NO/NC switch (RS 275-678), modified for momentary operation as described in the sidebar, "Modifying the Push-Button Switches for Momentary Operation."
- R1-R6—150- $\Omega$ ,  $\frac{1}{4}$ -W, carbon-film resistor (RS 271-1312).

of the Switcher. Table 22.10 is a complete parts list. Switching between 767 and 940 modes is accomplished by K1, K2 and K3. The inactive transceiver's mike, ground and PTT lines are disconnected from the Switcher to prevent accidental operation of the inactive transceiver if its mike PTT switch is pressed. K1 and K2 switch the audio-in and PTT lines; K3 switches the audio-out line.

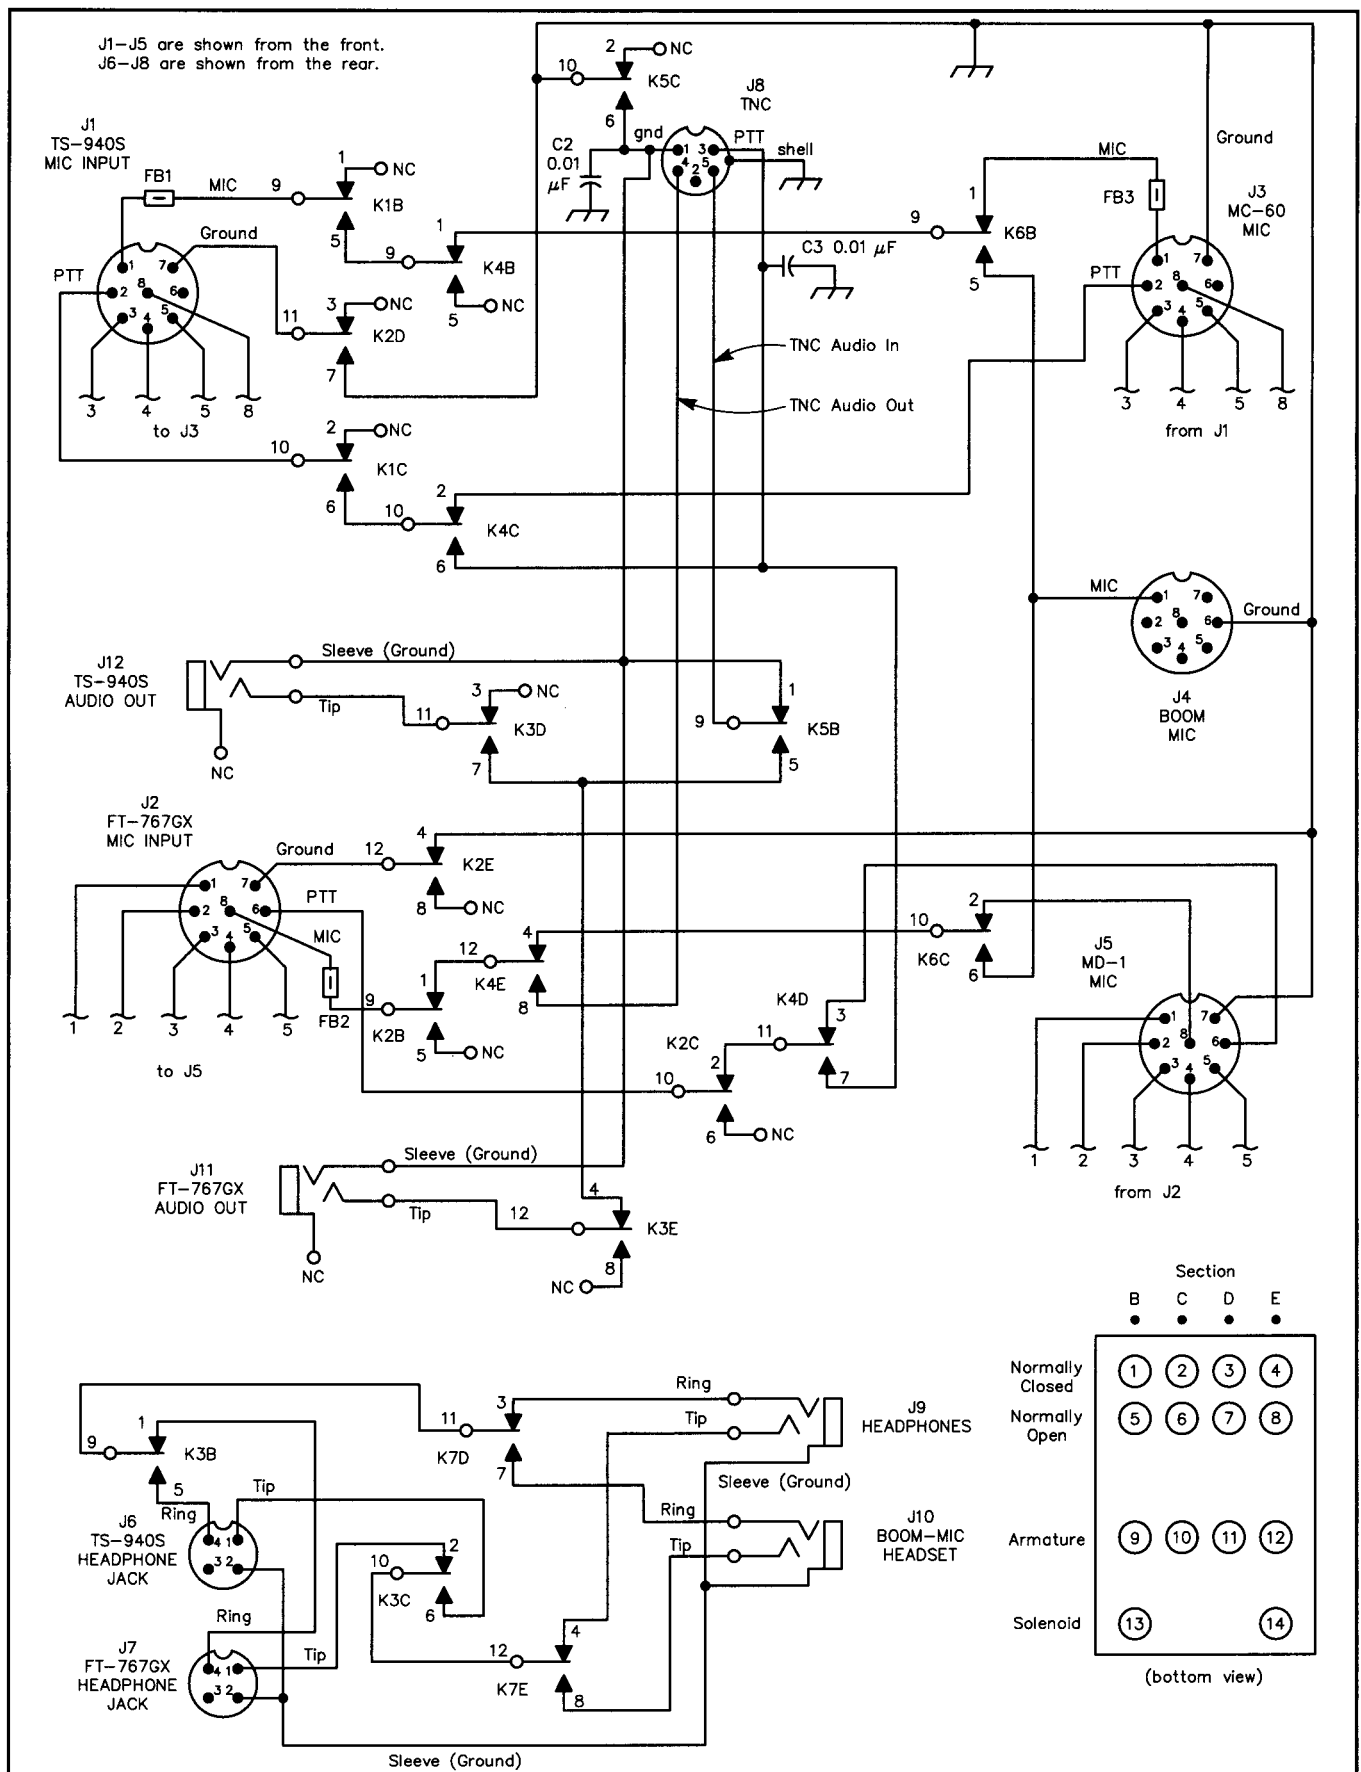

K4 and K5 handle switching between the Voice and Digital modes. Because the TS-940S supports direct frequency-shift keying (FSK), this version of the Switcher does not perform voice/digital switching of the TS-940S mike line. Instead the TS-940's FSK input is connected directly to the TNC's FSK output. Voice/digital mike-line switching is necessary with the

FT-767GX, however, because *audio* frequency-shift-keying (AFSK) must be applied to the '767 for digital operation. For digital operation with the FT-767GX, then, the Switcher (1) disconnects the Switcher's mike line from the '767GX and (2) connects the TNC's audio output to the FT-767GX's mike input. The TNC-audio-output line floats in all other Switcher modes.

To better isolate the Switcher's voice/digital switching, the TNC-Switcher ground connection is opened in the Voice mode. Also in the Voice mode, the TNC-audio-input is grounded and the TNC-to-Switcher PTT line is opened. K6 and K7 switch between desk and boom mikes.

In addition to the audio and control-line switching described above, the Switcher

<sup>1</sup>A Mode-by-mode listing of the function of each section of the Switcher's relays is available for a business-size SASE from Switcher Relay Listing, Technical Secretary, ARRL HQ.

**Fig 22.83—The Switcher's audio and PTT switching. All relays are shown in their default modes (767, Voice, Desk). Table 22.10 lists the parts used in this circuit.**

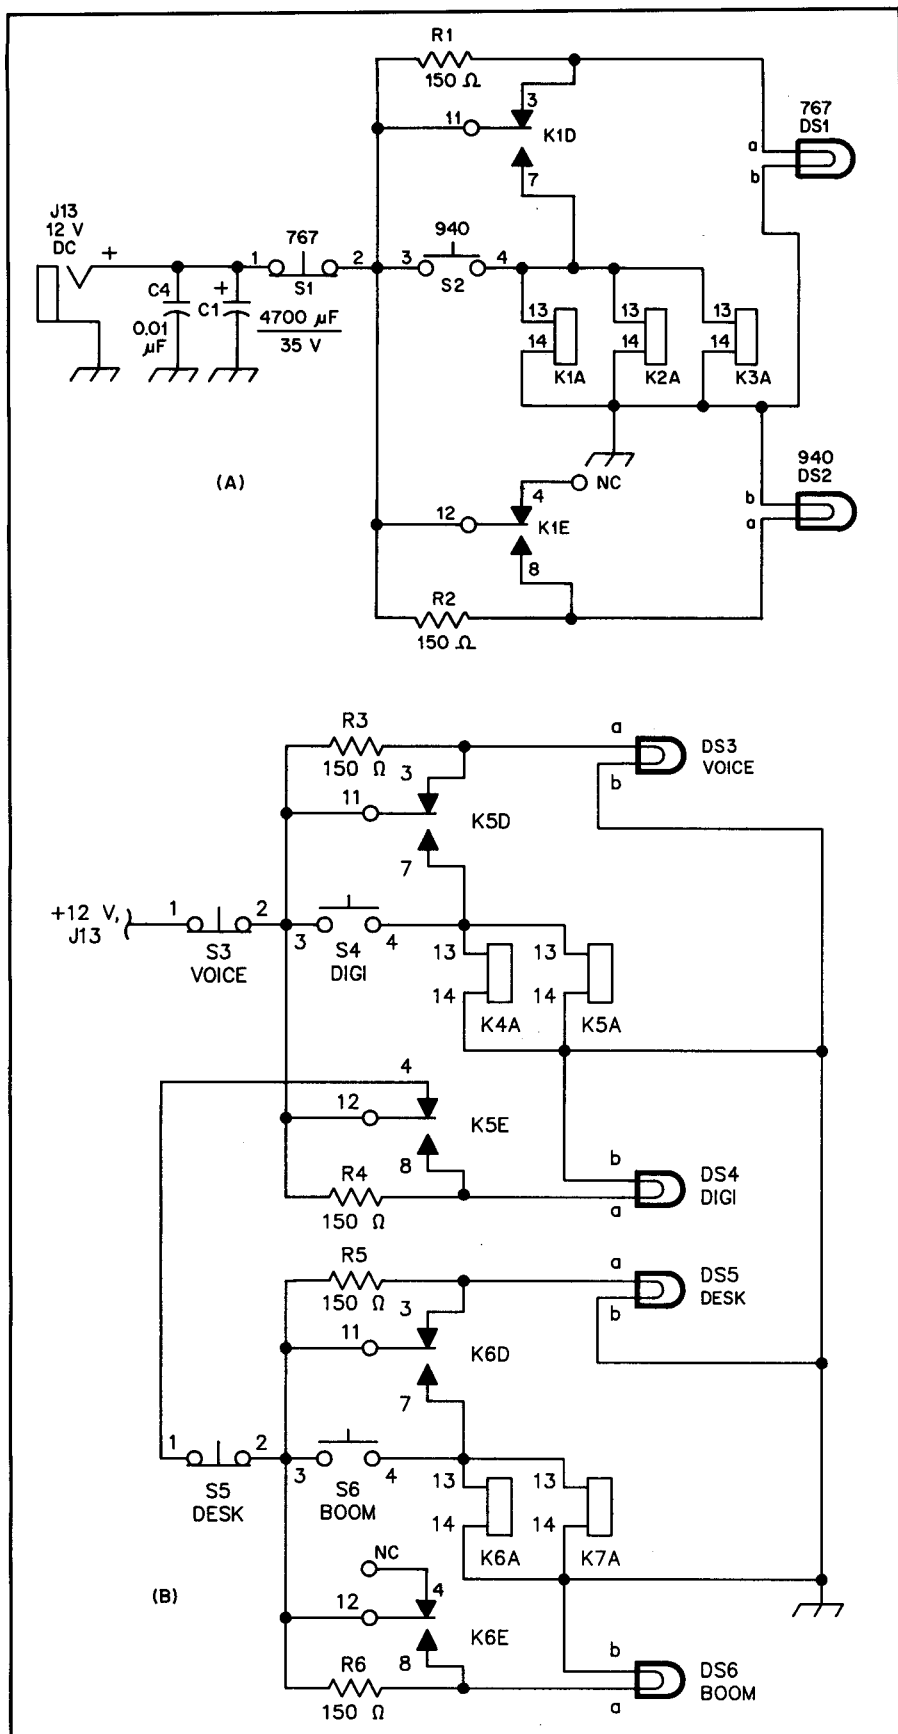

Fig 22.84—At A, relay and lamp switching for the Switcher's 767 and 940 modes; at B, relay and lamp switching for the Voice, Digital, Desk and Boom modes. Table 22.10 lists the parts used in these circuits; the inset in the lower right-hand corner of Fig 22.83 shows the relays' pinout.

## Modifying the Push-Button Switches for Momentary Operation

The Switcher uses push-on, push-off switches (S1 through S6) that must be modified for momentary action. The modification procedure is as follows:

1. Set the switch to its "out" position.
2. Remove the switch's red lens and white-plastic light diffuser.
3. Using a small screwdriver, pry out and remove the rectangular, white-plastic lamp holder from the back-plastic shell. (Be careful not to bend the two silver coil springs. These springs provide the electrical connection between the lamp assembly and the base of the switch assembly.)
4. The black plastic shell contains a detent spring, one end of which is inserted in a small brass eyelet located on the flat side of the shell. Remove and discard the spring.
5. Remove the self-adhesive label from the black plastic shell. Retain the label so you can replace it later. (The three access holes visible with the label removed will be used to guide the coil springs into place during replacement of the white-plastic lamp holder.)
6. Carefully insert the lamp holder into the black plastic shell. Note that the flat sides of the shell and the lamp holder must be aligned.
7. Guide the coil springs over the plastic pins in the base of the shell, taking care not to bend the springs. When the coil springs are properly engaged, press the lamp holder until it snaps in place.
8. Test for correct lamp operation by applying 12 V dc to solder lugs a and b. If the lamp tests good, replace the label you removed in Step 5.
9. Replace the switch's white plastic diffuser and lens. (Two lenses, one red and one green, are furnished with the switch. Use the color of your choice.) When replacing the light diffuser, be sure to correctly position its indexing tab in the lamp holder. Once you've done this, you have successfully converted a push-on, push-off switch to momentary operation.

The prototype uses the illuminated switches specified in the parts list because their white-plastic light diffusers can be marked to identify the switches' functions. Dry-transfer lettering works well for this. Many stationery stores carry dry-transfer lettering in various styles.—K1YDG

lights the push buttons of selected functions and dims or extinguishes those associated with unselected functions. For example, selecting the Switcher's Voice mode fully lights the VOICE lamp and dims the DIGI lamp.<sup>2</sup> In the Digital mode, the

<sup>2</sup>This dimming feature is useful under low-ambient-light conditions, in which the buttons of unselected functions might otherwise be invisible. If this feature doesn't interest you, you can eliminate it and use the lamp-dimming relay contacts for other purposes.

DESK and BOOM lamps are turned off.

The Switcher requires 12-V dc, floating negative power. (A grounded power supply introduces hum into the switched audio circuits and should not be used.) The maximum current drain, 650 mA, occurs when the Switcher is in the 940, Voice and Boom modes.

## CONSTRUCTING THE SWITCHER

Radio Shack carries all Switcher components except FB1-3 and the eight-pin chassis-mount, male mike jacks

(J1-J5).<sup>3</sup> Figs 22.85 and 22.86 show the Switcher's connector layout and internal wiring. Mount K1 through K7 directly to the cabinet with double-stick foam tape. The sidebar, "Modifying the Push-Button Switches for Momentary Operation," tells how to modify the push-on, push-on switches (S1-S6) for use in the Switcher.

To avoid ground loops,<sup>4</sup> insulate all connector ground lines (except for those of mike connectors J3, J4 and J5) from the Switcher chassis. J9 and J10 can be insulated from the chassis with nonconductive (fiber shoulder washers and four-pin connectors can be used at J6 and J7 to keep the transceiver headphone-output commons separate from the Switcher chassis. (You can use phone jacks at J6 and J7 if you insulate them from the chassis with non-conductive shoulder washers.)

Ground the bus that connects pin 7 of J3, pin 6 of J5 and pin 7 of J5 to the Switcher chassis at one point only. (J8's ground terminal is a convenient point for this.) Be sure that the positive *and* negative sides of the Switcher's 12-V dc supply float above ground outside the Switcher and that the supply negative connects to the Switcher chassis *only* at the common ground point described above. Hum or feedback problems may occur if you don't take these precautions.

## OTHER DESIGN POSSIBILITIES

Because a separate coaxial switch is used for RF switching, this version of the Switcher does not switch the transceivers' RF-output lines. Additional relay switching can be incorporated to do this and to permit the use of one microphone with both transceivers. In this version of the Switcher, however, the mike switching circuitry was simplified and the up/down tuning capability the MD-1 and MC-60 microphones provide when used with their respective transceivers was retained.

<sup>3</sup>Amateur Electronic Supply lists suitable connectors in its catalog. Other Amateur Radio equipment dealers likely carry such connectors as well.—Ed.

<sup>4</sup>A *ground loop* is a common path along which two or more points intended to be at the same ground potential are actually at *different* potentials. Ground loops are undesirable because the unintended intercircuit coupling they support can cause hum, noise, feedback and data errors.—Ed.

Fig 22.85—The Switcher's wiring emphasizes short interconnections. From left to right, the relays are K1, K2, K4, K6, K5, K3 and K7. The sidebar, "Modifying the Push-Button Switches for Momentary Operation," tells how to modify and label the Switcher's push buttons.

Fig 22.86—All of the Switcher's connectors mount on the rear cabinet panel. See text for how to wire the connectors to avoid ground loops. The phone jack at lower right is unused.

## TR TIME-DELAY GENERATOR

If you've ever blown up your new GaAsFET preamp or hard-to-find coaxial relay, or are just plain worried about it, this transmit/receive (TR) time-delay generator is for you. This little circuit makes it simple to put some reliability into your present station or to get that new VHF or UHF transverter on the air fast, safe and simple. Its primary application is for VHF/UHF transverter, amplifier and antenna switching, but it can be used in any amplifier-antenna scheme. An enable signal to the TR generator will produce sequential output commands to receive relay, a TR relay, an amplifier and a transverter—automatically. All you do is sit back and work DX! This project was designed and built by Chip Angle, N6CA.

### WHY SEQUENCE?

Several problems may arise in stations using transverters, extra power amplifiers and external antenna-mounted TR relays. The block diagram of a typical station is shown in Fig 22.87. When the HF exciter is switched into transmit by the PTT or VOX line, it immediately puts out a ground (or in some cases a positive voltage) command for relay control, and an RF signal.

If voltage is applied to the transverter, amplifier and antenna relays simultaneously, RF can be applied as the relay contacts bounce. In most cases, RF will be applied before a relay can make full closure. This can easily arc contacts on dc and RF relays and cause permanent damage. In addition, if the TR relay is not fully closed before RF from the power amplifier is applied, excessive RF may leak into the receive side of the relay. The likely result—preamplifier failure!

Fig 22.88 is a block diagram of a station with a remote-mounted preamp and antenna relays. The TR time-delay generator supplies commands, one after another, going into transmit and going back to receive from transmit, to turn on all station relays in the right order, eliminating the problems just described.

### CIRCUIT DETAILS

Here's how it works. See the schematic diagram in Fig 22.89. Assume we're in receive and are going to transmit. A ground command to Q2 (or a positive voltage command to Q1) turns Q2 off. This allows C1 to charge through R1 plus 1.5 k $\Omega$ . This rising voltage is applied to all positive (+) inputs of U1, a quad comparator. The ladder network on all negative (–) inputs of U1 sets the threshold point of each comparator at a successively higher

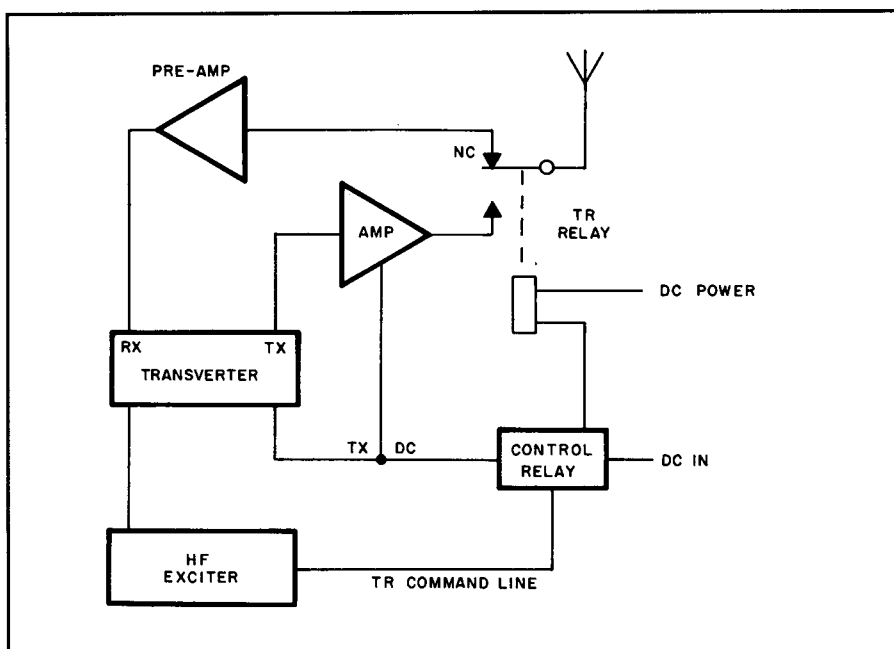

Fig 22.87—A typical VHF or UHF station arrangement with transverter, preamp and power amp. As shown, most TR relays change at the same time.

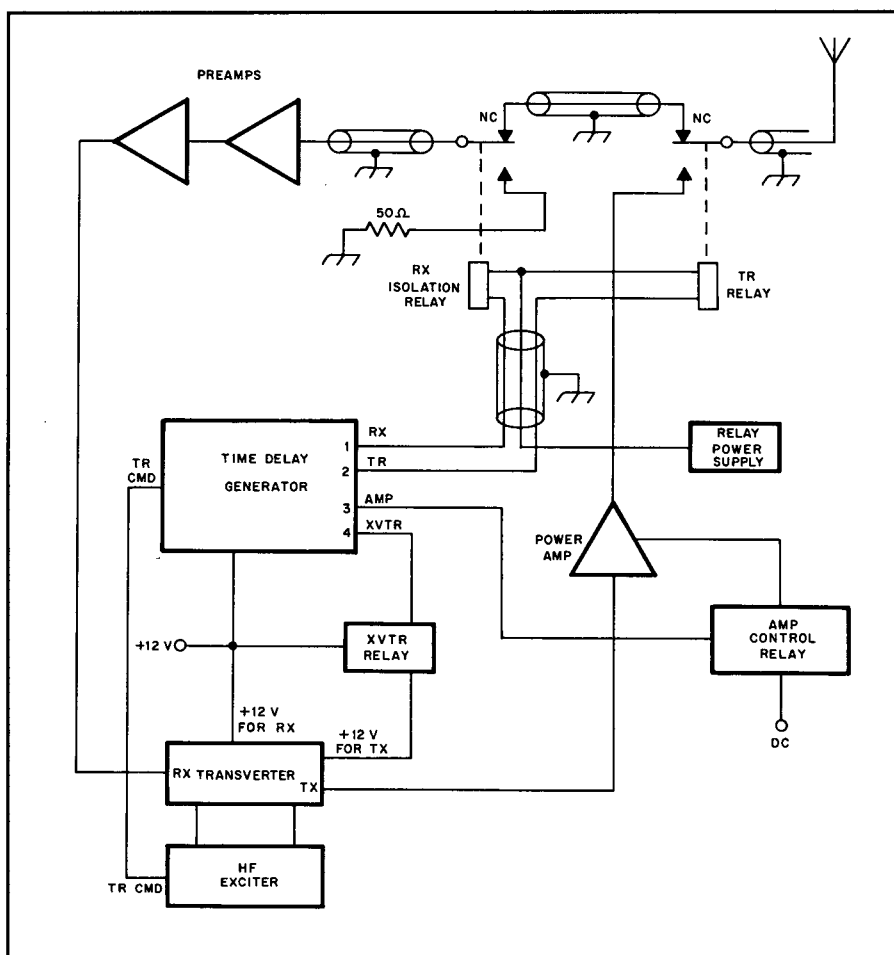

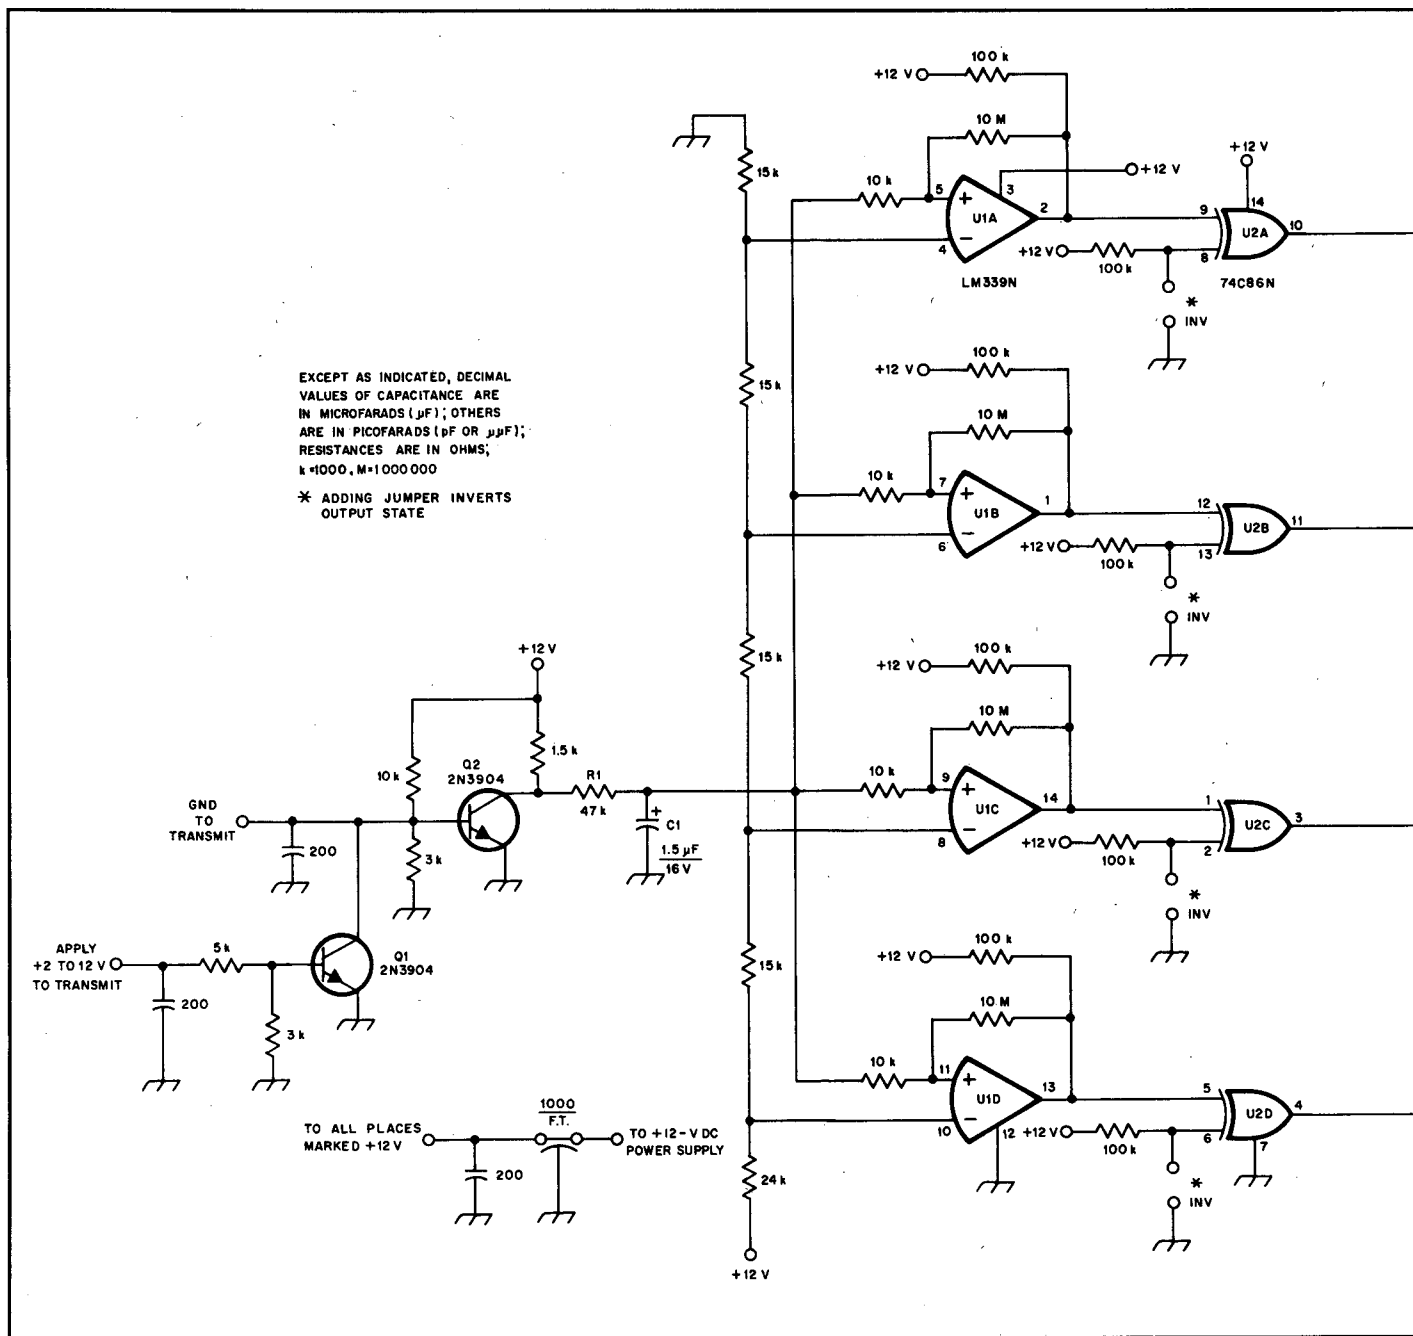

Fig 22.88—Block diagram of the VHF/UHF station with a remote-mounted preamp and antenna relays. The TR time-delay generator makes sure that everything switches in the right order.

level. As C1 charges up, each comparator, starting with U1A, will sequentially change output states.

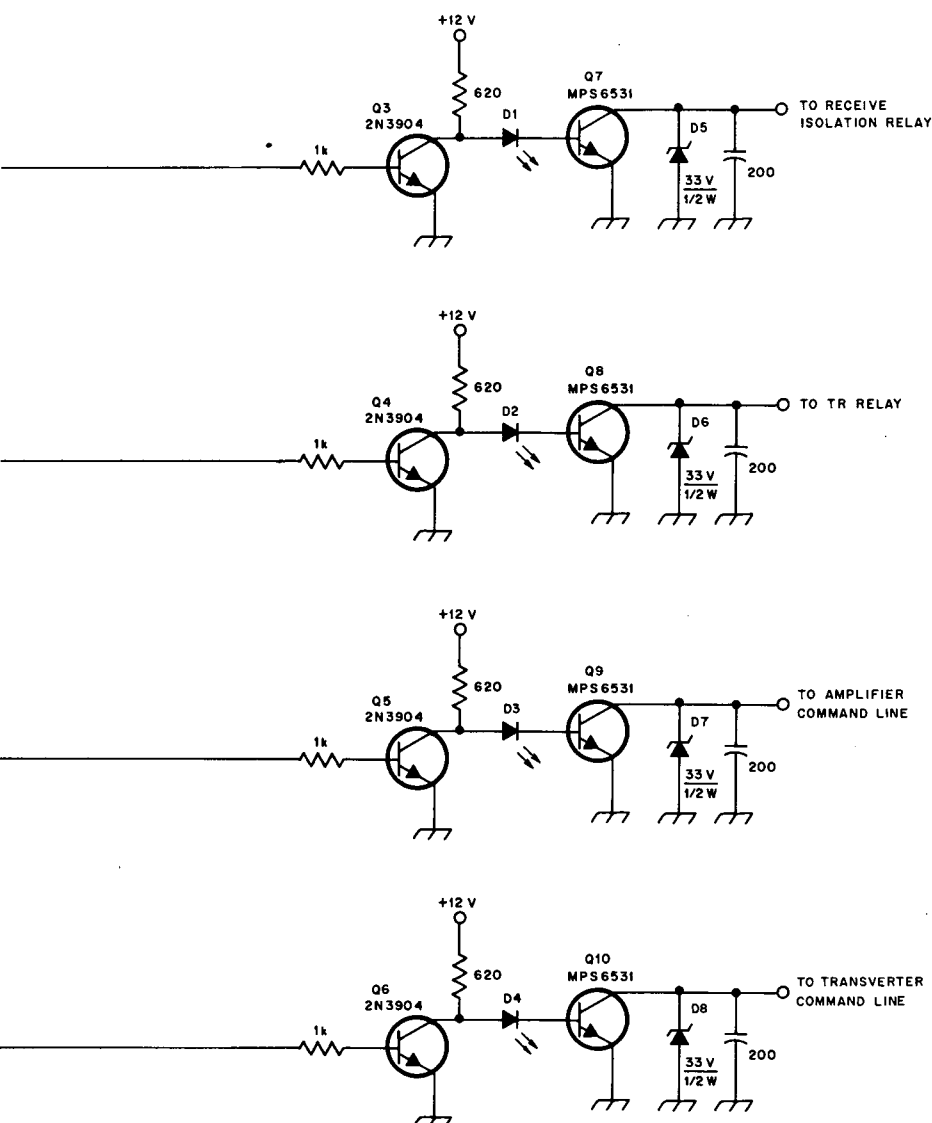

The comparator outputs are fed into U2, a quad exclusive-OR gate. This was included in the design to allow "state programming" of the various relays throughout the system. Because of the wide variety of available relays, primarily coaxial, you may be stuck with a relay that's exactly what you need—except its contacts are open when it's energized. To use this relay, you merely invert the output state of the delay generator by using a jumper between the appropriate OR-gate

input and ground. Now, the relay will be "on" during receive and "off" during transmit. This might seem kind of strange; however, high-quality coaxial relays are hard to come by and if "backwards" relays are all you have, you'd better use them.

The outputs of U2 drive transistors Q3-Q6, which are "on" in the receive mode. Drive from the OR gates turns these transistors "off." This causes the collectors of Q3-Q6 to go high, allowing the base-to-emitter junctions of Q7-Q10 to be forward-biased through the LEDs to turn on the relays in sequential order. The LEDs serve as built-in indicators to check per-

formance and sequencing of the generator. This is convenient if any state changes are made.

When the output transistors (Q7-Q10) are turned on, they pull the return side of the relay coils to ground. These output transistors were selected because of their high beta, a very low saturation voltage ( $V_{CE}$ ) and low cost. They can switch (and have been tested at) 35 V at 600 mA for many days of continuous operation. If substitutions are planned, test one of the new transistors with the relays you plan to use to be sure that the transistor will be able to power the relay for long periods.

**Fig 22.89—Schematic diagram of the TR time-delay generator.** Resistors are  $\frac{1}{4}$  W. Capacitors are disc ceramic. Capacitors marked with polarity are electrolytic.

**D1-D4—Red LED (MV55, HP 5082-4482 or equiv.)**

**D5-D8—33-V, 500-mW Zener diode (1N973A or equiv.)**

**C1—1.5- $\mu$ F, 16-V or greater, axial-lead electrolytic capacitor. See text.**

**Q1-Q6—General purpose NPN transistor (2N3904 or equiv.)**

**Q7-Q10—Low-power NPN amplifier transistor, MPS6531 or equiv. Must be able to switch up to 35 V at 600 mA continuously. See text.**

**R1—47-k $\Omega$ ,  $\frac{1}{4}$ -W resistor. This resistor sets the TR delay time constant and may have to be varied slightly to achieve the desired delay. See text.**

**U1—Quad comparator, LM339 or equiv.**

**U2—Quad, 2-input exclusive or gate (74C86N, CD4030A or equiv.)**

To go from transmit to receive, the sequencing order is reversed. This gives additional protection to the various system components. C1 discharges through R1 and Q2 to ground.

**Fig 22.90** shows the relative states and duration of the four output commands when enabled. With the values specified for R1 and C1, there will be intervals of 30 to 50 milliseconds between the four output commands. Exact timing will vary because of component tolerances. Most likely everything will be okay with the values shown, but it's a good idea to check the timing with an oscilloscope

just to be sure. Minor changes to the value of R1 may be necessary.

Most relays, especially coaxial, will require about 10 ms to change states and stop bouncing. The 30-ms delay will give adequate time for all closures to occur.

### CONSTRUCTION AND HOOKUP

One of the more popular antenna changeover schemes uses two coaxial relays: one for actual TR switching and one for receiver/preamplifier protection. See Fig 22.88.

Many RF relays have very poor isolation especially at VHF and UHF

frequencies. Some of the more popular surplus relays have only 40-dB isolation at 144 MHz or higher. If you are running high power, say 1000 W (+60 dBm) at the relay, the receive side of the relay will see +20 dBm (100 mW) when the station is transmitting. This power level is enough to inflict fatal damage on your favorite preamplifier.

Adding a second relay, called the RX isolation relay here, terminates the preamp in a 50- $\Omega$  load during transmission and increases the isolation significantly. Also, in the event of TR relay failure, this extra relay will protect the receive preamplifier.

As shown in Fig 22.88, both relays can be controlled with three wires. This scheme provides maximum protection for the receiver. If high-quality relays are used and verified to be in working order, relay losses can be kept well below 0.1 dB, even at 1296 MHz. The three-conductor cable

to the remote relays should be shielded to eliminate transients or other interference.

By reversing the RX-TX state of the TR relays (that is, connecting the transmitter Hardline and 50- $\Omega$  preamp termination to the normally open relay ports instead of the normally closed side), receiver protec-

**Fig 22.92—The completed time-delay generator fits in a small aluminum box.**

tion can be provided. When the station is not in use and the system is turned off, the receive preamplifier will be terminated in 50  $\Omega$  instead of being connected to the antenna. The relays must be energized to receive. This might seem a little backward; however, if you are having static-charge-induced preamplifier failures, this may solve your problem.

Most coaxial relays aren't designed to be energized continuously. Therefore, adequate heat sinking of coaxial relays must be considered. A pair of Transco Y relays can be energized for several hours when mounted to an aluminum plate 12 inches square and  $\frac{1}{4}$  inch thick. Thermal paste will give better heat transfer to the plate. For long-winded operators, it is a good idea to heat sink the relays even when they are energized only in transmit.

**Fig 22.91** shows typical HF power amplifier interconnections. In this application, amplifier in/out and sequencing are all provided. The amplifier will always have an antenna connected to its output before drive is applied.

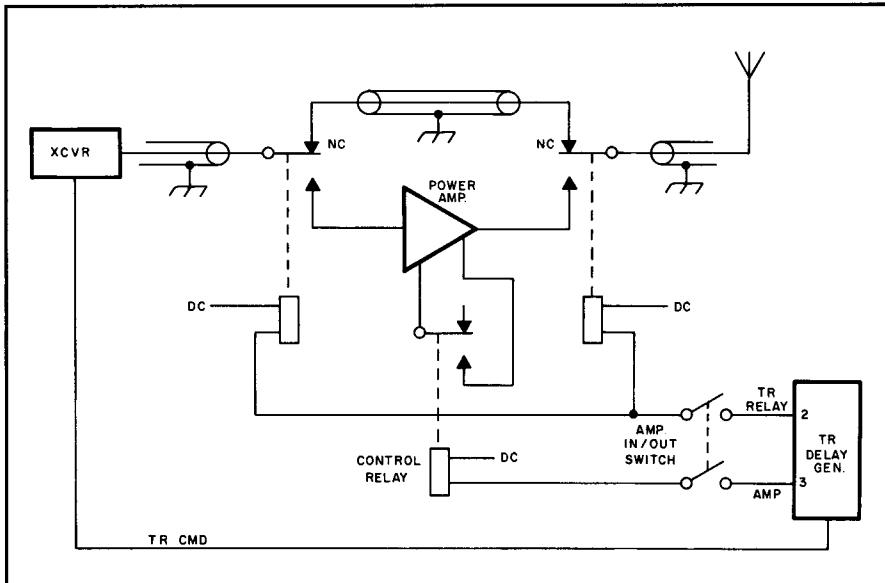

Many TR changeover schemes are possible depending on system requirements. Most are easily satisfied with this TR delay generator.

The TR delay generator is built on a  $2\frac{1}{2} \times 3\frac{1}{4}$ -inch PC board.<sup>1</sup> See **Fig 22.92**. Connections to the rest of the system are made through feedthrough capacitors. Do not use feedthrough capacitors larger than 200 pF because peak current through the output switching transistors may be excessive.

<sup>1</sup>A PC Template is available free from the ARRL Technical Secretary. Enclose an 8  $\times$  10 or larger SASE and ask for the 1996 *Handbook N6CA TR TIME-DELAY* template.

**Fig 22.90—The relative states and durations of the four output commands when enabled. This diagram shows the sequence of events when going from receive to transmit and back to receive. The TR delay generator allows about 30 to 50 ms for each relay to close before activating the next one in line.**

**Fig 22.91—The TR time-delay generator can also be used to sequence the relays in an HF power amplifier.**

## KEEPING HTs HANDY

Hand-held transceivers are lightweight and small, and you can take them almost anywhere. The problem is how and where to carry them. Herbert Leyson, AA7XP, needed a way to mount his HT in his car.

The radio had to be in front of him so he could easily change frequencies without taking his eyes off the road for more than a few seconds. It also had to be within the length of the speaker/mike cable and not block the view of the instruments. His solution is shown in **Fig 22.93A** and **B**.

A rectangular wire loop, covered with plastic tubing, is made from about 3 ft of stiff wire. The fin hooks drop into the air vents (or defroster outlets) on the horizontal portion of the dash.

The fin hooks are long enough to prevent vibrations from bouncing the mount from the vents. Bend the hanger wire in the shape shown in **Fig 22.93A**. AA7XP used a length for the dashboard *saddle* of 8½ inches, and a *drop* of 3 inches for eye-level height on the dash. The *hanger* portion of the mount is 2 inches long. You will have to vary these dimensions to match your car's dashboard. The result should look similar to the photo in **Fig 22.93B**.

You may want to add a small piece of foam rubber to act as a cushion between the HT and the dash to help prevent bouncing and rattling. Spread the fin hooks for a firmer grip if it looks as if they will bounce out of the air vents.

Nona Norman, N8CKS, had a different problem. She wanted to pack her HT in a suitcase but was concerned it could rattle around and be damaged. Her solution was to use an oven mitt and stuff the HT into the finger area. You could cut off the mitt's thumb, and sew it up for a neater package, or you could use the thumb for storage of a BNC-to-PL-259 converter.

If you are concerned about losing your HT when it is clipped on your belt, try Joe Simpson's idea. KD4LLV bought a *key-keeper* at a truck stop (hardware stores have them, too) for only \$4. A *key-keeper* is one of those little metal security clips that slips over your belt. It comes with a

**Fig 22.93—A: Measure your HT and dashboard to find the dimensions of this over-the-dash HT mount. At B, An HT sits firmly in view next to the dashboard.**

**(B)**

round split ring intended for keys. Attach it to the HT handstrap. The ring unclips easily with one hand, freeing the HT from your belt.

Joe also faced the problem of carrying and storing a full line of accessories: spare battery pack, earphone, speaker/mike, telescoping antenna and a BNC-to-UHF adapter. His solution uses a 12×8.5×2.5-inch foam-lined plastic pistol case. At various gun shows and sporting-goods stores they sell for \$4 to \$12.

Mark the outlines of your gear on the foam with ink, and *carefully* cut away the

marked foam with a single-edged razor blade. The result is a custom-fit slot for each item in the bottom piece of foam. Finish by cutting a small section from the top piece of foam above the radio slot to prevent pressure on the HT keypad when the case is closed.

When fully loaded, the case holds an HT, a spare battery pack, a speaker/mike, three antennas, a coax adapter, various papers and an earphone. Slight changes in the layout could leave room for a few small tools, too. The case fits neatly under the car seat when you want the gear out of sight.

## A SIMPLE 10-MINUTE ID TIMER

This project was originally described in "Hints and Kinks" in the November 1993 issue of *QST* by John Conklin, WD0O. It is an update to an earlier WD0O design for which parts are no longer available.

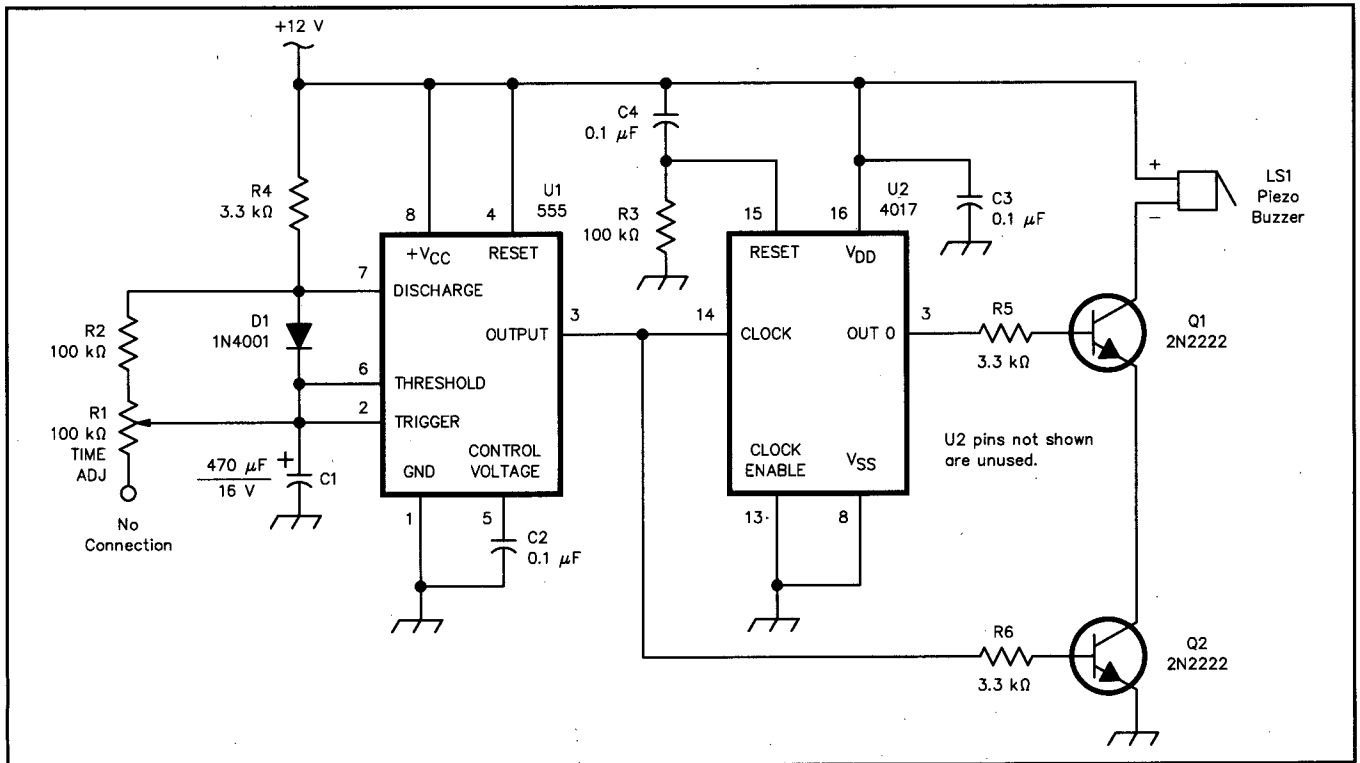

This simple and effective timer can be built in an evening and uses inexpensive and easily obtained parts. Its timing cycle

is independent of supply voltage and resets automatically upon power-up, as well as at the end of each cycle.

### CONSTRUCTION AND ADJUSTMENT

Assembly is straightforward and parts layout is not critical. The circuit of

Fig 22.94 can be built on a small piece of perfboard and housed in an inexpensive enclosure. To calibrate the time, set R1, TIME ADJ, at midpoint initially, and then adjust it by trial and error to achieve a 10-minute timing cycle. The buzzer will sound for about 1 second at the end of each cycle.

**Fig 22.94—The new and improved 10-minute reminder uses easy-to-get components. Part numbers in parentheses are Radio Shack; equivalent parts can be substituted. Resistors are 1/4-W, 5% or 10% tolerance units.**

C1—470-µF electrolytic, 16 V or more (272-957).

C2, C3, C4—0.1 F, 16 V or more (272-109).  
D1—1N4001, 50 PIV, 1 A (276-1101).

LS1—12-V piezo buzzer (273-074).

Q1, Q2—2N2222 or MPS2222A (276-2009).  
R1—100-kΩ trimmer potentiometer (271-284).

R2, R3—100-kΩ (271-1347).

R4, R5, R6—3.3 k (271-1328)

U1—555 timer IC (276-1723).

U2—4017 decade counter IC (276-2417).

## BNC CONNECTORS HANDLE SWITCHING IN A FLEXIBLE ANTENNA TUNER

You can electrically arrange inductors and capacitors to get maximum mileage out of expensive antenna-tuner parts—easily. This project, by ARRL Lab Engineer Zack Lau, KH6CP/1, originally appeared in October 1991 *QST*. It uses BNC connectors to handle antenna-tuner switching chores. (You can use RF connectors other than BNCs, but BNCs are reliable and offer quick connect/disconnect unobtainable with other common connector types.) Fig 22.95 shows the arrangement: four BNC connectors (J1, J2, J3 and J4), an air-dielectric variable capacitor (C1), a roller inductor (L1) and an air-core, tappable inductor (L2). Fig 22.96 shows how everything

looks in assembled form.

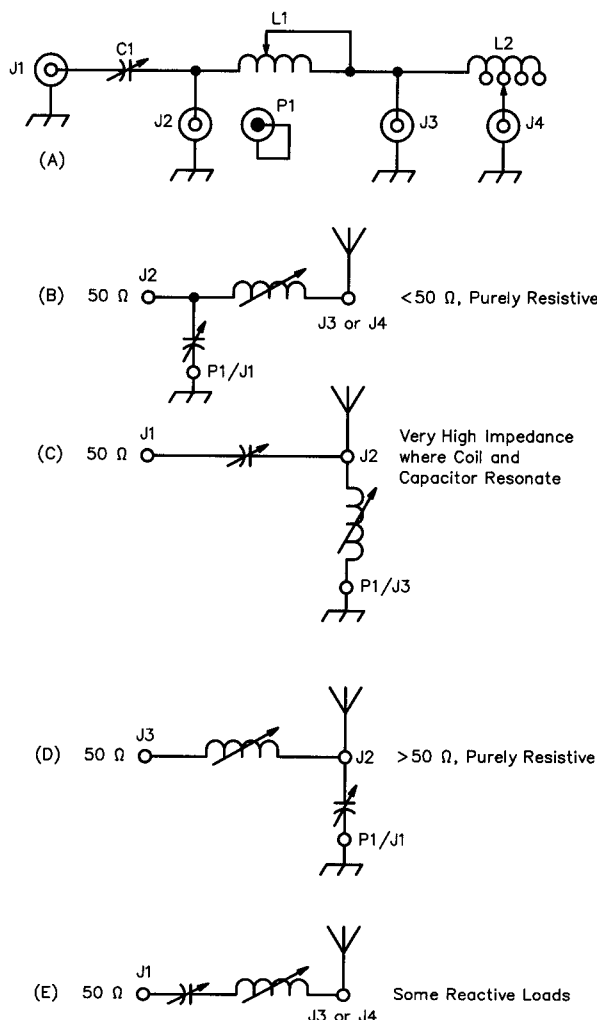

### GETTING THE RIGHT PARTS

A self-supporting, air-core coil (Miniductor or equivalent) works well at L2; a toroidal-core inductor wound on a powdered-iron core appropriate for the frequency range (mix-2 material 2 to 30 MHz; mix-6 material for 10 to 60 MHz) would work well, too. The roller inductor used at L1 is a luxury. Sometimes you can obtain these at flea markets at a reasonable price.

The capacitor you use may limit how much power your antenna tuner can handle. Wider capacitor plate spacings allow higher RF voltages before arcing

occurs, but arcing at the circuit's RF connectors may be the limiting factor in many cases. BNC connectors are rated to withstand 500 V. (Actually, it's better that the connectors are first if arcing occurs at all, because connectors can be replaced cheaply. Arced-over, carbonized capacitors are sometimes repairable, but only with a lot of work.) Teflon-dielectric connectors are strongly recommended in this application. Avoid bargain connectors; jacks containing cheap plastic insulation have been known to bubble and melt in the ARRL Lab!

In addition to the jacks called out in Fig 22.95, you'll need one shorting plug (P1) to complete some matching configura-

**Fig 22.95—Zack Lau's flexible antenna tuner (A) uses BNC jacks and one shorted-plug jumper (P1) for easy, efficient switching between matching configurations. No jack is labeled INPUT or OUTPUT because of the network's flexibility and reversibility. B through E show the four LC networks possible with this component arrangement, including P1's role (if any) in their implementation. The load characteristics shown at B through E are approximations only. The best way to adjust this tuner is to experiment with various configurations and settings until you achieve minimum reflected power or SWR.**

The component values below are those used in the tuner pictured in Fig 22.96; you need not duplicate them (or the particular parts used) exactly. Ocean State Electronics, Fair Radio Sales and Surplus Sales of Nebraska (see the Address List in the References chapter), among other *QST* advertisers, carry coils, capacitors, connectors and fasteners suitable for this project. And don't forget flea markets—scrounge!

C1—250 pF; exact value not critical.  
J1-J4—Chassis-mount coaxial jack, Teflon-dielectric BNC recommended.  
L1—Roller inductor, approximately 10 μH, exact value not critical.  
L2—Approximately 30 μH; exact value not critical. The coil shown in Fig 22.96, a PI DUX 1212A, may have been discontinued; it consists of 2¾ inches of 1½-inch-diameter, 16-turns-per-inch stock wound from #16 wire. A 2¾-inch-long piece of Barker & Williamson 3055 stock would be a close substitute.  
P1—Shorted coaxial plug to match J1-J4.

**Fig 22.96**—The prototype version of the Fig 22.95 circuit. From left to right, the jacks are J4-J1; the components are L2, L1 and C1. The tap clip on L2 is an Ocean State Electronics #3942.

tions. Commercial shorting plugs, complete with chains that allow the plug to be made capacitive, are available (military number CW-159, available as Amphenol 31-17 and Kings KC-89-62, for instance), but you can save money and time by making your own.

### BUILDING IT

Perhaps the biggest advantage BNC-jumper switching offers over multi-position switches is short lead length, as Fig 22.96 shows. The parts are positioned so *short* pieces of copper strap and wire can connect everything together. This sure beats wiring multisection switches!

If you use a solenoidal inductor at L1, be sure to preserve its *Q*—that is, keep its RF losses low—by mounting it away from metal enclosure walls by at least its diameter. Likewise, *do not* build your antenna tuner into an iron or steel box! An iron or

steel enclosure can raise a solenoidal coil's losses sky high. And don't use steel clips in making connections to L2—use brass or copper instead.

Some matching configurations require that you not ground one or more of the network components, so be sure to maximize your network's flexibility by insulating C1, L1 and L2 from the chassis and ground. C1 and L2 were mounted on 1/2-inch-square plastic bars. (The coil used for L2 includes a plastic mounting plate; you can add a plate to air-wound coils that don't include one.) Like most roller inductors, the part used at L1 required no additional insulation because its mounting brackets are insulated.

Variable components insulated from ground must be adjusted via nonconductive shafts or couplers. L1's shaft is insulated from the rest of the coil, but C1's shaft is connected to its rotor. In this tuner,

**Fig 22.97**—Can't locate a shaft coupler? Make your own out of an acrylic-plastic block. Drill a hole for the shafts through a small block of plastic. Then make two more holes, threaded to take setscrews, that intersect the shaft hole. You can make knobs for odd-sized shafts using much the same approach.

C1 is adjusted via a relatively expensive shaft coupler (Ocean State Electronics SC39005), but you can machine a cheaper plastic equivalent as shown in **Fig 22.97**.

### Tuning the Tuner

Using the tuner is easy: First, experiment with the tuner's configurations and setting to maximize received noise. Then, through a series of short, identified test transmissions, experiment further to minimize your system's reflected power of SWR. You can easily add external inductance by installing BNC connectors on both terminals of your add-on inductors and plugging them into the network as necessary.

One challenge remains unmet with this antenna tuner design, though: an elegant way to parallel capacitance with C1 for a network that will match *anything* at MF/HF. Binding posts and switches are obvious solutions, but is there a better way?

## A TRANSMATCH FOR BALANCED OR UNBALANCED LINES

Most modern transmitters are designed to operate into loads of approximately 50  $\Omega$ . Solid-state transmitters produce progressively lower output power as the SWR on the transmission line increases, owing to the built-in SWR protection circuits. Therefore, it is useful to employ a matching network between the transmitter and the antenna feeder when antennas with complex impedances are used.

One example of this need can be seen in the case of an 80-m, coax-fed dipole antenna, which has been cut for resonance at say, 3.6 MHz. If this antenna were used in the 75-m phone band, the SWR would be fairly high. A Transmatch could be used to give the transmitter a 50- $\Omega$  load, even though a significant mismatch was present at the antenna feedpoint.

It is important to remember that the Transmatch will not correct the actual

SWR condition; it only conceals it as far as the transmitter is concerned. A Transmatch is useful also when using a single-wire antenna for multiband use. By means of a balun at the Transmatch output it is possible to operate the transmitter into a balanced transmission line, such as a 300- or 600- $\Omega$  feed system of the type that would be used with a multiband tuned dipole, V beam or rhombic antenna.

A secondary benefit can be realized from Transmatches of certain varieties: The matching network can, if it has a band-

pass response, attenuate harmonics from the transmitter. The amount of attenuation is dependent upon the loaded  $Q(Q_L)$  of the network after the impedance has been matched. The higher the  $Q_L$ , the greater the attenuation. Some Transmatches, such as the Ultimate Transmatch of Fig 22.99, can exhibit a high-pass response (undesirable), depending on the transformation ratio they are adjusted to accommodate. In a worst-case condition the attenuation of harmonic currents may be as low as 3 to 5 dB. Under different (better) conditions

Fig 22.98—Exterior view of the SPC Transmatch. Radio Shack vernier drives are used for the tuning capacitors. A James Millen turns-counter drive is coupled to the rotary inductor.

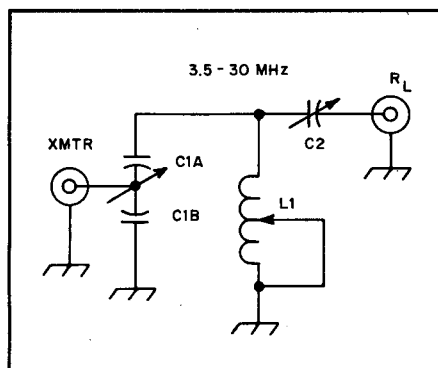

Fig 22.99—Circuit for the Ultimate Transmatch. The network can degenerate to a high-pass network under some conditions (see text). A T-network configuration provides identical matching range and does not require a splitstator capacitor at C1.

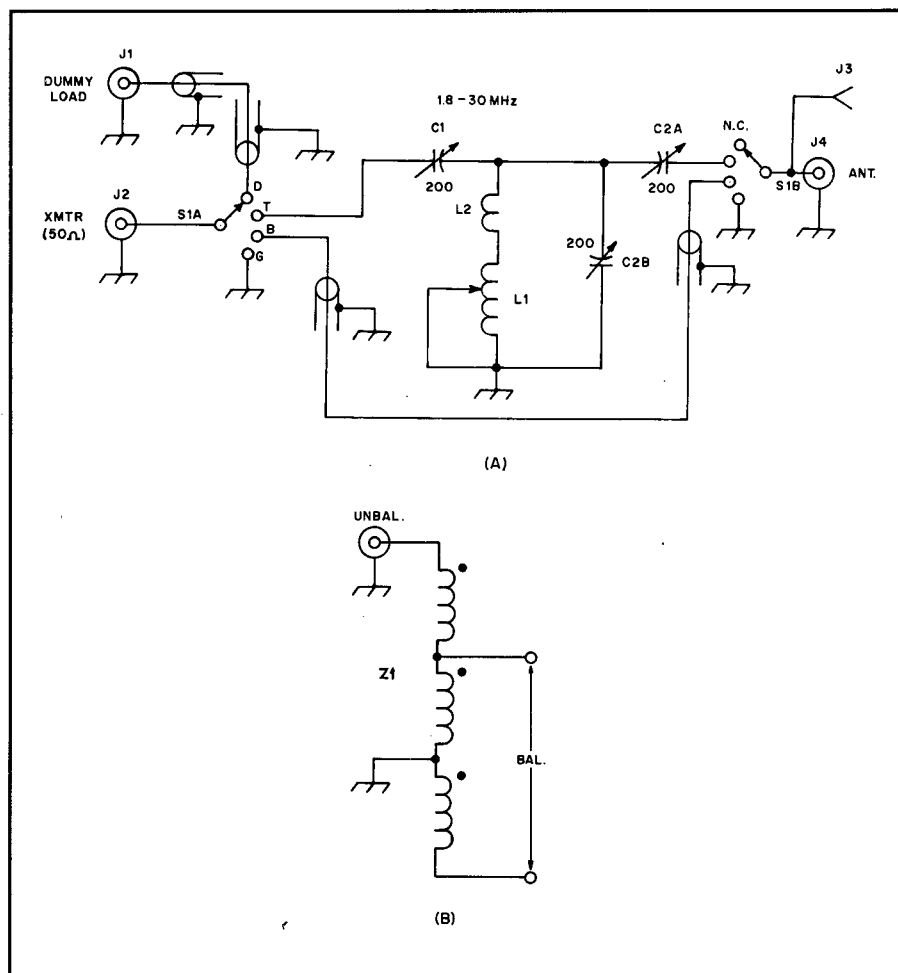

Fig 22.100—Schematic diagram of the SPC circuit. Capacitance is in pF. Contact information for parts suppliers appears in the Address List in the **References** chapter.

C1—200-pF transmitting variable with plate spacing of 0.074 inch or greater (supplier: RADIOKIT).

C2—Dual-section variable, 200 pF per section. Same plate spacing as C1 (supplier: RADIOKIT).

J1, J2, J4—SO-239 coaxial connectors. J4 should have high-dielectric-strength insulation (such as Teflon) if high-Z single-wire antennas are used at J3.

J4—Ceramic feedthrough bushing.

L1—Rotary inductor, 25  $\mu$ H minimum inductance (supplier: RADIOKIT).

L2—Three turns #8 copper wire, 1 inch ID $\times$ 1 $\frac{1}{2}$  inches long.

S1—Two-pole, four-position ceramic rotary wafer switch with heavy contacts. Two positions are unused.

Z1—Balun transformer: 12 turns no. 12 Formvar wire, trifilar, close-wound on 1-inch-OD phenolic or PVC-tubing form.

**Fig 22.101—Interior view of the W1FB SPC Transmatch. L2 is mounted on the rear wall by means of two ceramic standoff insulators. C1 is on the right and C2 is at the left. The coaxial connectors, ground post and J3 are on the lower part of the rear panel.**

of impedance transformation, the attenuation can be as great as 20 to 25 dB.

The SPC Transmatch described here was developed to correct for the sometimes poor harmonic attenuation of the network in the Ultimate Transmatch. The SPC (series-parallel capacitance) circuit maintains a band-pass response under load conditions of less than 25  $\Omega$  to more than 1000  $\Omega$  (from a 50- $\Omega$  transmitter). This is because a substantial amount of capacitance is always in parallel with the rotary inductor (C2B and L1 of Fig 22.100). In comparison with the Ultimate circuit of Fig 22.99, it can be seen that at high load impedances, the Ultimate Transmatch will have minimal effective output capacitance in shunt with the inductor, giving rise to a high-pass response.

Another advantage of the SPC Transmatch is its greater frequency range with the same component values used in the Ultimate Transmatch. The circuit of Fig 22.100 operates from 1.8 to 30 MHz with the values shown. Only three-fourths

of the available inductance of L1 is needed on 160 m. For this reason there are vernier-drive dials on C1 and C2. They are also useful in logging the dial settings for changing bands or antennas.

### Construction

Figs 22.98 and 22.101 show the structural details of the Transmatch. The cabinet is homemade from 16-gauge aluminum sheeting. L brackets are affixed to the right and left sides of the lower part of the cabinet to permit attachment of the U-shaped cover.

The conductors that join components should be of heavy-gauge material to minimize stray inductance and heating. Wide strips of flashing copper are suitable for the conductor straps. The center conductor and insulation from RG-59 polyfoam coaxial cable is used in this model for the wiring between the switch and the related components. The insulation is sufficient to prevent breakdown and arcing at 2-kW PEP input to the transmitter.

All leads should be kept as short as possible to help prevent degradation of the circuit Q. The stators of C1 and C2 should face toward the cabinet cover to minimize the stray capacitance between the capacitor plates and the bottom of the cabinet (important at the upper end of the Transmatch frequency range). Insulated ceramic shaft couplings are used between the vernier drives and C1 and C2, since the rotors of both capacitors are floating in this circuit. C1 and C2 are supported above the bottom plate on steatite cone insulators. S1 is attached to the rear apron of the cabinet by means of two metal standoff posts.

### Operation

The SPC Transmatch is designed to handle the output from transmitters that operate up to 1.5 kW PEP output. L2 has been added to improve the circuit Q at 10 and 15 m. However, it may be omitted from the circuit if the rotary inductor (L1) has a tapered pitch at the minimum-inductance end. It may be necessary to omit L2 if the stray wiring inductance of the builder's version is high. Otherwise, it may be impossible to obtain a matched

condition at 28 MHz with certain loads.

An SWR indicator is used between the transmitter and the Transmatch to show when a matched condition is achieved. The builder may want to integrate an SWR meter in the Transmatch circuit between J2 and the arm of S1A (Fig 22.100A). If this is done there should be room for an edgewise panel meter above the vernier drive for C2.

Initial transmitter tuning should be done with a dummy load connected to J1 and with S1 in the D position. This will prevent interference that could otherwise occur if tuning is done on the air. After the transmitter is properly tuned into the dummy load, unkey the transmitter and switch S1 to T (Transmatch). Never hot-switch a Transmatch, as this can damage both transmitter and Transmatch. Set C1 and C2 at midrange. With a few watts of RF, adjust L1 for a decrease in reflected power. Then adjust C1 and C2 alternately for the lowest possible SWR. If the SWR cannot be reduced to 1:1, adjust L2 slightly and repeat the procedure. Finally, increase the transmitter power to maximum and touch up the Transmatch controls if necessary. When tuning, keep your transmissions brief and identify your station.

The air-wound balun of Fig 22.100B can be used outboard from the Transmatch if a low-impedance balanced feeder is contemplated. Ferrite or powdered-iron core material is not used in the interest of avoiding TVI and harmonics that can result from core saturation.

The B position of S1 permits switched-through operation when the Transmatch is not needed. The G position is used for grounding the antenna system, as necessary; a quality earth ground should be attached to the Transmatch chassis at all times.

### Final Comments

Surplus coils and capacitors are okay in this circuit. L1 should have at least 25  $\mu\text{H}$  of inductance and the tuning capacitors need to have 150 pF or more of capacitance per section. Insertion loss through this Transmatch was measured at less than 0.5 dB at 600 W of RF power on 7 MHz.

## A 12-V JUNCTION BOX FOR YOUR SHACK

Today, many of the accessories we use around the shack are powered by 12-V dc. Robert Capon, WA3ULH, became frustrated with the proliferation of 12-V power connectors and described this junction box in the August 1994 *QST*. The box has an on/off switch, an LED and a panel-mounted fuse. You can build the junction box in one evening for about \$25 or less.

### Construction

Fig 22.102 shows the layout of the top of the case. Use a photocopy of this figure as the drilling template. Begin with ten small,  $\frac{1}{16}$ -inch guide holes. Then remove the template, and use larger bits to drill the remaining holes.

Next, install all the panel-mounted components. Wire them as shown in Fig 22.103.

Finally, you'll need to round up all of your accessories and standardize your shack on the mating male dc plugs. Remove the old plugs from these devices, and solder the new plugs to each. The positive lead goes to the center conductor, and the negative or grounded lead goes to the shield of the plug. Do not automatically assume the red or the striped wire from your accessory is the positive lead. Check the documentation to determine the correct polarity of each lead.

### A High-Powered Version for Your Mobile Rig

WA3ULH's junction box uses a 1.5-A fuse and low current jacks and plugs. A high-current version, fused for 10-A, can fit in the same space. Use the female MOLEX connector, recommended earlier in this chapter, for standard connection of VHF and UHF radios. A mating pair of these connectors is sold by Radio Shack with the part number 274-222. The female snaps into a rectangular hole. Use the matching male as the connector on the leads from the rig or accessory.

Drill one or more of the six output connector holes on the left side of the layout with a  $\frac{1}{4}$ -in drill. Then file each hole in the soft plastic case to  $\frac{11}{16} \times \frac{1}{4}$ -in. Replace the power input connector in the top-right corner with a set of #14 wire leads fed through the panel hole and a grommet. These leads connect directly to your power source. Use a 10-A fuse in place of the 1.5-A unit. Now you can plug your mobile rig directly into the junction box.

Fig 22.102 — Drilling template. Photocopy this page, cut out the template and tape it to the box as a drilling guide.

Fig 22.103 — Wiring diagram of the 12-V junction box. All parts are available at Radio Shack.

D1—LED in panel-mount holder (276-068A).

F1—10 A fuse holder (270-362).

J1-J7—5.5 mm/2.1 mm dc power jacks (7\*), (274-1563).

R1—470-Ω resistor (271-1317).

S1—SPST microminiature switch (275-324).

#20 stranded hook-up wire (278-1225).  
5.5 mm/2.1 mm dc power plugs (7)\*, (274-1569A)

Plastic project box (270-221).

## AN RF SNIFFER METER

The RF Sniffer Meter shown in Fig 22.104 has served Emerson Hoyt, WX7E, for almost 50 years. It gets its name from its function—sniffing out the presence of RF (or even high audio) energy. The Sniffer can show if RF has made its way to undesired places, such as the outside of coax cable shields, or into regulated power supplies or audio amplifiers. Of course, the Sniffer can also confirm the presence of RF where it *should* be, as in oscillators.

The circuit consists of a sensitive milliammeter or a low-range microammeter, two germanium diodes, a short piece of bus wire for a probe and some suitable support hardware. The bus wire acts as antenna, and the diodes rectify the RF, feeding dc through the meter.

The diodes are germanium, such as the Radio Shack 1N34A (#276-1123). Germanium diodes are better than silicon diodes because they will conduct with a much lower applied voltage. You can use almost any dc meter, but the detection sensitivity will be better with lower range microammeters—namely, 100  $\mu$ A or less.

Construction is not critical, but leads should be kept short. Either solder the diode leads directly to meter terminals or use solder lugs. Fig 22.104 shows WX7E's method of using a stud-terminal meter.

Fig 22.104—A sensitive meter, two diodes and some wire are all you need to detect the presence of RF energy in circuits.

Cover the probe wire with insulating sleeving, leaving only a very short length of the tip exposed. When working with

vacuum-tube circuits or other high-voltage devices, be careful if the probe is close to or in contact with the higher voltages.

## 23

### Repeaters

**T**his section was written by Paul M. Danzer, N111.

In the late 1970s two events occurred that changed the way radio amateurs communicated. The first was the explosive advance in solid state components — transistors and integrated circuits. A number of new “designed for communications” integrated circuits became available, as well as improved high-power transistors for RF power amplifiers. Vacuum tube-based equipment, expensive to maintain and subject to vibration damage, was becoming obsolete.

At about the same time, in one of its periodic reviews of spectrum usage, the Federal Communications Commission (FCC) mandated that commercial users of the VHF spectrum reduce the bandwidth of truck, taxi, police, fire and all other commercial services from 15 kHz to 5 kHz. This meant that thousands of new narrowband FM radios were put into service and an equal number of wideband radios were no longer needed.

As the new radios arrived at the front door of the commercial users, the old radios went out the back door, and hams lined up to take advantage of the newly available “commercial surplus.” Not since the end of World War II had so many radios been made available to the ham community at very low or at least acceptable prices. With a little tweaking, the transmitters and receivers were modified for

ham use, and the great repeater boom was on.

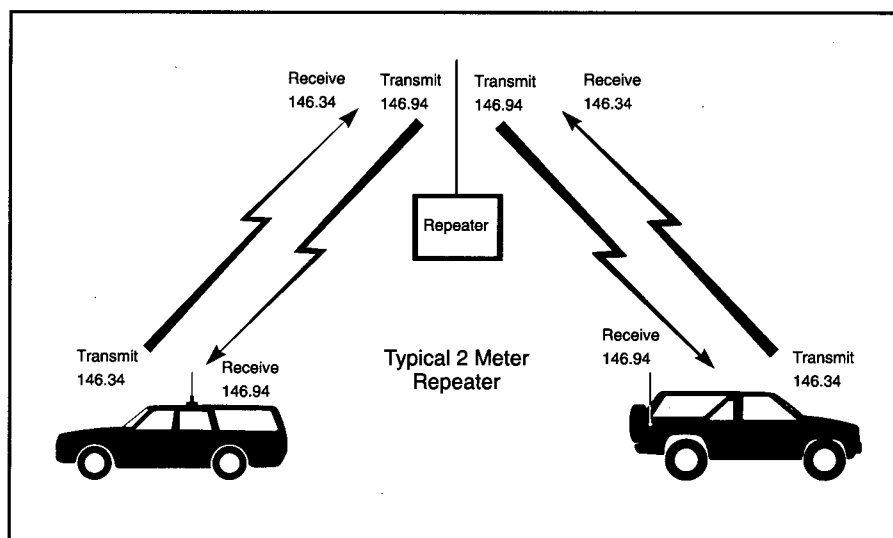

#### WHAT IS A REPEATER?

Trucking companies and police departments learned long ago that they could get much better use from their mobile radios by using an automated relay station called a repeater. Not all radio dispatchers are located near the highest point in town or have access to a 300-ft tower. But a repeater, whose basic idea is shown in Fig

23.1, can be more readily located where the antenna system is as high as possible and can therefore cover a much greater area.

#### Types of Repeaters

The most popular and well-known type of amateur repeater is an FM voice system on the 29, 144, 222 or 440-MHz bands. Tens of thousands of hams use small 12-V powered radios in their vehicles for both casual ragchewing and staying in touch

**Fig 23.1 — Typical 2-m repeater, showing mobile-to-mobile communication through a repeater station. Usually located on a hill or tall building, the repeater amplifies and retransmits the received signal on a different frequency.**

**Table 23.1****Types of Repeaters**

ATV — Amateur TV	Same coverage advantages as voice repeaters to hams using wideband TV in the VHF and UHF bands. Often consist of pairs of repeaters — one for the ATV and the other for the voice coordination.
AM and SSB	There is no reason to limit repeaters to FM. There are a number of other modulation-type repeaters, some experimental and some long-established.
Digipeaters	Digital repeaters used primarily for packet communications (see the <b>Modes</b> chapter). Can use a single channel (single port) or several channels (multi-port) on one or more VHF and UHF bands.
Multi-channel (wideband)	Amateur satellites are best-known examples. Wide bandwidth (perhaps 50 to 200 kHz) is selected to be received and transmitted so all signals in bandwidth are heard by the satellite (repeater) and retransmitted, usually on a different VHF or UHF band. Satellites are discussed elsewhere in this chapter.  Although not permitted or practical for terrestrial use in the VHF or UHF spectrum, there is no reason wideband repeaters cannot be established in the microwave region where wide bandwidths are allowed. This would be known as frequency multiplexing.

with what is going on during heavy traffic or commuting times. Others have low-power battery-operated hand-held units, known as “handi-talkies” or “HTs” for 144, 222 or 440 MHz. Some mobile and hand-held transceivers operate on two bands. But there are several other types of ham radio repeaters. **Table 23.1** describes them.

FM is the mode of choice, as it was in commercial service, since it provides a high degree of immunity to mobile noise pulses. Operations are *channelized* — all stations operate on the same transmit frequency and receive on the same receive frequency. In addition, since the repeater receives signals from mobile or fixed stations and retransmits these signals simultaneously, the transmit and receive frequencies are different, or *split*. Direct contact between two or more stations that listen and transmit on the same frequency is called operating *simplex*.

Individuals, clubs, amateur civil defense support groups and other organizations all sponsor repeaters. Anyone with a valid amateur license for the band can establish a repeater in conformance with the FCC rules. No one owns specific repeater frequencies, but nearly all repeaters are *coordinated* to minimize repeater-to-repeater interference. Frequency coordination and interference are discussed later in this chapter.

**Block Diagrams**

Repeaters normally contain at least the sections shown in **Fig 23.2**. After this, the sky is the limit on imagination. As an example, a remote receiver site can be used to try to eliminate interference (**Fig 23.3**).

The two sites can be linked either by telephone (“hard wire”) or a VHF or UHF link. Once you have one remote receiver site it is natural to consider a second site to better hear those “weak mobiles” on the other side of town (**Fig 23.4**). Some of the stations using the repeater are on 2 m while others are on 440? Just link the two repeaters! (**Fig 23.5**).

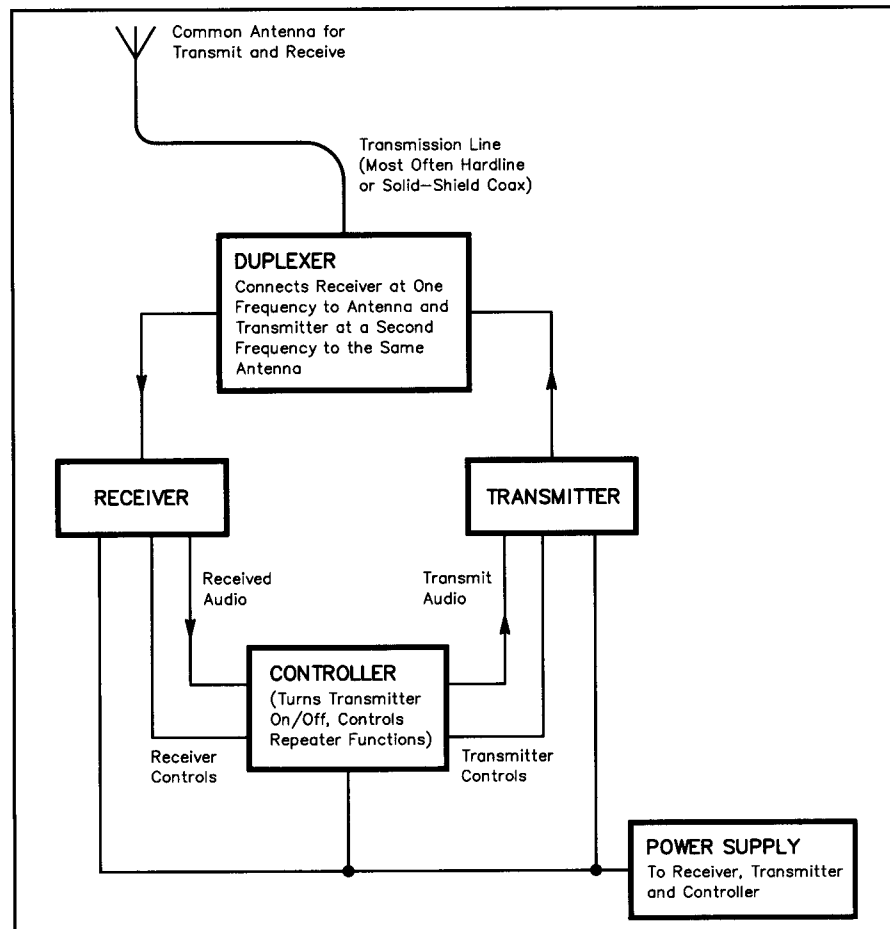

Want to help the local Civil Air Patrol (CAP)? Add a receiver for aircraft emergency transmitters (ELT). Tornadoes? It is now legal to add a weather channel receiver (**Fig 23.6**).

The list goes on and on. Perhaps that is why so many hams have put up repeaters.

**Repeater Terminology**

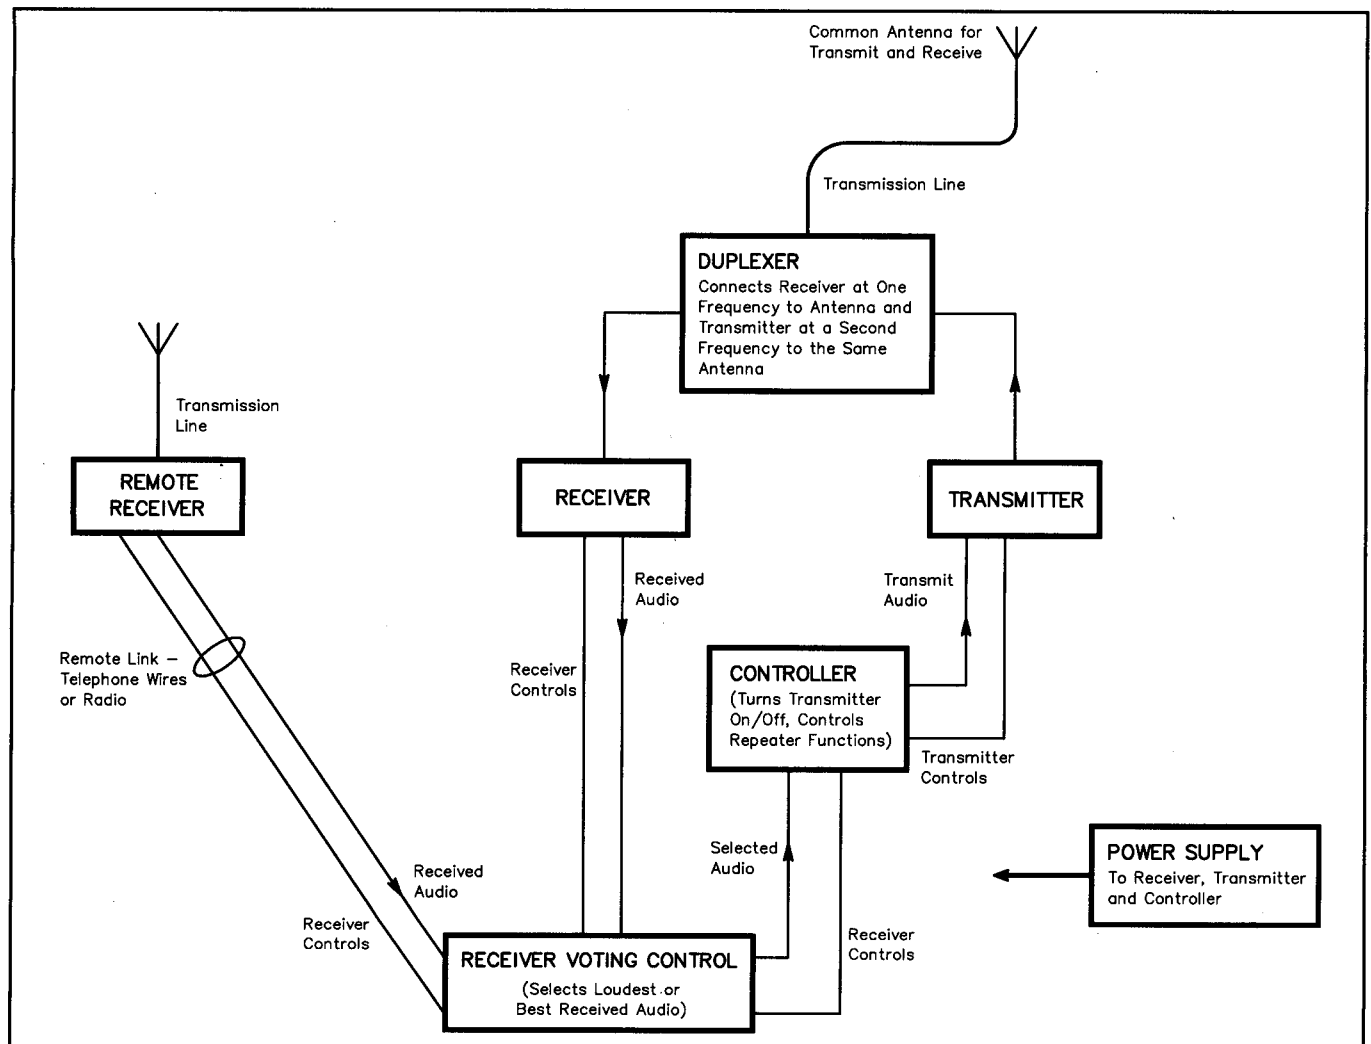

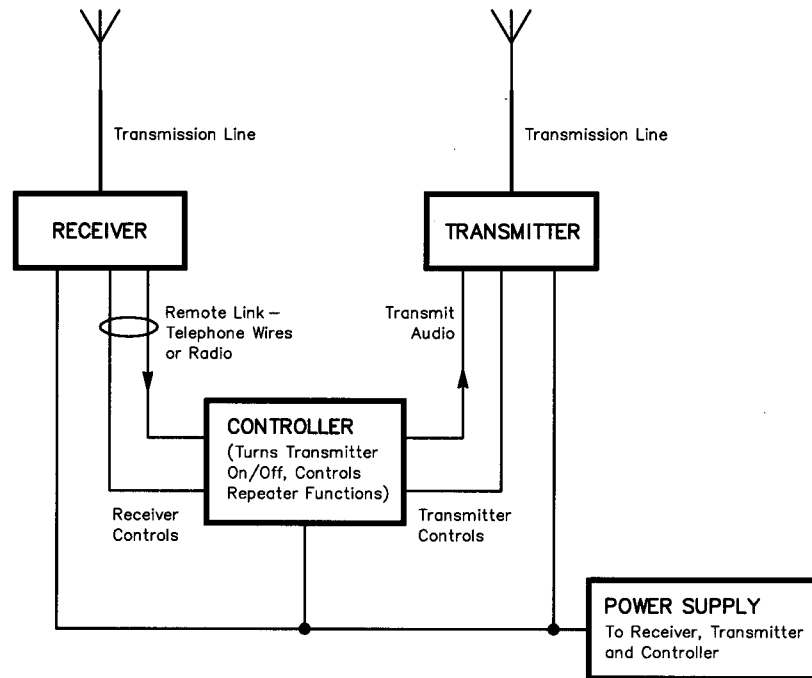

Here are some definitions of terms used in the world of Amateur Radio FM and repeaters:

**access code** — one or more numbers and/or symbols that are keyed into the repeater with a DTMF tone pad to activate

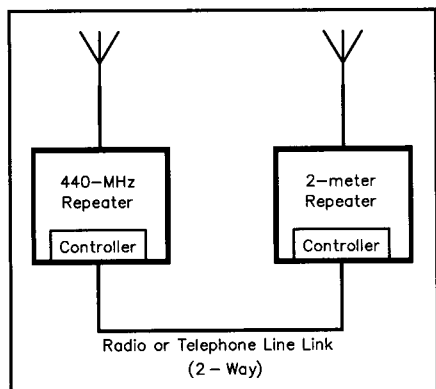

**Fig 23.2 — The basic components of a repeater station. In the early days of repeaters, many were home-built. These days, most are commercial, and are far more complex than this diagram suggests.**

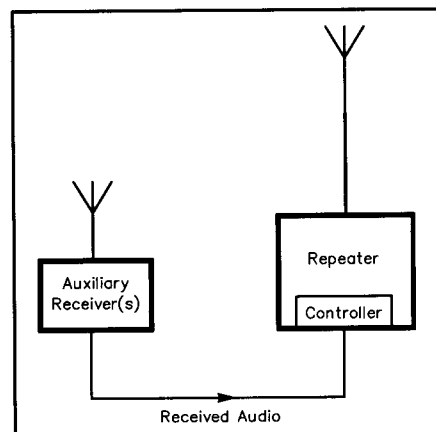

**Fig 23.3 — Separating the transmitter from the receiver helps eliminate certain types of interference. The remote receiver can be located on a different building or hill, or consist of a second antenna at a different height on the tower.**

**Fig 23.4 — A second remote receiver site can provide solid coverage on the other side of town.**

**Fig 23.5** — Two repeaters using different bands can be linked for added convenience.

**Fig 23.6** — For even greater flexibility, you can add an auxiliary receiver.

**Fig 23.7** — In the upper diagram, stations A and B cannot communicate because their mutual coverage is limited by the mountains between them. In the lower diagram, stations A and B can communicate because the coverage of each station falls within the coverage of repeater C, which is on a mountaintop.

a repeater function, such as an autopatch.

**autopatch** — a device that interfaces a repeater to the telephone system to permit repeater users to make telephone calls. Often just called a “patch.”

**break** — the word used to interrupt a conversation on a repeater *only* to indicate that there is an emergency.

**carrier-operated relay (COR)** — a device that causes the repeater to transmit in response to a received signal.

**channel** — the pair of frequencies (input and output) used by a repeater.

**closed repeater** — a repeater whose access is limited to a select group (see *open repeater*).

**control operator** — the Amateur Radio operator who is designated to “control” the operation of the repeater, as required by FCC regulations.

**courtesy beep** — an audible indication that a repeater user may go ahead and transmit.

**coverage** — the geographic area within which the repeater provides communications.

**CTCSS** — abbreviation for continuous tone-controlled squelch system, a series of subaudible tones that some repeaters use to restrict access. (see *closed repeater*)

**digipeater** — a packet radio (digital) repeater.

**DTMF** — abbreviation for dual-tone multifrequency, the series of tones gener-

ated from a keypad on a ham radio transceiver (or a regular telephone).

**duplex or full duplex** — a mode of communication in which a user transmits on one frequency and receives on another frequency simultaneously (see *half duplex*).

**duplexer** — a device that allows the repeater transmitter and receiver to use the same antenna simultaneously.

**frequency coordinator** — an individual or group responsible for assigning frequencies to new repeaters without causing interference to existing repeaters.

**full quieting** — a received signal that contains no noise.

**half duplex** — a mode of communication in which a user transmits at one time and receives at another time.

**hand-held** — a small, lightweight portable transceiver small enough to be carried easily; also called HT (for Handie-Talkie, a Motorola trademark).

**hang time** — the short period following a transmission that allows others who want to access the repeater a chance to do so; a *courtesy beep* sounds when the repeater is ready to accept another transmission.

**input frequency** — the frequency of the repeater’s receiver (and your transceiver’s transmitter).

**intermodulation distortion (IMD)** — the unwanted mixing of two strong RF signals that causes a signal to be transmitted on an unintended frequency.

**key up** — to turn on a repeater by transmitting on its input frequency.

**machine** — a repeater system.

**magnetic mount or mag-mount** — an antenna with a magnetic base that permits quick installation and removal from a motor vehicle or other metal surface.

**NiCd** — a nickel-cadmium battery that may be recharged many times; often used to power portable transceivers. Pronounced “NYE-cad.”

**open repeater** — a repeater whose access is not limited.

**output frequency** — the frequency of the repeater’s transmitter (and your transceiver’s receiver).

**over** — a word used to indicate the end of a voice transmission.

**Repeater Directory** — an annual ARRL publication that lists repeaters in the US, Canada and other areas.

**separation or split** — the difference (in kHz) between a repeater’s transmitter and receiver frequencies. Repeater users that use unusual separations, such as 1 MHz on 2 m, are sometimes said to have “oddball splits.”

**simplex** — a mode of communication in

which users transmit and receive on the same frequency.

**time-out** — to cause the repeater or a repeater function to turn off because you have transmitted for too long.

**timer** — a device that measures the length of each transmission and causes the repeater or a repeater function to turn off after a transmission has exceeded a certain length.

**tone pad** — an array of 12 or 16 numbered keys that generate the standard telephone dual-tone multifrequency (DTMF) dialing signals. Resembles a standard telephone keypad. (see *auto-patch*)

### Advantages of Using a Repeater

When we use the term *repeater* we are almost always talking about transmitters and receivers on VHF or higher bands, where radio-wave propagation is normally line of sight. Sometimes a hill or building in the path will allow refraction or other types of edge effects, reflections and bending. But for high quality, consistently solid communications, line of sight is the primary mode.

We know that the effective range of VHF and UHF signals is related to the height of each antenna. Since repeaters can usually be located at high points, one great advantage of repeaters is the extension of coverage area from low-powered mobile and portable transceivers.

Fig 23.7 illustrates the effect of using a repeater in areas with hills or mountains. The same effect is found in metropolitan areas, where buildings provide the primary blocking structures.

Siting repeaters at high points can also have disadvantages. When two nearby repeaters use the same frequencies, your transceiver might be able to receive both. But since it operates FM, the *capture effect* usually ensures that the stronger signal will capture your receiver and the weaker signal will not be heard — at least as long as the stronger repeater is in use.

It is also simpler to provide a very sensitive receiver, a good antenna system, and a slightly higher power transmitter at just one location — the repeater — than at each mobile, portable or home location. A superior repeater system compensates for the low power (5 W or less), and small, inefficient antennas that many hams use to operate through them. The repeater maintains the range or coverage we want, despite our equipment deficiencies. If both the hand-held transceiver and the repeater are at high elevations, for example, communication is possible over great distances, despite the low output power and inefficient antenna of the

**Fig 23.8** — In the Rocky Mountain west, hand-held transceivers can often cover great distances, thanks to repeaters located atop high mountains. (photo courtesy WB0KRX and N0IET)

transceiver (see Fig 23.8).

Repeaters also provide a convenient meeting place for hams with a common interest. It might be geographic — your town — or it might be a particular interest such as DX or passing traffic. Operation is channelized, and usually in any area you can find out which channel — or repeater — to pick to ragchew, get highway information, or whatever your need or interest is. The fact that operation is channelized also provides an increased measure of driving safety — you don't have to tune around and call CQ to make a contact, as on the HF bands. Simply call on a repeater frequency — if someone is there and they want to talk, they will answer you.

### Emergency Operations

When there is a weather-related emergency or a disaster (or one is threatening), most repeaters in the affected area immediately spring to life. Emergency operation and traffic always take priority over other ham activities, and many repeaters are equipped with emergency power sources just for these occasions.

Almost all Amateur Radio emergency organizations use repeaters to take advantage of their extended range, uniformly good coverage and visibility. Most repeaters are well known — everyone active in an area with suitable equipment knows the local repeater frequencies. For those who

don't, many transceivers provide the ability to scan for a busy frequency. See Fig 23.9.

### Repeaters and the FCC

The law in the United States changes over time to adapt to new technology and changing times. Since the early 1980s, the trend has been toward deregulation, or more accurately in the case of radio amateurs, self-regulation. Hams have established band plans, calling frequencies, digital protocols and rules that promote efficient communication and interchange of information.

Originally, repeaters were licensed separately with detailed applications and control rules. Repeater users were forbidden to use their equipment in any way that could be interpreted as commercial. In some cases, even calling a friend at an office where the receptionist answered with the company name was interpreted as a problem.

The rules have changed, and now most nonprofit groups and public service events can be supported and businesses can be called — as long as the participating radio amateurs are not earning a living from this specific activity.

We can expect this trend to continue. For the latest rules and how to interpret them, see *QST* and *The FCC Rule Book*, published by the ARRL.

## FM REPEATER OPERATION AND EQUIPMENT

### Operating Techniques

There are almost as many operating procedures in use on repeaters as there are repeaters. Only by listening can you determine the customary procedures on a particular machine. A number of common operating techniques are found on many repeaters, however.

One such common technique is the transmission of *courtesy tones*. Suppose several stations are talking in rotation — one following another. The repeater detects the end of a transmission of one user, waits a few seconds, and then transmits a short tone or beep. The next station in the rotation waits until the beep before transmitting, thus giving any other station wanting to join in a brief period to transmit their call sign. Thus the term *courtesy tone* — you are politely pausing to allow other stations to join in the conversation.

Another common repeater feature that encourages polite operation is the *repeater timer*. Since repeater operation is channelized — allowing many stations to use the same frequency — it is polite to keep your transmissions short. If you forget this little politeness many repeaters simply cut off your transmission after 2 or 3 minutes of continuous talking. After the repeater “times out,” the timer is reset and the repeater is ready for the next transmission. The timer length is often set to 3 minutes or so during most times of the day and 1 or 1½ minutes during commuter rush hours when many mobile stations want to use the repeater.

A general rule, in fact law — both internationally and in areas regulated by the FCC — is that emergency transmissions always have priority. These are defined as relating to life, safety and property damage. Many repeaters are voluntarily set up to give mobile stations priority, at least in checking onto the repeater. If there is going to be a problem requiring help, the request will usually come from a mobile station. This is particularly true during rush hours; some repeater owners request that fixed stations refrain from using the repeater during these hours. Since fixed stations usually have the advantages of fixed antennas and higher power, they can operate simplex more easily. This frees the repeater for mobile stations that need it.

A chart of suggested operating priorities is given in Fig 23.10. Many but not all repeaters conform to this concept, so it can be used as a general guideline.

The figure includes a suggested priority control for *closed repeaters*. These are

Fig 23.9 — During disasters like the Mississippi River floods of 1993, repeaters over a wide area are used solely for emergency-related communication until the danger to life and property is past. (photo courtesy WA9TZL)

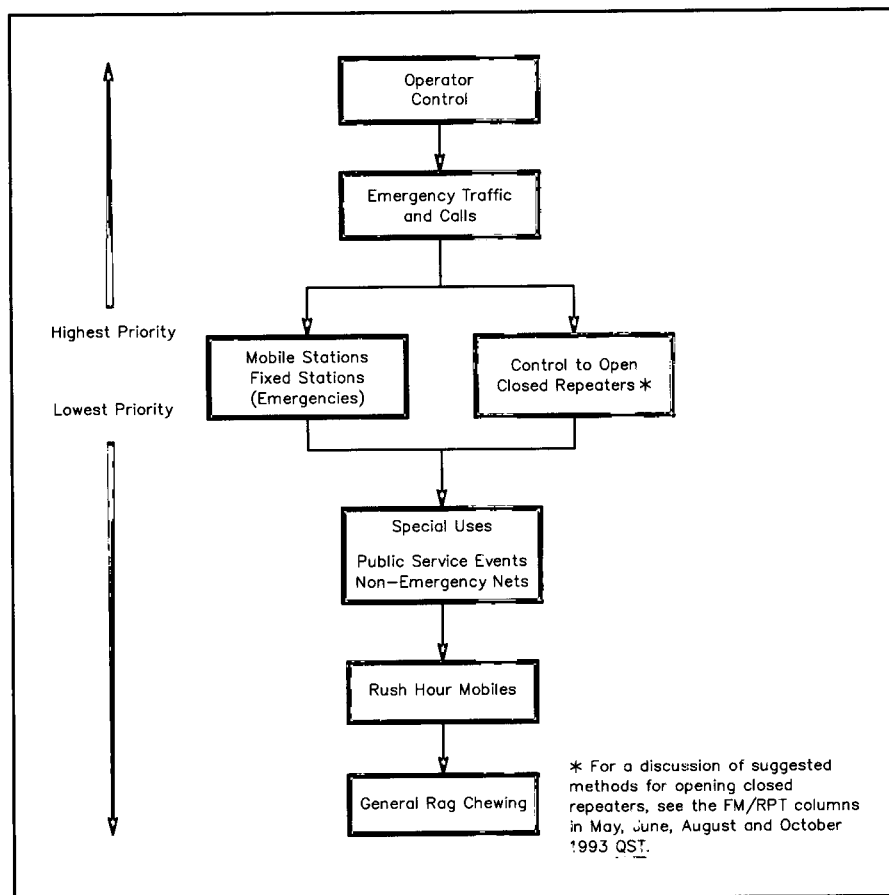

Fig 23.10 — The chart shows recommended repeater operating priorities. Note that, in general, priority goes to mobile stations.

repeaters whose owners wish, for any number of reasons, not to have them listed as available for general use. Often they require transmission of a *subaudible* or *CTCSS* tone (discussed later). Not all repeaters requiring a CTCSS tone are closed. Other closed repeaters require the transmission of a coded telephone push-button (*DTMF*) tone sequence to turn on. It is desirable that all repeaters, including generally closed repeaters, be made available

at least long enough for the presence of emergency information to be made known.

Repeaters have many uses. In some areas they are commonly used for formal traffic nets, replacing or supplementing the nets usually found on 75-m SSB. In other areas they are used with tone alerting for severe-weather nets. Even when a particular repeater is generally used for ragchewing it can be linked for a special purpose. As an example, an ARRL volun-

teer official may hold a periodic section meeting across her state, with linked repeaters allowing both announcements and questions directed back to her.

One of the most common and important uses of a repeater is to aid visiting hams. Since repeaters are listed in the *ARRL Repeater Directory* and other directories, hams traveling across the country with mobile or hand-held radios often check into local repeaters asking for travel route,

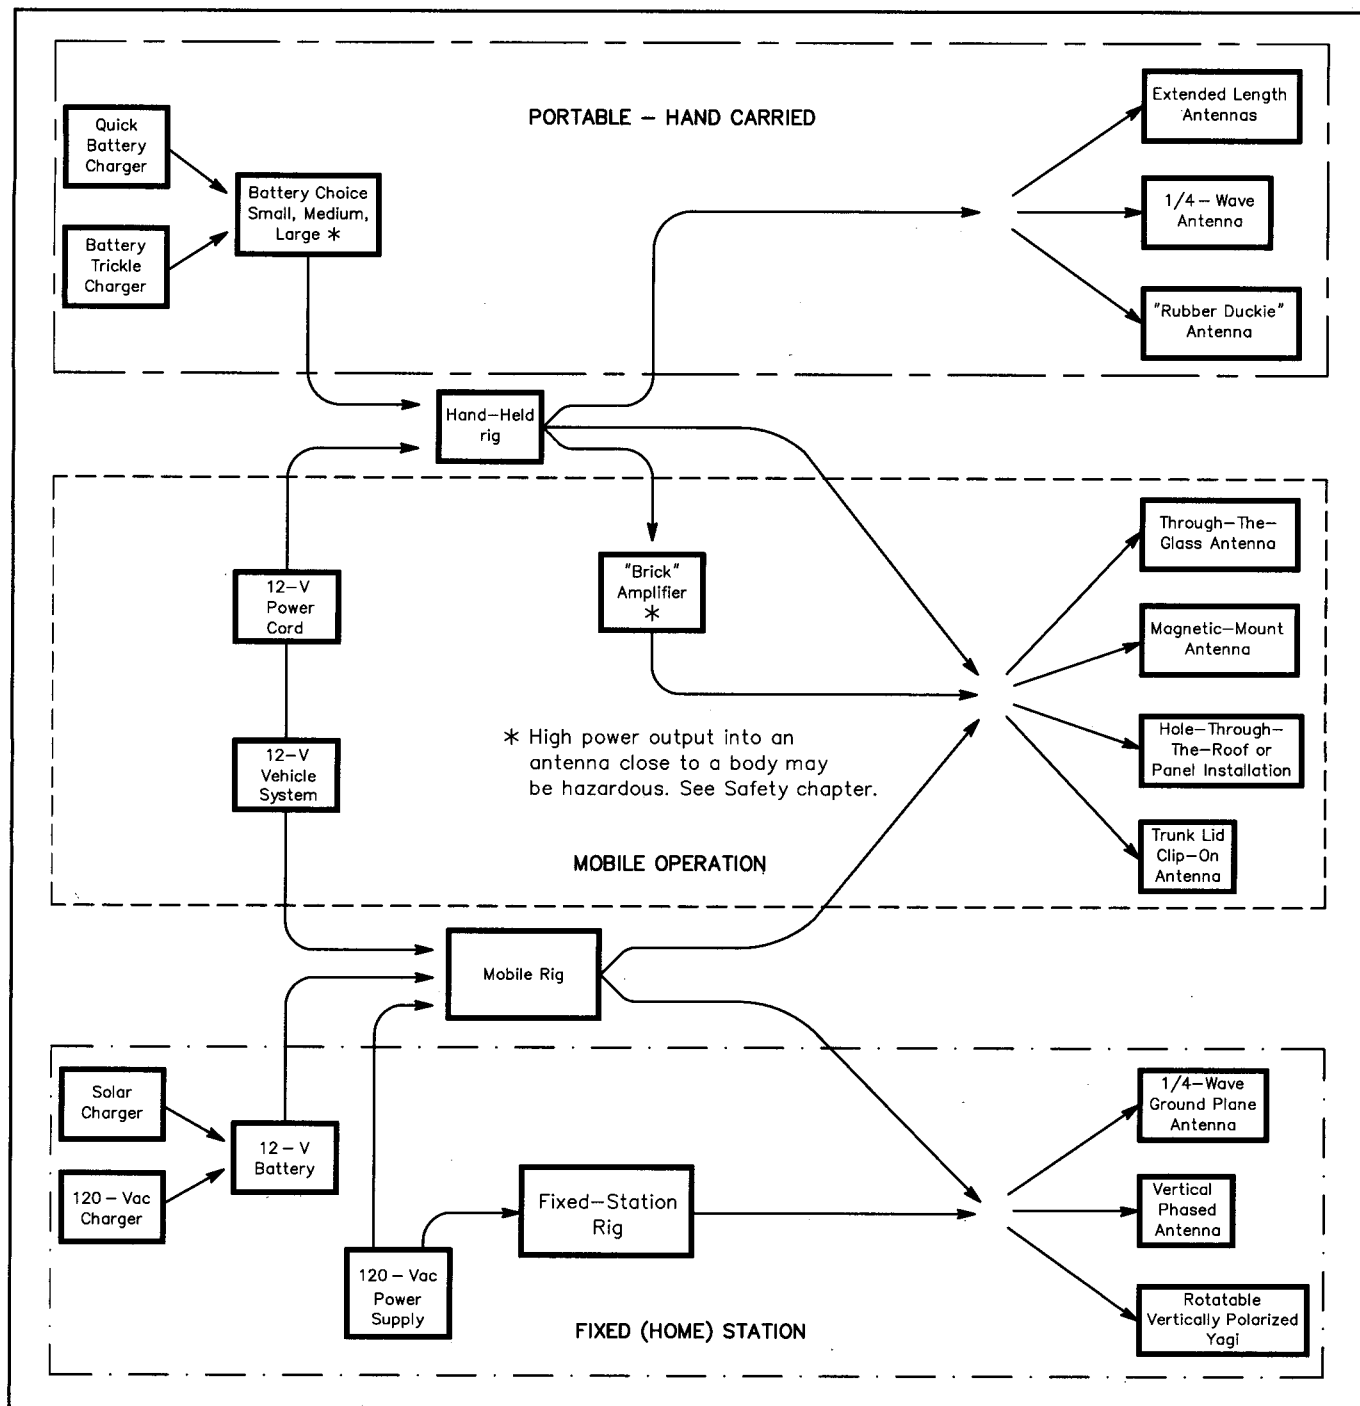

Fig 23.11 — Equipment choices for use with repeaters are varied. A hand-held transceiver is perhaps the most versatile type of radio, as it can be operated from home, from a vehicle and from a mountaintop.

restaurant or lodging information. Others just come on the repeater to say hello to the local group. In most areas courtesy prevails — the visitor is given priority to say hello or get the needed help.

Detailed information on repeater operating techniques is included in a full chapter of the *ARRL Operating Manual*.

## Home and Mobile Equipment

There are many options available in equipment used on repeaters—both home-built and commercial. It is common to use the same radio for both home station and mobile, or mobile and hand-held use. A number of these options are shown in Fig 23.11.

### Hand-Held Transceivers

A basic hand-held radio with 100 mW to 5 W output can be mounted in an automobile with or without a booster amplifier or “brick.”

Several types of antennas can be used in the hand-held mode. The smallest and most convenient is a rubber flex antenna, known as a “rubber duckie,” a helically wound antenna encased in a flexible tube. Unfortunately, to obtain the small size the use of a wire helix or coil often produces a very low efficiency.

A quarter-wave whip, which is about 19 inches long for the 2-m band, is a good choice for enhanced performance. The rig and your hand act as a ground plane and a reasonably efficient result is obtained. A longer antenna, consisting of several electrical quarter-wave sections in series, is also commercially available. Although this antenna usually produces extended coverage, the mechanical strain of 30 or more inches of antenna mounted on the

radio’s antenna connector can cause problems. After several months, the strain may require replacement of the connector.

Selection of batteries will change the output power from the lowest generally available — 0.1 or 0.5 W — to the 5-W level. Charging is accomplished either with a “quick” charger in an hour or less or with a trickle charger overnight.

Power levels higher than 7 W may cause a safety problem on hand-held units, since the antenna is usually close to the operator’s head and eyes. See the **Safety** chapter for more information.

For mobile operation, a 12-V power cord plugs into the auto cigarette lighter. In addition, commercially available brick amplifiers — available either assembled or as kits — can be used to raise the output power level of the hand-held radio to 10 to 70 W. These amplifiers often come with transmit-receive sensing and optional preamplifiers. One such unit is shown in block form in Fig 23.12.

### Mobile Equipment

Mobile antennas range from quick and easy “clip-it-on” mounting to “drill through the car roof” assemblies. The four general classes of mobile antennas shown in the center section of Fig 23.11 are the most popular choices. Before experimenting with antennas for your vehicle, there are some precautions to be taken.

**Through-the-glass antennas:** Rather than trying to get the information from your dealer or car manufacturer, test any such antenna first using masking tape or some other temporary technique to hold the antenna in place. Some windshields are metallicized for defrosting, tinting and AM car radio reception. Having this metal

in the way of your through-the-glass antenna will seriously decrease its efficiency.

**Magnet-mount antennas** are convenient, but only if your car has a metal roof. The metal roof serves as the ground plane.

**Through-the-roof antenna mounting:** Drilling a hole in your car roof may not be the best option unless you intend to keep the car for the foreseeable future. This mounting method provides the best efficiency, however, since the (metal) roof serves as a ground plane. Before you drill, carefully plan and measure how you intend to get the antenna cable down under the interior car headliner to the radio.

**Trunk lid and clip-on antennas:** These antennas are good compromises. They are usually easy to mount and they perform acceptably. Cable routing must be planned. If you are going to run more than a few watts, do not mount the antenna close to one of the car windows — a significant portion of the radiated power may enter the car interior.

Mobile rigs used at home can be powered either from rechargeable 12-V batteries or fixed power supplied from the 120-V ac line. Use of 12-V batteries has the advantage of providing back-up communications ability in the event of a power interruption. When a storm knocks down power lines and telephone service, it is common to hear hams using their mobile or 12-V powered rigs making autopatch calls to the power and telephone company to advise them of loss of service.

### Home Station Equipment

The general choice of fixed-location antennas is also shown in Fig 23.11. A rotatable Yagi is normally not only unnecessary but undesirable for repeater use, since it has the potential of extending your transmit range into adjacent area repeaters on the same frequency pair. All antennas used to communicate through repeaters should be vertically polarized for best performance.

Both commercial and home-made  $\frac{1}{4}$ - $\lambda$  and larger antennas are popular for home use. A number of these are shown in the **Antennas** chapter. Generally speaking,  $\frac{1}{4}$ - $\lambda$  sections may be stacked up to provide more gain on any band. As you do so, however, more and more power is concentrated toward the horizon. This may be desirable if you live in a flat area. See Fig 23.13.

While most hams do not try to build transceivers for use on repeaters, accessories provide a fertile area for construction and experimentation. What mobile operator has not wished that there was no need to hold the microphone continuously? The

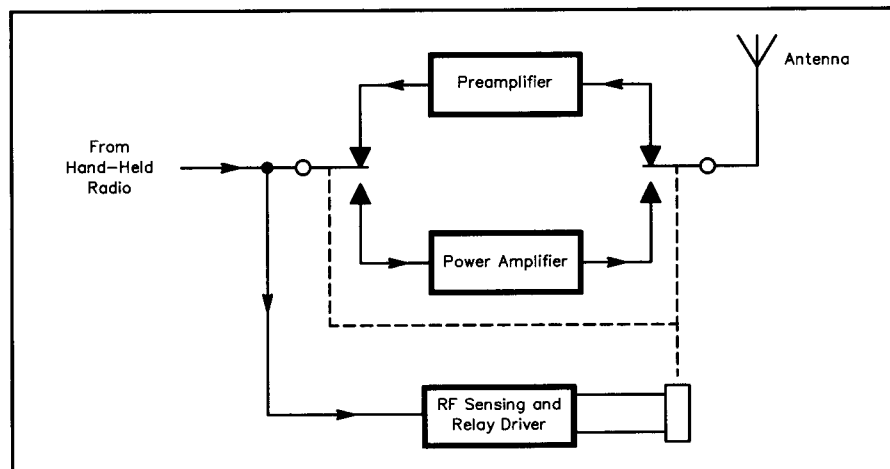

Fig 23.12 — This block diagram shows how a “brick” amplifier can be used with a receiver preamplifier. RF energy from the transceiver is detected, turns on the relay, and puts the RF power amplifier in line with the antenna. When no RF is sensed from the transceiver, the receiving preamp is in line.

**Fig 23.13** — As with all line-of-sight communications, terrain plays an important role in how your signal gets out.

**Station Accessories** chapter includes a boom microphone unit that can be adapted to mobile use.

A single-pole, single-throw switch can be mounted in a small box and Velcro used to attach it temporarily to your seat. Flip the lever on to transmit and flip it off to listen — in the meantime your hands are free.

### Autopatches and Tones

One of the most attractive features of repeaters is the availability of autopatch services. This allows the mobile or portable station to use a standard telephone key pad to connect the repeater to the local telephone line and make outgoing calls.

**Table 23.2** shows the tones used for these services. Some keyboards provide the standard 12 sets of tones corresponding to the digits 0 through 9 and the special signs # and \*. Others include the full set of 16 pairs, providing special keys A through D. The tones are arranged in two groups, usually called the low tones and high tones. Two tones, one from each group, are required to define a key or digit. For example, pressing 5 will generate a 770-Hz tone and a 1336-Hz tone simultaneously.

The standards used by the telephone company require the amplitudes of these two tones to have a certain relationship. Fortunately, most tone generators used for this purpose have the amplitude relationship as part of their construction. Initially, many hams used surplus telephone company keypads. These units were easily installed — usually just two or three wires were connected. Unfortunately they were constructed with wire contacts and their reliability was not great when used in a moving vehicle.

Many repeaters require pressing a code number sequence or the special figures \* or # to turn the autopatch on and off. Out-of-area calls are usually locked out, as are

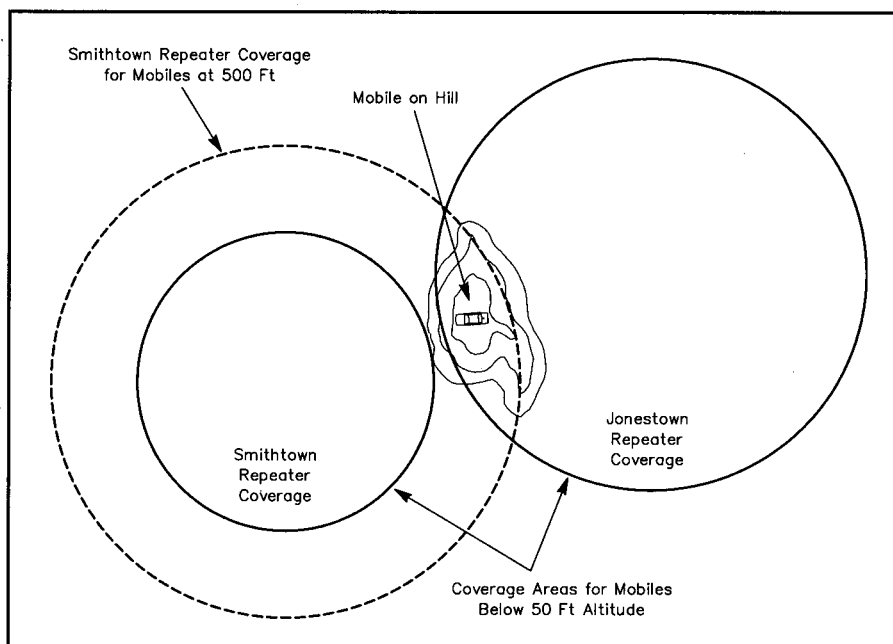

**Table 23.2**

### Standard Telephone (DTMF) Tones

#### Low Tone Group

#### High Tone Group

	1209 Hz	1336 Hz	1447 Hz	1633 Hz
697 Hz	1	2	3	A
770 Hz	4	5	6	B
852 Hz	7	8	9	C
941 Hz	#	0	*	D

**Fig 23.14** — When two repeaters operate on the same frequencies, a well-situated operator can key up both repeaters simultaneously. Frequency coordination prevents this occurrence.

services requiring the dialing of the prefix 0 or 1. "Speed dial" is often available, although occasionally this can conflict with the use of \* or # for repeater control, since these special symbols are used by the telephone company for its own purposes.

Some repeaters require the use of *subaudible* or CTCSS tones to utilize the autopatch, while others require these tones just to access the repeater in normal use. Taken from the commercial services, subaudible tones are not generally used to keep others from using a repeater but rather are a method of minimizing interference from users of the same repeater frequency.

For example, in **Fig 23.14** a mobile

station on hill A is nominally within the normal coverage area of the Jonestown repeater (146.16/76). The Smithtown repeater, also on the same frequency pair, usually cannot hear stations 150 miles away but since the mobile is on a hill he is in the coverage area of both Jonestown and Smithtown. Whenever the mobile transmits he is heard by both repeaters.

The common solution to this problem, assuming it happens often enough, is to equip the Smithtown repeater with a CTCSS decoder and require all users of the repeater to transmit a CTCSS tone to access the repeater. Thus, the mobile station on the hill does not come through the Smithtown repeater, since he is not trans-

mitting the required CTCSS tone.

**Table 23.3** shows the available CTCSS tones. They are usually transmitted by adding them to the transmitter audio but at an amplitude such that they are not readily heard by the receiving station. It is common to hear the tones described by their code designators — a carryover from their use by Motorola in their commercial com-

munications equipment.

Listings in the *ARRL Repeater Directory* include the CTCSS tone required, if any.

### Frequency Coordination and Band Plans

Since repeater operation is channelized, with many stations sharing the same frequency pairs, the amateur community has formed coordinating groups to help minimize conflicts between repeaters and among repeaters and other modes. Over the years, the VHF bands have been divided into repeater and nonrepeater subbands. These frequency-coordination groups maintain lists of available frequency pairs in their areas. A complete list of frequency coordinators, band plans and repeater pairs is included in the *ARRL Repeater Directory*.

Each VHF and UHF repeater band has been subdivided into repeater and nonrepeater channels. In addition, each band has a specific *offset* — the difference between the transmit frequency and the receive frequency for the repeater. While most repeaters use these standard offsets, others use “oddball splits.” These non-standard repeaters are generally also coordinated through the local frequency coor-

dinator. **Table 23.4** shows the standard frequency offsets for each repeater band.

The 10-m repeater band offers an additional challenge for repeater users. It is the only repeater band where ionospheric propagation is a regular factor. Coupled with the limited number of repeater frequency assignments available, the standard in this band is to use CTCSS tones on a regional basis. **Table 23.5** lists the coordinated tone assignments. As can be seen, 10-m repeaters in the 4th call area will use either the 146.2 or 100.0 (4B or 1Z) CTCSS tone.

### AT THE REPEATER SITE

For details on the many elements that go into planning and installing a repeater at a particular site, request the 96 Handbook Repeater template from the ARRL Technical Secretary.

**Table 23.3**

#### CTCSS (PL) Tone Frequencies

The purpose of CTCSS (PL) is to reduce cochannel interference during band openings. CTCSS (PL) equipped repeaters would respond only to signals having the CTCSS tone required for that repeater. These repeaters would not respond to weak distant signals on their inputs and correspondingly not transmit and repeat to add to the congestion. The standard Electronic Industries Association (EIA) frequency codes, in hertz, with their Motorola alphanumeric designators, are as follows:

67.0—XZ	136.5—4Z
69.3—WZ	141.3—4A
71.9—XA	146.2—4B
74.4—WA	151.4—5Z
77.0—XB	156.7—5A
79.7—WB	162.2—5B
82.5—YZ	167.9—6Z
85.4—YA	173.8—6A
88.5—YB	179.9—6B
91.5—ZZ	186.2—7Z
94.8—ZA	192.8—7A
97.4—ZB	203.5—M1
100.0—1Z	206.5—8Z
103.5—1A	210.7—M2
107.2—1B	218.1—M3
110.9—2Z	225.7—M4
114.8—2A	229.1—9Z
118.8—2B	233.6—M5
123.0—3Z	241.8—M6
127.3—3A	250.3—M7
131.8—3B	254.1—0Z

**Table 23.4**

#### Standard Frequency Offsets for Repeaters

Band	Offset
29 MHz	100 kHz
52 MHz	1 MHz
144 MHz	600 kHz
222 MHz	1.6 MHz
440 MHz	5 MHz
902 MHz	12 MHz
1240 MHz	12 MHz

**Table 23.5**

#### 10-M CTCSS Frequencies

In 1980 the ARRL Board of Directors adopted the 10-m CTCSS (PL) tone-controlled squelch frequencies listed below for voluntary incorporation into 10-m repeater systems to provide a uniform national system.

Call Area	Tone 1	Tone 2
W1	131.8 Hz-3B	91.5 Hz-ZZ
W2	136.5 -4Z	94.8 -ZA
W3	141.3 -4A	97.4 -ZB
W4	146.2 -4B	100.0 -1Z
W5	151.4 -5Z	103.5 -1A

# Satellites

Unless propagation enhancements are used, radio communication distances are essentially limited by the curvature of the Earth. Propagation effects that are dependent upon the atmosphere or ionosphere can be conditionally (and sometimes unpredictably) used to transmit radio signals around the Earth's curvature, thus thwarting the straight-line radio range concept, even at VHF and UHF frequencies. Communicating beyond line-of-sight distances, however, may require the use of high power and gain antennas. These types of communications are defined as "terrestrial communications."

Because objects in space are visible from a number of locations on the Earth at the same time, it is possible to predict communications between stations within this "circle of visibility." This can be achieved by using the space object as a

passive reflector for radio energy, or if the space object contains a transponding radio transmitter/receiver, it can act as a radio relay. The predictable signal path to the space object and back avoids the uncertain attenuation inherent in terrestrial propagation.

Amateur Radio space communications have two major facets: artificial satellites and our natural satellite, the Moon. Together, they make VHF and higher frequencies usable for amateur intercontinental communications and push today's technology to the limit. This section, written by Robert Diersing, N5AHD, covers communication from and through artificial spacecraft. EME or moonbounce communication is covered later in this chapter.

## THE AMATEUR SATELLITES

The Amateur Radio satellite program be-

gan with the design, construction and launch of OSCAR I in 1961 under the auspices of the Project OSCAR Association in California. The acronym "OSCAR," which has been attached to almost all Amateur Radio satellite designations on a worldwide basis, stands for *Orbiting Satellite Carrying Amateur Radio*. Project OSCAR was instrumental in organizing the construction of the next three Amateur Radio satellites — OSCARs II, III and IV. *The Satellite Experimenter's Handbook*, published by ARRL has details of the early days of the amateur space program.

In 1969, the Radio Amateur Satellite Corporation (AMSAT) was formed in Washington, DC. AMSAT has participated in the vast majority of amateur satellite projects, both in the United States and internationally, beginning with the launch of OSCAR 5. Now, many

## Current Amateur Satellites

OSCAR 10, the second Phase 3 satellite, was launched on June 16, 1983, aboard an ESA Ariane rocket, and was placed in an elliptical orbit. OSCAR 10 carries Mode B and Mode L transponders. Despite a failure of the main computer memory, due to radiation damage, it still provides good communications when seasonal sun angles are favorable.

OSCAR 11, a scientific/educational low-orbit satellite, was built at the University of Surrey in England and launched on March 1, 1984. This UoSAT spacecraft has also demonstrated the feasibility of store-and-forward packet digital communications and is fully operational.

*Radio Sputniks 10/11*, launched on June 23, 1987, as a transponder package aboard a Russian COSMOS navigation satellite. RS-10/11 carries Mode A and K transponders. At the time of this writing, only the Mode A transponder is operational.

OSCAR 13, the third Phase 3 satellite, was launched on June 15, 1988, aboard the first ESA Ariane 4 launch vehicle (an A4LP vehicle, to be specific) and placed in an elliptical geosynchronous transfer orbit (GTO). Two subsequent burns of a self-contained rocket motor on OSCAR 13 moved the satellite to a near-Molnyia, high-inclination orbit. OSCAR 13 carries transponders for Modes B, J and L and also has experimental Mode S transponders. The 70-cm downlink failed in 1993. OSCAR 13 will reenter Earth's atmosphere in 1996.

*Radio Sputniks 12/13*, launched in 1989 aboard a Russian COSMOS satellite. It carries Mode A and K transponders. At the time of this writing, only the Mode K transponder is operational.

OSCAR 16, also known as PACSAT, is a digital store-and-forward packet radio file server. It has an experimental S-band beacon at 2401.143 MHz.

OSCAR 17, also known as DOVE (for Digital Orbiting Voice Encoder), was designed primarily for classroom use. Telemetry is downlinked using standard AX.25

packets and the Bell 202 standard. There is an experimental S-band beacon at 2401.220 MHz.

OSCAR 18, also known as WEBERSAT, contains scientific and educational experiments designed and built by faculty, students and volunteers at the Center for Aerospace Technology, Weber State University, Ogden, Utah.

OSCAR 19, also known as LUSAT, was sponsored by AMSAT Argentina, and is nearly identical to OSCAR 16.

OSCAR 20, launched into low Earth orbit in February 1990, is the second amateur satellite designed and built in Japan. It carries Mode J and Mode JD (digital store-and-forward) transponders. Its digital functions are no longer operational.

OSCAR 22, another of the UoSAT series for both amateur and commercial services launched in July 1991. UO-22 now operates in amateur store-and-forward service as well as a 110°-wide CCD camera viewing the Earth.

OSCAR 23, also known as KITSAT-A (the Korean Institute of Technology), was launched in August 1992, and is functionally very similar to UO-22 with its high speed digital BBS and CCD camera operations.

OSCAR 25 also known as KITSAT-B, was launched in September 1993. It is a clone of OSCAR 23.

OSCAR 26, designed and built by AMSAT-IT (Italy), was launched in September 1993. ITAMSAT, as it is also known, provides a 1200-bit/s packet BBS.

OSCAR 27 is a companion module aboard the commercial EyeSat-A microsat. Launched in September 1993, OSCAR 27 is an experimental platform designed by AMRAD. At the time of this writing, it is being used primarily as an FM voice repeater.

RS 15, launched in December 1994, is a Mode A spacecraft: its uplink is on the 2-m band, and its downlink is on 10 m.

countries have their own AMSAT organizations, such as AMSAT-UK in England, AMSAT-DL in Germany, BRAMSAT in Brazil and AMSAT-LU in Argentina. All of these organizations operate independently but may cooperate on large satellite projects and other items of interest to the worldwide Amateur Radio satellite community. Because of the many AMSAT organizations now in existence, the US AMSAT organization is frequently designated AMSAT-NA.

Beginning with OSCAR 6, amateurs started to enjoy the use of satellites with lifetimes measured in years as opposed to weeks or months. The operational lives of OSCARs 6, 7, 8 and 9, for example, ranged between four and eight years. All of these satellites were low Earth orbiting (LEO) with altitudes approximately 800-1200 km. LEO Amateur Radio satellites have also been launched by other groups not associated with any AMSAT organization such as the Radio Sputniks 1-8 and the ISKRA 2 and 3 satellites launched by the former Soviet Union.

The short-lifetime LEO satellites (OSCARs 1 through IV and 5) are sometimes designated the *Phase I* satellites, while the long-lifetime LEO satellites are sometimes called the *Phase II* satellites. There are other conventions in satellite naming that are useful to know. First, it is common practice to have one designation for a satellite before launch and another after it is successfully launched. Thus, OSCAR 10 (discussed later) was known as Phase 3B before launch. Next, the

AMSAT designator may be added to the name, for example, AMSAT-OSCAR 10, or just AO-10 for short. Finally, some other designator may replace the AMSAT designator such as the case with Japanese-built Fuji-OSCAR 20 (FO-20).

In order to provide wider coverage areas for longer time periods, the high-altitude Phase 3 series was initiated. Phase 3 satellites often provide 8-12 hours of communications for a large part of the Northern Hemisphere. After losing the first satellite of the Phase 3 series to a launch vehicle failure in 1980, AMSAT-OSCAR 10 was successfully launched and became operational in 1983. AMSAT-OSCAR 13, the followup to the AO-10 mission, was launched in 1988. AO-13 now provides most of the wide-area SSB and CW communications capability available in the Amateur Satellite Service. AO-10 also provides some wide-area communications capability at certain times of the year despite the failure of its onboard computer memory. The successor to AO-13, Phase 3D, is under construction and is scheduled for launch in 1996.

With the availability of the long access time and wide coverage of satellites like AO-10 and AO-13, it may seem that the lower altitude orbits and shorter access times of the Phase II series would be obsolete. This certainly might be true were it not for the incorporation of digital store-and-forward technology into many current satellites operating in low Earth orbit. Satellites providing store-and-forward communication services using packet radio

techniques are generically called *PACSATs*. Files stored in a PACSAT message system can be anything from plain ASCII text to digitized pictures and voice.

The first satellite with a digital store-and-forward feature was UoSAT-OSCAR 11. UO-11's Digital Communications Experiment (DCE) was not open to the general Amateur Radio community although it was utilized by designated "gateway" stations. The first satellite with store-and-forward capability open to all amateurs was the Japanese Fuji-OSCAR 12 satellite, launched in 1986. FO-12 was succeeded by FO-20, launched in 1990. In addition to providing digital store-and-forward service, FO-12 and FO-20 also have analog linear transponders for CW and SSB communication.

By far the most popular store-and-forward satellites are the *PACSATs* utilizing the PACSAT Broadcast Protocol. These PACSATs fall into two general categories — the *Microsats*, based on technology developed by AMSAT-NA, and the *UOSATs*, based on technology developed by the University of Surrey in the UK. While both types are physically small spacecraft, the Microsats represent a truly innovative design in terms of size and capability. A typical Microsat is a cube measuring 23 cm (9 in) on a side and weighing about 10 kg (22 lb). The satellite will contain an onboard computer, enough RAM for the message storage, two to three transmitters, a multichannel receiver, telemetry system, batteries and the battery charging/power conditioning system.

Amateur Radio satellites have evolved to provide two primary types of communication services — analog transponders for real-time CW and SSB communication and digital store-and-forward for non real-time communication. Which of the two types interest you the most will probably depend on your current Amateur Radio operating habits. If you enjoy real-time DX QSOs on the HF bands, you may be most interested in the high-altitude wide-coverage satellites such as AO-13. On the other hand, if you are a computer and terrestrial packet radio enthusiast you may be more interested in the digital store-and-forward satellites like AO-16, UO-22 and KO-23. Whatever your preference, the remainder of this section should provide the information to help you make a successful entry into the specialty of amateur satellite communications.

## Basic Operations and Terminology

Since both low and high Earth orbit (LEO and HEO) satellites are available for use, it would be a good idea to acquire a mental picture of the communication

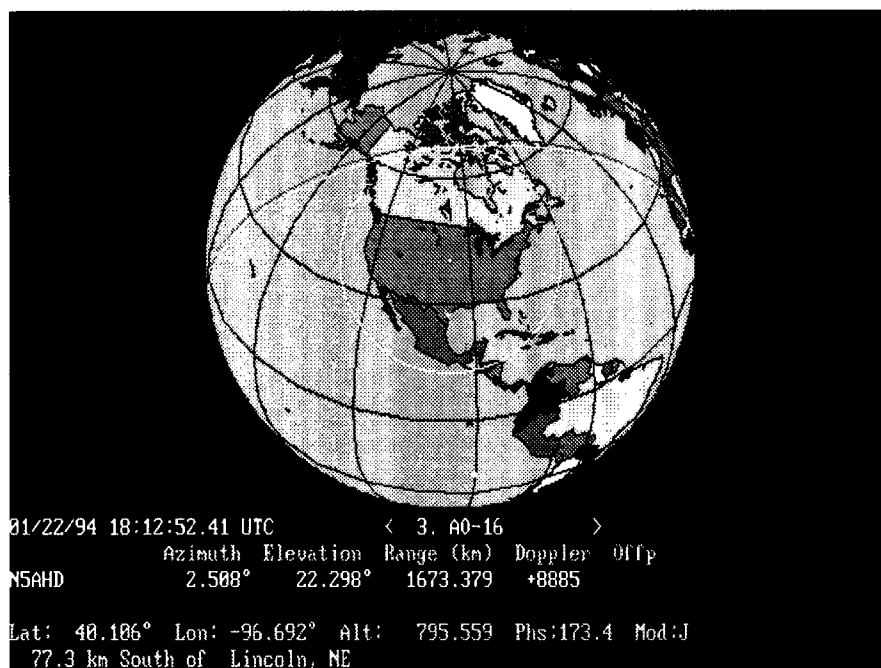

Fig 23.15— Communication range circle or "footprint" for AO-16.

range for each type of orbit. In Fig 23.15, the white circle, centered roughly on the United States, is a typical footprint for a low Earth orbit satellite like AO-16. Stations within the footprint can store and/or retrieve messages to/from the store-and-forward message system. For satellites that are used for real-time SSB and CW QSOs, only stations that are in the footprint simultaneously can communicate.

In Fig 23.16, for high altitude orbit AO-13, no footprint or range circle is visible because the whole area of the globe shown is in the satellite footprint. Keep in mind that for LEO satellites like AO-16 the footprint is moving quickly, and for HEO satellites like AO-13 it is moving slowly. LEO satellites will typically have access times of 12 to 20 minutes while HEO satellites can have access times as long as 10 to 12 hours. For a more complete discussion of orbital mechanics and other topics in this section, see *The Satellite Experimenter's Handbook* published by the ARRL.

When accessing an Amateur Radio satellite, the ground station receiver is tuned to the satellite's *downlink* frequency. If the particular satellite supports two-way communication, the ground station transmits on the satellite's *uplink* frequency. The uplink and downlink frequencies will be in different bands, and each combination of bands used will have a *mode* designator. For example, the combination of an uplink in the 2-m band and a downlink in the 10-m band is called Mode A. More discussion of operating modes can be found in the next two sections, but you may wish to look at **Tables 23.6** and **23.7** for some examples of the different modes available.

The exact manner in which satellite uplinks and downlinks are utilized depends on whether the primary purpose of the satellite is to provide analog or digital communication services. Satellites such as AO-13 make use of *transponders*. Transponders regenerate all signals appearing in their input (uplink) frequency band on their output (downlink) frequency band. CW, SSB and FM signals appearing at the input will appear as CW, SSB, or FM signals on the output. Depending on the design of the transponder, USB on the input may appear either as USB or LSB on the output. The low-to-high frequency relationship of the uplink and downlink frequency bands may also differ. Note in Table 23.6, for example, that AO-13 Mode B uplink is 435.423 to 435.573 MHz, while the downlink is 145.975 to 145.825 MHz. This means that a signal at the low end of the uplink will be retransmitted at the high end of the downlink. On the other hand, RS-10 Mode A uplink is 145.860 to

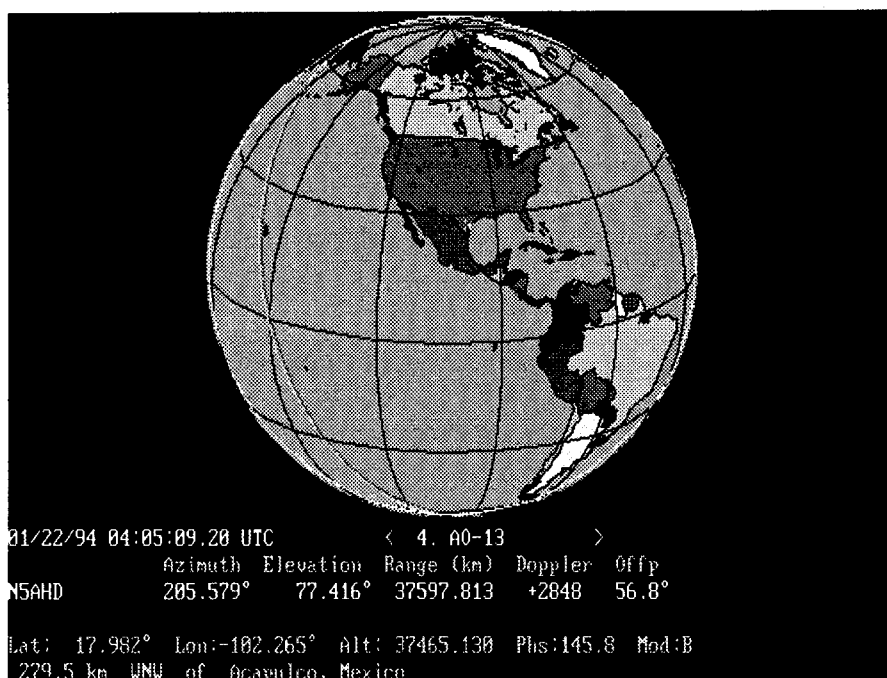

Fig 23.16 — Typical communications coverage area for AO-13.

Table 23.6

**Uplink and Downlink Frequencies for Satellites with Analog Communications Transponders**

Satellite	Mode	Uplink (MHz)	Downlink (MHz)	Beacon	Notes
AO-10	B	435.030-435.180	145.975-145.825	145.810	(1)
AO-13	B	435.423-435.573	145.975-145.825	145.812	
	J	144.423-144.473	435.990-435.940	435.651	(2)

RS-15	A	145.858-145.898	29.354-29.394	29.352.5	
				29.398.7	

**Notes**

1. Available for use only when orientation produces sufficient power.
2. Modes J and L no longer available due to 70-cm transmitter failure.
3. The Mode S transponder is noninverting.
4. Telemetry beacons and outputs for Mode A and K robots.
5. Telemetry beacons and outputs for Mode T robot.
6. Telemetry beacons and outputs for Mode A and K robots.
7. Telemetry beacons and outputs for Mode T robot.
8. Telemetry beacons and outputs for Mode A and K robots.
9. Telemetry beacons and outputs for Mode T robot.

## Glossary of Satellite Terminology

**AMSAT** — A registered trademark of the Radio Amateur Satellite Corporation, a nonprofit scientific/educational organization located in Washington, DC. It builds and operates Amateur Radio satellites and has sponsored the OSCAR program since the launch of OSCAR 5. (AMSAT, PO Box 27, Washington, DC 20044.)

**Anomalistic period** — The elapsed time between two successive perigees of a satellite.

**AO-#** — The designator used for AMSAT OSCAR spacecraft in flight, by sequence number.

**AOS** — Acquisition of signal. The time at which radio signals are first heard from a satellite, usually just after it rises above the horizon.

**Apogee** — The point in a satellite's orbit where it is farthest from Earth.

**Area coordinators** — An AMSAT corps of volunteers who organize and coordinate amateur satellite user activity in their particular state, municipality, region or country. This is the AMSAT grassroots organization set up to assist all current and prospective OSCAR users.

**Argument of perigee** — The polar angle that locates the perigee point of a satellite in the orbital plane; drawn between the ascending node, geocenter, and perigee; and measured from the ascending node in the direction of satellite motion.

**Ascending node** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Southern Hemisphere into the Northern Hemisphere.

**Az-el mount** — An antenna mount that allows antenna positioning in both the azimuth and elevation planes.

**Azimuth** — Direction (side-to-side in the horizontal plane) from a given point on Earth, usually expressed in degrees. North = 0° or 360°; East = 90°; South = 180°; West = 270°.

**Circular polarization (CP)** — A special case radio energy emission where the electric and magnetic field vectors rotate about the central axis of radiation. As viewed along the radiation path, the rotation directions are considered to be right-hand (RHCP) if the rotation is clockwise, and left-hand (LHCP) if the rotation is counterclockwise.

**Descending node** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Northern Hemisphere into the Southern Hemisphere.

**Desense** — A problem characteristic of many radio receivers in which a strong RF signal overloads the receiver, reducing sensitivity.

**Doppler effect** — An apparent shift in frequency caused by satellite movement toward or away from your location.

**Downlink** — The frequency on which radio signals originate from a satellite for reception by stations on Earth.

**Eccentricity** — The orbital parameter used to describe the geometric shape of an elliptical orbit; eccentricity values vary from  $e = 0$  to  $e = 1$ , where  $e = 0$  describes a circle and  $e = 1$  describes a straight line.

**EIRP** — Effective isotropic radiated power. Same as ERP except the antenna reference is an isotropic radiator.

**Elliptical orbit** — Those orbits in which the satellite path describes an ellipse with the Earth at one focus.

**Elevation** — Angle above the local horizontal plane, usually specified in degrees. (0° = plane of the Earth's surface at your location; 90° = straight up, perpendicular to the plane of the Earth).

**Epoch** — The reference time at which a particular set of parameters describing satellite motion (**Keplerian elements**) are defined.

**EQX** — The reference equator crossing of the ascending node of a satellite orbit, usually specified in UTC time and degrees of longitude of the crossing.

**ERP** — Effective radiated power. System power output after transmission-line losses and antenna gain (referenced to a dipole) are considered.

**ESA** — European Space Agency. A consortium of European governmental groups pooling resources for space exploration and development.

**FO-#** — The designator used for Japanese amateur satellites, by sequence number. Fuji-OSCAR 12 and Fuji-OSCAR 20 are the first two such spacecraft.

**Geocenter** — The center of the Earth.

**Geostationary orbit** — A satellite orbit at such an altitude (approximately 22,300 miles) over the equator that the satellite appears to be fixed above a given point.

**Ground station** — A radio station, on or near the surface of the Earth, designed to transmit or receive to/from a spacecraft.

**Groundtrack** — The imaginary line traced on the surface of the Earth by the subsatellite point (SSP).

**Inclination** — The angle between the orbital plane of a satellite and the equatorial plane of the Earth.

**Increment** — The change in longitude of ascending node between two successive passes of a specified satellite, measured in degrees West per orbit.

**Iskra** — Soviet low-orbit satellites launched manually by cosmonauts aboard Salyut missions. Iskra means "spark" in Russian.

**JAMSAT** — Japan AMSAT organization.

**Keplerian Elements** — The classical set of six orbital element numbers used to define and compute satellite orbital motions. The set is comprised of inclination, Right Ascension of Ascending Node (RAAN), eccentricity, argument of perigee, mean anomaly and mean motion, all specified at a particular epoch or reference year, day and time. Additionally, a decay rate or drag factor is usually included to refine the computation.

**LHCP** — Left-hand circular polarization.

**LOS** — Loss of signal — The time when a satellite passes out of range and signals from it can no longer be heard. This usually occurs just after the satellite goes below the horizon.

**Mean anomaly (MA)** — An angle that increases uniformly with time, starting at perigee, used to indicate where a satellite is located along its orbit. MA is usually specified at the reference epoch time where the Keplerian elements are defined. For AO-10 the orbital time is divided into 256 parts, rather than degrees of a circle, and MA (sometimes called phase) is specified from 0 to 255. Perigee is therefore at MA = 0 with apogee at MA = 128.

**Mean motion** — The Keplerian element to indicate the complete number of orbits a satellite makes in a day.

**Microsat** — Collective name given to a series of small amateur satellites having store-and-forward capability (OSCARs 14-19, for example).

**NASA** — National Aeronautics and Space Administration, the US space agency.

**Nodal period** — The amount of time between two successive ascending nodes of satellite orbit.

**Orbital elements** — See **Keplerian Elements**.

**Orbital plane** — An imaginary plane, extending throughout space, that contains the satellite orbit.

**OSCAR** — Orbiting Satellite Carrying Amateur Radio.

**PACSAT** — Packet radio satellite (see **Microsat** and **UoSAT-OSCAR**).

**Pass** — An orbit of a satellite.

**Passband** — The range of frequencies handled by a satellite translator or transponder.

**Perigee** — The point in a satellite's orbit where it is closest to Earth.

**Period** — The time required for a satellite to make one complete revolution about the Earth. See **Anomalistic period** and **Nodal period**.

**Phase 1** — The term given to the earliest, short-lived OSCAR satellites that were not equipped with solar cells. When their batteries were depleted, they ceased operating.

**Phase 2** — Low-altitude OSCAR satellites. Equipped with solar panels that powered the spacecraft systems and recharged their batteries, these satellites have been shown to be capable of lasting up to five years (OSCARs 6, 7 and 8, for example).

**Phase 3** — Extended-range, high-orbit OSCAR satellites with very long-lived solar power systems (OSCARs 10 and 13, for example).

**Phase 4** — Proposed OSCAR satellites in geostationary orbits.

**Precession** — An effect that is characteristic of AO-10 and Phase 3 orbits. The satellite apogee SSP will gradually change over time.

**Project OSCAR** — The California-based group, among the first to recognize the potential of space for Amateur Radio; responsible for OSCARs I through IV.

**QRP days** — Special orbits set aside for very low power

uplink operating through the satellites.

**RAAN** — Right Ascension of Ascending Node. The Keplerian element specifying the angular distance, measured eastward along the celestial equator, between the vernal equinox and the hour circle of the ascending node of a spacecraft. This can be simplified to mean roughly the longitude of the ascending node.

**Radio Sputnik** — Russian Amateur Radio satellites (see **RS #**).

**Reference orbit** — The orbit of Phase II satellites beginning with the first ascending node during that UTC day.

**RHCP** — Right-hand circular polarization.

**RS #** — The designator used for most Russian Amateur Radio satellites (RS-1 through RS-15, for example).

**Satellite** — A graphical tracking device, similar to Oscarlocator, designed to be used with satellites in elliptical orbits.

**Satellite pass** — Segment of orbit during which the satellite "passes" nearby and in range of a particular ground station.

**Sidereal day** — The amount of time required for the Earth to rotate exactly 360° about its axis with respect to the "fixed" stars. The sidereal day contains 1436.07 minutes (see **Solar day**).

**Solar day** — The solar day, by definition, contains exactly 24 hours (1440 minutes). During the solar day the Earth rotates slightly more than 360° about its axis with respect to "fixed" stars (see **Sidereal day**).

**Spin modulation** — Periodic amplitude fade-and-peak resulting from the rotation of a satellite's antennas about its spin axis, rotating the antenna peaks and nulls.

**SSC** — Special service channels. Frequencies in the downlink passband of AO-10 that are set aside for authorized, scheduled use in such areas as education, data exchange, scientific experimentation, bulletins and official traffic.

**SSP** — Subsatellite point. Point on the surface of the Earth directly between the satellite and the geocenter.

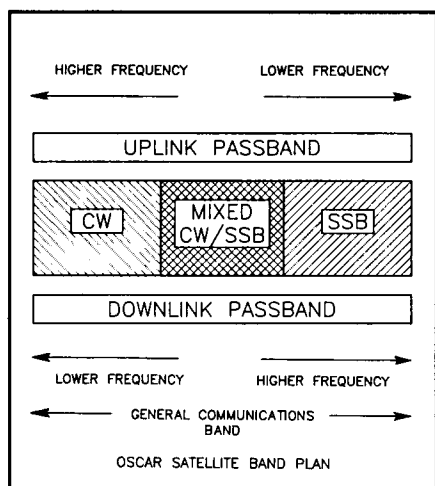

**Telemetry** — Radio signals, originating at a satellite, that convey information on the performance or status of onboard subsystems. Also refers to the information itself.

**Transponder** — A device onboard a satellite that receives radio signals in one segment of the spectrum, amplifies them, translates (shifts) their frequency to another segment of the spectrum and retransmits them. Also called linear translator.

**UoSAT-OSCAR (UO #)** — Amateur Radio satellites built under the coordination of radio amateurs and educators at the University of Surrey, England.

**Uplink** — The frequency at which signals are transmitted from ground stations to a satellite.

**Window** — Overlap region between acquisition circles of two ground stations referenced to a specific satellite. Communication between two stations is possible when the subsatellite point is within the window.

**Fig 23.17 — The OSCAR satellite band plan allows for CW-only, mixed CW/SSB, and SSB-only operation. Courteous operators observe this voluntary band plan at all times.**

146.000 MHz, while the downlink is 29.360 to 29.400 MHz. Consequently, a signal at the low end of the uplink band will appear at the low end of the downlink band. The band plan used on AO-13 and other satellites is given in Fig 23.17. FM is rarely used on amateur satellite transponders.

In contrast to satellites such as AO-13 and RS-10, whose primary mission is providing linear transponders for CW and SSB communications, uplink and downlink frequencies on digital communications satellites are usually channelized. Tables 23.8 and 23.9 show that specific frequencies are used for both uplink and downlink. The reason for multiple uplinks and a single downlink on some satellites is the uncoordinated *Aloha* access used by ground stations. Generally, the satellite can handle requests from more than one ground station without overloading its own downlink.

Remember that the ground station will experience *Doppler* shift of the downlink frequency as the satellite moves with respect to the observer. For satellites with linear transponders, operating procedures have been established to minimize interference to other stations in the passband while staying tuned to the desired station. For digital satellites, the modem usually tunes the receiver frequency to compensate for Doppler shift.

### Satellites with Analog Transponders

Table 23.6 is a list of frequencies for all Amateur Radio satellites providing linear transponder communication facilities, and Table 23.7 contains the frequencies pro-

**Table 23.7**

### Uplink and Downlink Frequencies for the Phase-3D Satellite

#### Uplinks

Band	Digital (MHz)	Analog (MHz)	Center (MHz)
15 m	N/A	21.210-21.250	21.230
2 m	145.800-145.840	145.840-145.990	145.915
70 cm	435.300-435.550	435.550-435.800	435.675
23 cm(1)	1269.000-1269.250	1269.250-1269.500	1269.375
23 cm(2)	1268.075-1268.325	1268.325-1268.575	1268.450
13 cm(1)	2400.100-2400.350	2400.350-2400.600	2400.475
13 cm(2)	2446.200-2446.450	2446.450-2446.700	2446.575
6 cm	5668.300-5668.550	5668.550-5668.800	5668.675

#### Downlinks

Band	Digital (MHz)	Analog (MHz)	Center (MHz)
10 m	29.330 (±5 kHz)	(used for digitized voice bulletins)	
2 m	145.955-145.990	145.805-145.955	145.880
70 cm	435.900-436.200	435.475-435.725	435.600
13 cm	2400.650-2400.950	2400.225-2400.475	2400.350
3 cm	10451.450-10451.750	10451.025-10451.275	10451.150
1.5 cm	24048.450-24048.750	24048.025-24048.275	24048.150

**All downlink passbands are inverted from the uplink passbands.**

#### Beacons

Band	Beacon-1 (MHz)	Beacon-2 (MHz)
2 m	N/A	N/A
70 cm	435.450	435.850
13 cm	2400.200	2400.600
3 cm	10451.000	10451.400
1.5 cm	24048.000	24048.400

Note: The absence of a 2-m beacon is due strictly to characteristics of the IF Matrix and the limited bandwidth available on that band. Studies are underway with the intent of providing a 2-m beacon, but it is not clear at this time whether this effort will be successful. The beacons on the other bands are for various purposes, including providing spacecraft engineering data to the command stations. All beacons can be modulated with 400 bits per second BPSK and possibly other formats.

**Table 23.8**

### Uplink and Downlink Frequencies for Special-Purpose Satellites with Digital Communications Links

Satellite	Freq (MHz)	Modulation	Rate (bps)
UO-11	145.825	AFSK	1200
	435.025	AFSK	4800
	2401.500	AFSK	
DO-17	145.825	AFSK NRZI	1200
	2401.220	BPSK NRZI	1200
WO-18	437.075	BPSK	1200
	437.102	RCBPSK	1200

posed for Phase 3D, to be launched in 1996. Both were accurate as of January 1995.

A sensible approach for getting started in amateur satellite communication is to choose one of the low Earth orbit satellites (RS-10/11 or RS-13, for example) operating on frequencies for which you already have equipment. Even though the access times will be much shorter than with the higher orbit satellites, experience can be gained using existing equipment and simple antennas. Then, if the bug bites hard, assemble a station to work the wider

coverage birds such as AO-13.

There is so much emphasis on the wide-area coverage of high altitude satellites, that the low Earth orbit (LEO) satellites often do not receive proper attention. There is a great amount of satisfaction to be gained from working other stations via LEO satellites, however. Moreover, such contacts provide practice at tracking and tuning that will prove valuable no matter which satellite is eventually used.

A first attempt at amateur satellite communication should be undertaken as inexpensively as possible. Successful opera-

Table 23.9

## Uplink and Downlink Frequencies for Satellites with Two-Way Digital Communications Links

Fig 23.18 — Some stations worked from a QTH on the lower Texas Gulf Coast using simple antennas.

tion on LEO satellites can be realized using omnidirectional antennas, an uplink power in the area of 100 W EIRP and a good receiver. If Mode A is used, a 10-m receive preamp might prove useful. Similarly, if Mode J is used, a 70-cm preamp could be beneficial. One goal of an entry-level approach is to eliminate the complexity of high-gain steerable antennas. A power level of 50-100 W into an omnidirectional antenna is more than adequate for CW QSOs and at times will support SSB QSOs. The author has had many satellite contacts using the approach de-

scribed here. Fig 23.18 shows a few QSL cards from contacts made from his QTH on the lower Texas Gulf Coast. Fig 23.19 shows the ground plane and small Yagi antennas used on the 2-m and 70-cm bands. On 10 m, either a dipole or wire loop antenna was used.

## Assembling an AO-13 Station

If antenna installation restrictions and budget constraints are not a problem, you may want to try the high-orbit satellites such as AO-13. This section gives the important considerations for assembling

an AO-10/AO-13 class station. Obviously, these requirements can be realized in many different system configurations. More information can be found in the section on equipping a station.

A typical AO-13 station will use a 145-MHz circularly polarized antenna of at least 13 dBic having switchable polarization sense between RHCP and LHCP. If switchable polarization is not available, then RHCP is the preferred choice. Even though antennas with gain exceeding 18 dBi are available, they are not cost effective because the local noise floor becomes the limiting factor. Keep in mind that this antenna is used for both the Mode B downlink and the Mode J uplink.

Similarly, the 435-MHz antenna should be circularly polarized and have at least 13 dBic gain. Higher gains, in the range of 14 to 18 dBic, are preferred. Switchable polarization is even more desirable because the 435-MHz antenna serves as the uplink on Modes B and S as well as the downlink for Mode J. Increased antenna gain is more usable because the local noise floor is not usually a limiting factor as it is at 145 MHz.

The 1269-MHz Mode-L uplink antenna should have at least 20-dBic gain. Due to the short wavelength (23 cm), the required gain is achievable with relatively small antenna arrays such as four phased helices. Arrays of loop Yagis and standard horizontally polarized Yagis can be used but there will be a 3-dB penalty for polarization mismatch.

The 2400-MHz Mode-S downlink antenna should have at least 26 dBic gain.

However, the required gain is easily achievable using a 4-ft parabolic dish or a quad helix array.

The antenna array must be steerable in both azimuth and elevation. The elevation rotator boom must be made of a nonmetallic material such as fiberglass. Feed-line loss should be held below 2 dB, and less than 1 dB is preferable.

The EIRP of the 435 and 145-MHz transmitting system should be no more than 1000 W and adjustable, allowing the lowest required power level to be used. For Modes B and J most communications can be conducted using 100 to 300 W EIRP. A higher EIRP may be needed on Mode S, but the requirement will still be below the 1000 W EIRP level. For Mode L, the required EIRP at 1269 MHz is between 3000 and 5000 W.

The 145-MHz receiving system should have a noise figure no greater than 2 dB but less than 1 dB is probably not usable even if it can be achieved. The 435 and 2400-MHz receiving system noise figures should be less than 1 dB.

Using high altitude satellites such as AO-13 should be considered weak signal work. Always improve the receiving system first before increasing transmit EIRP. Once Phase 3D is operating, the downlink gain requirements will be much lower due to the higher transmitter powers used at the spacecraft.

## ASSEMBLING A STATION FOR PHASE 3D

This section was written by ARRL Lab Engineer Zack Lau, KH6CP/1.

If all goes well, Phase 3D will be similar to OSCAR 13, but much more “user friendly” for voice users. Thus, a station that did well with OSCAR 13 has little to worry about; the equipment will be more than enough for Phase 3D. Those building new stations can take advantage of technology improvements in the satellite, and get acceptable performance with more modest SSB/CW stations. Due to the laws of physics, those expecting loud signals like those of low Earth orbit satellites will still be disappointed. A station 100 times farther away is 40 dB weaker (400 km vs 40,000 km). Thus, digital users won’t see any signal strength improvement compared to low Earth orbit satellites currently in use—the extra distance will eliminate improvements in power and antennas.

Perhaps the biggest change is the orbit—it will repeat every two days. Thus, manually rotated or even fixed antennas will become much more practical, possibly eliminating the need for an expensive rotator system, for those who just want to maintain a schedule with another station.

Stations without rotators may wish to use smaller antennas to maximize their operating time. This generally requires more power and better receivers to compensate. Mast mounting equipment near the antenna will reduce needed antenna size. Using circularly polarized antennas as opposed to higher gain linearly polarized antennas will help considerably toward optimizing your satellite time if the antennas don’t move. However, rotatable linear arrays are probably preferred for local use. Horizontal polarization is the standard for terrestrial SSB/CW.

The next biggest change for most users will be on the 2400-MHz downlink—there will be a linear 100-W transponder, as opposed to the 1-W experiment aboard OSCAR 13. Thus, it becomes possible to use a simple RHCP 16-turn helix instead of a 2-ft dish. However, it may be more cost effective to use a 2-ft dish with a 1.8 dB NF receiver than to obtain a 0.6-dB NF receiver for the helix. Since these are system noise figures, it isn’t unusual to need a 0.4-dB NF preamp to get that 0.6-dB NF receiver. The dish with a no-tune preamp and receive converter makes a lot more sense for a builder with minimal test equipment. The antenna gain to receiver temperature ratio (G/T) to shoot for is 0.53/kelvin. There will also be a 13-cm uplink—plan on +27-dBWic. This is 5 W at the feed of a 20-dBic 2-ft dish. 10 W to a loop Yagi would also work; the extra 3 dB compensates for the polarization mismatch. However, the satellite won’t be capable of in-band full duplex—a band can only be used on transmit or receive, not both simultaneously. Thus, since the 13-cm downlink is expected to be used heavily, the uplink is likely to get little use.

The 436-MHz uplink will need about 20 dBWic—10 W to a 5-turn 3-ft boom helix or a 5-ft boom circularly polarized Yagi. Slightly larger antennas can compensate for feed-line loss. Chances are, there will be little benefit to running a big amplifier—there will be an automatic notcher called LEILA to prevent stations from hogging the transponder. Hopefully, this will force stations to improve receive capability, when they find it difficult to hear themselves on the satellite.

On 436-MHz receive, you want a gain to system noise temperature ratio of 0.032/kelvin. A 12-dB antenna has a gain of 16. Thus, for a 12-dBic antenna you need a noise temperature under 500 kelvins, or 4 dB. Earth noise, feed-line noise and antenna noise all add to the receiver noise. A mast-mounted preamplifier and a small Yagi will work quite well. If the feed-line run is short, perhaps 50 ft,

a larger antenna would allow having the preamplifier near the operating position.

The 1269-MHz uplink will need about 26-dBWic—8 W to a 12-ft boom loop Yagi, 10 W to a RHCP 16-turn helix, or 6 W to a 3-ft dish. Current rules prohibit having a 1269-MHz downlink, so this isn’t planned for any of the satellites.

The 146-MHz uplink will need about 18 dBWic—10 W to a 5-ft boom circularly polarized Yagi or 3-turn helix. Again, this is power at the feed of the antenna.

The 146-MHz downlink depends heavily on your local noise level. Amateurs in rural areas can do just fine with a 2-dB system noise figure and an 8-dBic antenna. The predicted G/T needed is 0.008/kelvin. Those in heavily populated urban areas may be disappointed with the results—even with a big circularly polarized beam and a mast-mounted preamplifier. These amateurs should consider using a quieter band for the downlink.

Two meters does have a distinct advantage in one area—less attenuation through trees. As the frequency goes up, so does the attenuation through trees. Thus, while it is possible to hear the 2.4-GHz downlink indoors, tree blockages often degrade signals. It gets worse if you are using a small antenna with a low-noise preamplifier. Not only does a tree block more of a small antenna, but it also acts as a warm noise source. This noise adds to the system noise figure, degrading signals even more.

Amateurs attempting to contact the satellite on the horizon with microwaves may notice two degradations to the path. Atmospheric loss can add another 1.6 dB of path loss at 2.4 GHz, increasing to 3 dB at 10 GHz, though this is typically under 0.1 dB at 10 GHz for vertical paths. An antenna fixed on the horizon will also see noise from the warm Earth, reducing system sensitivity. A more serious problem may be finding excellent locations where one can worry about such details.

It is easy to overestimate the ease of obtaining a low noise figure, particularly at microwaves. A single bad connector, adapter or piece of coax can stop the system from meeting expectations. Avoid cheap connectors and coax. Getting all the pieces to work properly together can be a challenge. Fortunately, MMICs and computer aided design have resulted in designs that reduce potential problems. Still, it is possible to have pieces that work fine by themselves, but poorly as a system. People have even had problems with poorly designed power supplies generating spurs or modulating received signals. Fortunately microwave ovens have not interfered with 2.4-GHz amateur satellite work. Simi-

larly, it is easy to underestimate the ease of obtaining low angle radiation at 2 m. The antenna height required may not be practical. It is often wise to have a bit of excess capability, often called link margin. If you do have excess uplink power, you should have a method of easily scaling it back.

While they are not expected to be as popular as the lower bands, a 5668-MHz uplink (34 dBWic), a 10451-MHz downlink ( $G/T=13/\text{k}\text{elvin}$ ) and a 24048-MHz downlink will be included. Even with state-of-the-art equipment, it is likely that the latter will not be heard on long LOS paths due to atmospheric absorption.

The satellite may also have a 29.33-MHz downlink for both digital work and digitized voice bulletins, though, like 146-MHz, they may not be useable from noisy locations. The 28-MHz  $G/T$  is  $1/(9000 \text{ kelvins})$ . Simple antennas like the turnstile work well with the satellite overhead, but not so well near the horizon. A simple vertical works better near the horizon. It makes a lot of sense to match the orbit track with the antenna pattern, keeping in mind that some computer simulations aren't accurate with wires close to real ground. Ionized atmospheric layers can significantly disturb satellite communications by blocking signals to and from the satellite. There may also be a 21-MHz uplink, but it is likely that it will not work well for many users, due to the high galactic noise, and the modest antenna on the satellite.

The picture isn't quite so rosy for digital users—the 146-MHz uplink will need +22 dBWic, 10 W to a 12-ft boom circularly polarized Yagi. The 1270-MHz uplink will need +34 dBWic, or 10 W to a 6-ft dish.

The 436-MHz downlink will require a  $G/T$  of 0.12  $1/\text{k}\text{elvin}$ , or a 13 dBic antenna with a 1 dB preamp (allowing 50 kelvins for sky and antenna noise, and 0.5 dB extra receiver noise).

## DIGITAL COMMUNICATIONS SATELLITES

The amateur satellite enthusiast with an interest in digital communications will find a multitude of satellites with which to experiment. All of the digital communications satellites currently operating in the Amateur Satellite Service are in low Earth orbit. At first, it might seem that the short access times of LEO satellites would not support useful communications services. But, as will be seen shortly, this is certainly not the case.

There are three general categories of Amateur Radio satellites having digital communications links. First, there are those that transmit telemetry and other

information of interest using digital codes but do not provide store-and-forward message service. Satellites in this category include DOVE-OSCAR 17 (DO-17) and UoSAT-OSCAR 11 (UO-11). Also, WEBERSAT-OSCAR 18 transmits images of the Earth (see Fig 23.20). Satellites such as DO-17 and UO-11 provide an excellent opportunity to learn the mechanics of tracking LEO spacecraft and decoding their digital transmissions. At the same time, study of the captured telemetry data will provide an appreciation of many aspects of spacecraft engineering. A listing of the special-purpose digital satellites can be found in Table 23.8.

Another class of LEO satellites are those that provide store-and-forward message services via a user interface similar to those found on terrestrial packet radio bulletin board systems.

Finally, there are many satellites that provide store-and-forward services using the PACSAT Broadcast Protocol developed by Ward and Price. Satellites using the PACSAT Broadcast Protocol include:

AMSAT-OSCAR 16 (AO-16), LUSAT-OSCAR 19 (LO-19), UoSAT-OSCAR 22 (UO-22), KITSAT-OSCAR 23 (KO-23) and ITAMSAT-OSCAR 26 (IO-26). In addition to these satellites, there are other projects in the design and construction stages that will also use the PACSAT Broadcast Protocol (PBP). Table 23.9 contains a list of the digital store-and-forward satellites operating at the time of publication.

## Satellites Transmitting Digital Telemetry Data Only

Monitoring satellites transmitting digital telemetry data provides an excellent receive-only introduction to amateur satellite operations for the computer enthusiast. Of course, one could monitor telemetry from any of the digital satellites, but this section will deal primarily with UO-11 and DO-17 because they do not provide two-way communication capabilities.

### UoSAT-OSCAR 11

UO-11 transmits various kinds of data on its 2-m downlink (145.825 MHz) and most of it is plain-text ASCII, including bulletins and spacecraft telemetry. It is important to note that UO-11 transmits

plain text and not packets such as those used in terrestrial 2-m packet radio networks. This means that a packet radio TNC is not required at the ground station.

Fig 23.21 shows a typical equipment configuration for receiving UO-11 transmissions. As can be seen, all that is necessary is to connect the receiver audio output to the demodulator input and the serial data output from the demodulator to the computer serial port. If a modem is purchased at a flea market or other used equipment outlet, be sure that it is a Bell 202 standard as opposed to Bell 212. The type of modem is usually obvious from the model number but the 212 is much more common than the 202. Kits for Bell 202 demodulators are available commercially and construction plans have also been published in *QST*.

In a minimal equipment configuration it is also possible to eliminate the expense of a computer and substitute a serial terminal instead. However, capturing the received telemetry for later decoding or real-time telemetry decoding will require a computer. In this regard, remember that 80286 and earlier PCs are now sold at very reasonable prices and even discarded outright. These machines are entirely adequate to serve as substitutes for serial terminals and can perform the telemetry capture and decoding functions as well.

Fig 23.22 shows a typical UO-11 raw telemetry frame while Fig 23.23 shows a telemetry frame decoded to engineering data. Telemetry capture and decoding software for UO-11 is available from AMSAT-NA and AMSAT-UK.

### DOVE-OSCAR 17

For a number of reasons, DO-17 may be the easiest of the digital satellites to monitor. One reason is that its transmissions are compatible with standard packet radio TNCs, which means that anyone who operates terrestrial 2-m packet radio already has all the necessary equipment. Another reason is that its transmitter has a high enough power level to be received well on the ground even with a hand-held receiver.

Fig 23.24 gives a typical equipment configuration for receiving DO-17 transmissions. Many of the same comments made about the UO-11 equipment configuration also apply to DO-17; that is, a serial terminal may be substituted for the PC until such time as telemetry decoding is desired.

Fig 23.25 shows typical telemetry frames as they would appear using the TNC monitor mode and Fig 23.26 shows the data decoded to engineering units. In Fig 23.25, the value to the left of each colon is the telemetry channel number and the value on the right must be substituted into an equation to make the conversion to engineering units. Telemetry decoding software for DO-17, called TLMDCII, is available from AMSAT-NA.

In addition to transmitting digital telemetry data, DO-17 will eventually be programmed to "speak" some of the telemetry values and other messages using its onboard speech synthesizer. This will allow students who do not have access to packet radio equipment and computers to study the operation of some of the DO-17's systems.

## Satellites Utilizing the PACSAT File Broadcast Protocol

Many Amateur Radio operators make use of terrestrial packet radio bulletin board systems (PBBS). These PBBSs are

the Amateur Radio counterpart of micro-computer-based bulletin board systems, which use the public telephone network.

However, much of the activity on terrestrial PBBSs is taken up with the repeated retrieval of information of general inter-

est. For example, Amateur Radio operators interested in satellite operations may access a PBBS to obtain the reference elements used in their orbital prediction programs. Consequently, the exact same information may be transmitted many times. On terrestrial networks, repeated transmission of the same data can be tolerated because the system capacity is available by virtue of the 24-hour per day access time and multiple stations providing PBBS service. Such capacity obviously does not exist in the case of a LEO satellite-based system with limited visibility time at any particular ground station location. What is needed is a way for multiple users to benefit from the same transmission of a particular file since many users are within the satellite footprint at the same time.

Satellites such as AO-16 and UO-22 are in low Earth orbits at an average altitude of 800 km. From that vantage point, over populated areas such as the continental United States, hundreds and perhaps even thousands of potential users are within the satellite's footprint. Although at any given ground station location (in the middle latitudes) there will be only 50 to 60 minutes of access time per day, there is still sufficient time for any individual station to receive a large amount of data. For example, with AO-16 operating at 1200 bps, it is possible to receive approximately 500 kbytes of data per day. For UO-22, operating at 9600 bps, about 4 Mbytes of data could be received. This assumes, of course, that the ground station is in operation for all times the satellite is visible.

Based on the nature of the system components and on the experience gained with the UoSAT-2 Digital Communications Experiment (DCE)1, Ward and Price have developed the PACSAT Protocol Suite,

Fig 23.26 — DOVE-OSCAR 17 telemetry frame decoded to engineering units.

which is fully documented in Notes 2-6. Look to these references for the complete details of the protocol implementation. The data-link layer protocol used is AX.25.<sup>7</sup> The PACSAT Protocol Suite implements a file broadcast mode and a file server mode using a common file format. Each of these two modes will be described briefly. The hardware and software required to access the satellite will be presented in the next section.

### PACSAT File Header

Files being transmitted in broadcast mode and files being uploaded in file server mode make use of the PACSAT file header. Fig 23.27 shows an example of the information contained in the file header. In broadcast mode, an individual data-link layer frame information field contains only the file number (ID), file type and the offset to the location in the file where the data belongs. The other information needed to identify the file and its attributes are contained in the file header. User software (PFHADD) has been provided to add a PACSAT file header to a file before it is uploaded and to remove or display a file header after the file has been downloaded (PHS).

### File and Directory Broadcast Mode

The PACSAT Broadcast Protocol has the following attributes: (1) Any frame, when received independently, can be placed in the proper location within the file to which it belongs; (2) When all frames have been received, the receiving station can tell that the file is complete; and (3) For file types where it makes sense, partial files are usable. This implies that if a data compression scheme is used, it should be possible to incrementally decompress the file.

The broadcast mode transmits files in the message system memory and their directory entries by giving each file on the broadcast queue a certain amount of downlink time. The broadcasts continue in a round-robin fashion until the user's request has been filled.

File broadcasting is done as a series of AX.25<sup>7</sup> unnumbered information (UI) frames. UI frames are not acknowledged by the receiver and order of delivery is not guaranteed. The terminal node controller (TNC) passes the frame on to the application program only if the frame is correctly received. Error checking of the frame is done via CRC-16 by the TNC. The format of the information field of a broadcast frame is shown below.

```
<flags> <file id> <file type> <offset>

```

Fig 23.27 — PACSAT file header contents.

In the information field format above, the file ID field is a file number assigned by the file server system when the file is uploaded rather than an ASCII character string file name. The offset gives the position relative to the beginning of the file where the data belongs. The CRC shown is a check on the I-field contents only and is included to allow detection of errors on the serial link between the TNC and the computer.

Requests to place files in the broadcast queue are likewise done with UI frames. The spacecraft does respond to broadcast requests but not in terms of a data-link layer acknowledgment. It only sends a UI frame with "OK" in the information field to the station making a successful broadcast request. Error indications, such as broadcast queue full, are also transmitted as UI frames.

Even though a station may also access the satellite in a connected-mode transaction (described in the next section), the file and directory broadcast mode is the primary method of operation. Since multiple users in the satellite footprint may want to capture the same files and update their directories at the same time, downlink utilization is maximized when broadcasting is used. Individual users may request fills of specific "holes" in their captured files and directories, but the rebroadcast of entire files or directories for multiple users is eliminated.

### File Server Mode

AO-16, UO-22 and similar satellites can also operate in file server mode, which is transaction oriented. Currently, the file server mode is used only for uploading files to the message system. An upload transaction can be resumed later if it was previously interrupted (by LOS, for example).

When using the file server mode, an AX.25 connection exists between the ground station and the spacecraft. Standard balanced-mode HDLC procedures control the exchange at the data-link layer. The transaction-oriented operation ensures that the availability of the uplinks is maximized.

### PACSAT Ground Station Equipment

A typical equipment configuration for utilizing AO-16 and UO-22 is shown in Fig 23.28. Even though the diagram shows a station set up to operate on both AO-16 and UO-22, a sensible approach would be to set up for AO-16 operation first and then progress to UO-22. This is particularly true if you had been operating on FO-20 because the radios and modems are already in place and attention can be focused on installing and using the PB and PG software. Even if you have not used FO-20 it is still easier to set up for AO-16 first: 1200 bps operation does not usually require any internal connections and/or modifications to the transmitter and receiver, whereas 9600 bps operation usually does require some internal connections.

### PACSAT Ground Station Software Capabilities and Operation

To use all of the communication facilities available, four computer programs, PB, PG, PHS and PFHADD, are available free of charge to the Amateur Radio community. PB allows files and directories being broadcast to be captured on the receiving station's computer. PB also allows a station to request the broadcast of hole fills in partially received files and directories. PG is used to upload files to the spacecraft for later broadcast. PFHADD adds the header required for uploading a user file. PHS will display or remove the file

Fig 23.29 — PB display while receiving data from UoSAT-OSCAR 22 satellite downlink.

header after downloading a file. PB, PG, PFHADD and PHS run on IBM-PC/AT and compatible systems.

Recall that file and directory broadcasting is done in AX.25 unconnected mode and file uploads are done in AX.25 connected mode. Consequently, PB looks for UI frames from the spacecraft and places them in the proper location in the file being received if the user has requested that the file be captured. PG, on the other hand, establishes a connection with the file server and attempts to complete the transaction requested by the user. The follow-

ing brief discussion of user software operation will provide some insight into the mechanics of utilizing the communications facilities of the satellites.

A user wishing to monitor files and directories being broadcast on the downlink would configure his/her station equipment as shown in Fig 23.28 and execute the PB program on the station computer. Fig 23.29 shows a typical screen display from the PB program while monitoring UO-22 downlink traffic. The lower half of the screen shows certain informational messages exactly as they appear on the down-

link. The upper left corner of the screen shows files for which capture is in progress (in this case none), and the upper right corner shows directory headers and message numbers being heard on the downlink.

The last line of the screen is a status line. "DIR: Part (05)" means that an updated directory has been partially received and there are five holes (missing pieces). "AUTO: Dir" shows that the ground station computer directory is being updated automatically from the monitored directory data. "Dir" could be replaced by a file number being downloaded. The values labeled "s:", "b:", "d:" and "e:" stand for data rate in bytes per second for the last five seconds, number of bytes monitored from broadcast files, number of bytes monitored from broadcast directories and number of CRC errors between the TNC and the ground station computer.

The line beginning with "PB:" shows which stations have made requests for files or directories (or hole fills) to be broadcast. Station call signs with the suffix "\D" have made directory requests while the others have made file broadcast requests. The message "Open: 1 a: W5ERO" shows that station W5ERO is a connected-mode user (probably doing a file upload) on uplink 2 and that uplink 1 is available for another user.

Fig 23.30 shows a portion of the ground station computer directory after it has been captured from the downlink traffic. The upper right corner of the screen shows the file broadcast selection criteria in the message "Select = All Mail." This means that message traffic addressed to "All" or traffic to this specific station's call sign will be downloaded automatically. These criteria can be changed to suit the station operator through selection equations employing relational and logical operators that test appropriate fields in the PACSAT File Header. Consistent with the selection of "All," note that file numbers 5136, 511f and 5118 have a square block in the "S(tatus)" column. This indicates that these files, which have a "to" address of "ALL," have already been downloaded. At the lower left corner of the screen the message "All Mail AL BL" appears. These are the selection criteria for the directory display, as opposed to the criteria for automatic file downloading. Thus, the directory display will show AL (activity log) and BL (broadcast log) files in addition to files addressed to other satellite users.

A user wishing to upload a file would first attach the PACSAT file header to the file and then use the PG program to upload it to the satellite. PG is used only for file uploading and operates in connected mode using the AX.25 data link layer protocol.

When using PG, a connection is established, an upload transaction executed and the connection terminated as a result of a single operator command. The one-transaction-per-connection philosophy ensures maximum utilization of the uplinks in connected mode. There is no wasted time

while a ground station operator executes a command and then pauses deciding what to do next.

## WiSP

The software package just described, consisting of the PB, PG, PHS and PFHADD programs, is the set of programs initially made available for accessing satellites utilizing the PACSAT Broadcast Protocol (PBP). More recently, considerable software development activity has resulted in several alternatives to the original program suite. The most significant of these new programs is the Windows application WiSP developed by Chris Jackson, ZL2TPO. An alternative to PB called XPB has been developed for the Linux X-Windows environment by John Melton, GØRX/N6LYT, and Jonathan Naylor, G4KLX. Finally, a version of PB designed specifically for the IBM OS/2 environ-

**Fig 23.34—WiSP display produced by the View-DIR function. This is the WiSP equivalent to Fig 23.30 for PB.**

ment is currently in development. The WiSP and XPB packages are available via FTP from several different sites including [ftp.amsat.org](http://ftp.amsat.org). WiSP requires the payment of a registration fee to your national AMSAT organization while XPB falls under the GNU Public License. A brief explanation and a few examples of WiSP operation follow.

**Fig 23.31** shows the display produced by the WiSP ground station control (GSC) program. Although the display shows only one satellite, the program may be configured to track multiple satellites with priorities assigned to each. **Fig 23.32** shows the graphical tracking feature of WiSP that may be invoked by the user if desired. When a satellite comes into view, a user-specified program can be run. This program could be something as simple as a terminal program to display raw downlink data. For the digital store-and-forward satellites like AO-16, LO-19, UO-22, KO-23 and KO-25, the MSPE program that is

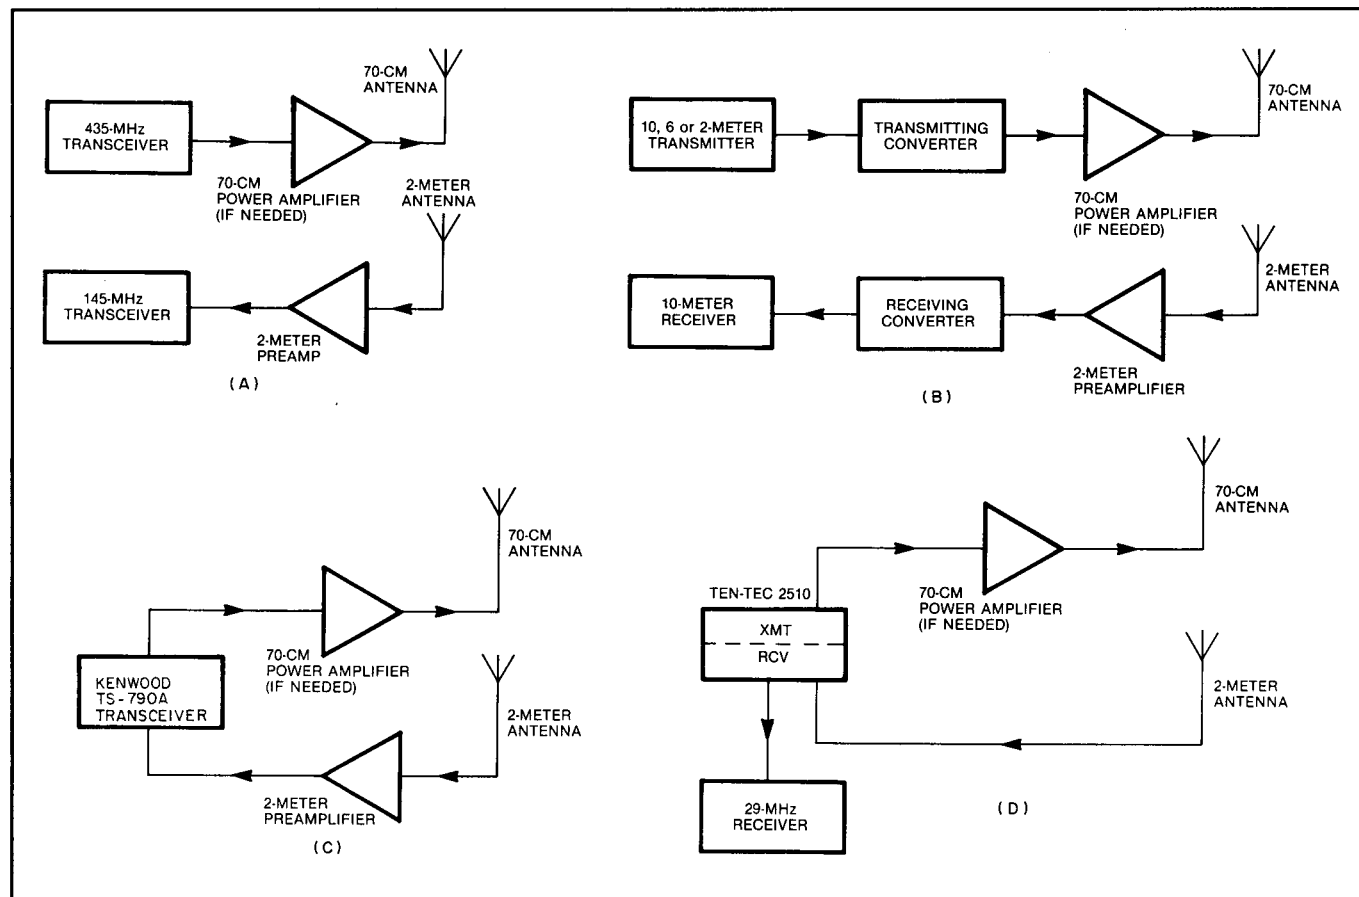

part of the WiSP package will usually be run. **Fig 23.33** shows a typical screen produced by MSPE while monitoring UO-22. Notice that this is WiSP's equivalent to **Fig 23.29** produced by the original PB program. Users may select which files should be automatically downloaded and processed for later reading. Finally, **Fig 23.34** shows a display produced by the View Dir(ectory) function. Once again there is a close parallel between the information shown my View-Dir and that shown in **Fig 23.30** from PB. The WiSP package also has radio tuning and rotator control features. Sophisticated ground station software packages such as WiSP truly demonstrate the maturity of the ground segment that supports digital store-and-forward Amateur Radio satellites.

### EQUIPPING A STATION

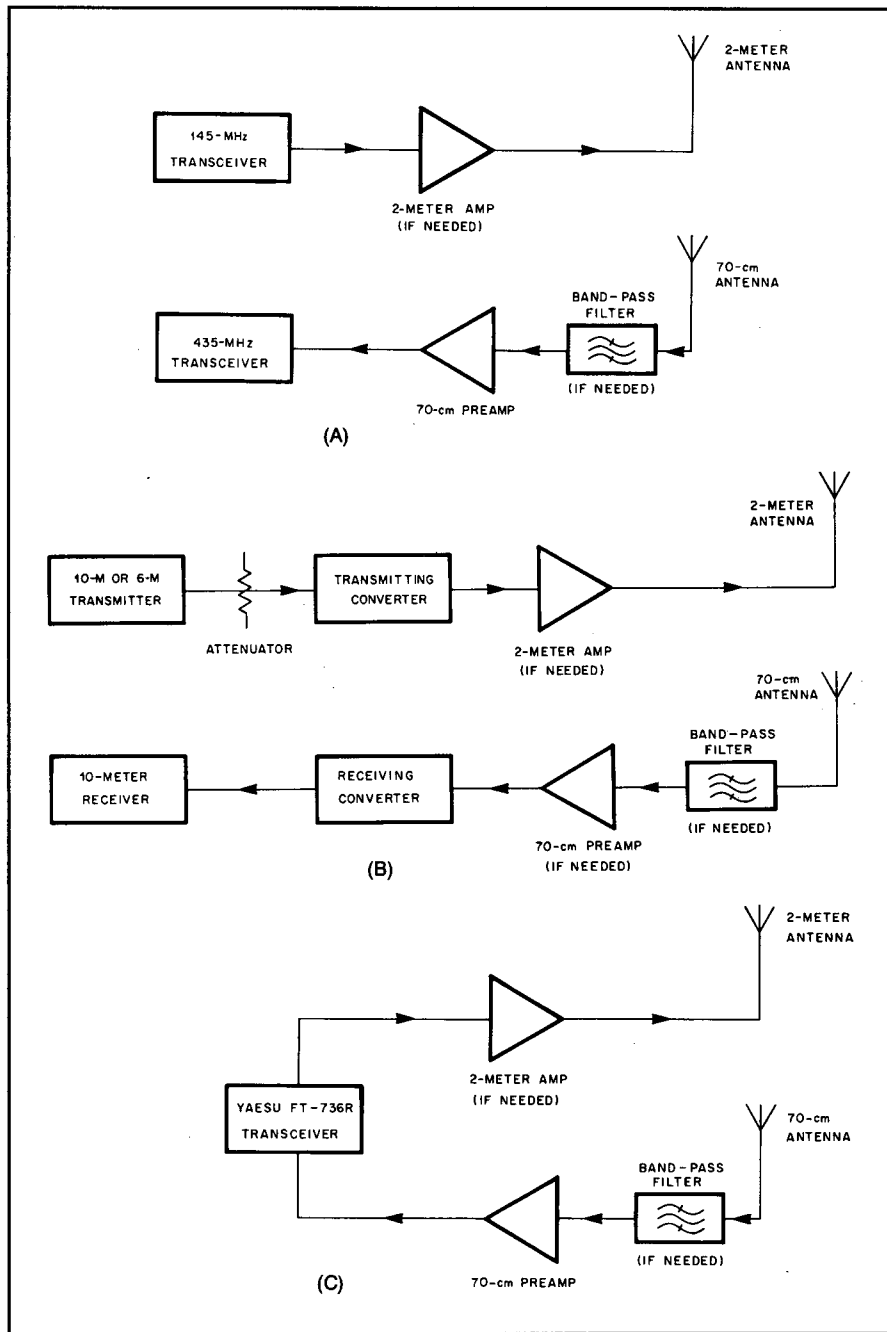

The previous sections have shown there are many satellites supporting Amateur Radio communications in many different

modes. The satellite enthusiast must take into consideration his/her own desires, goals and financial resources when purchasing and assembling equipment for an amateur satellite ground station. Because there are so many different combinations of station equipment possible, it would be a good idea to define some broad categories that arise naturally from a combination of the available satellites, individual operating goals and required expenditures.

One possible set of categories for amateur satellite stations consists of: (1) receive-only stations; (2) stations to work LEO satellites with analog transponders; (3) stations to work LEO digital store-and-forward satellites; (4) stations to work HEO satellites with analog transponders; and (5) stations utilizing satellites with uplinks and/or downlinks in the microwave bands (above 450 MHz [70 cm]). As always, there are many trade-offs that can be made. Some of the common ones will be mentioned later.

**Fig 23.35** — Several different Mode-B satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, a multimode, multiband transceiver can perform both transmitting and receiving function, full duplex, in one package. The Ten-Tec 2510 shown at D contains a 435-MHz transmitter and a 2 m to 10-m receiving converter.

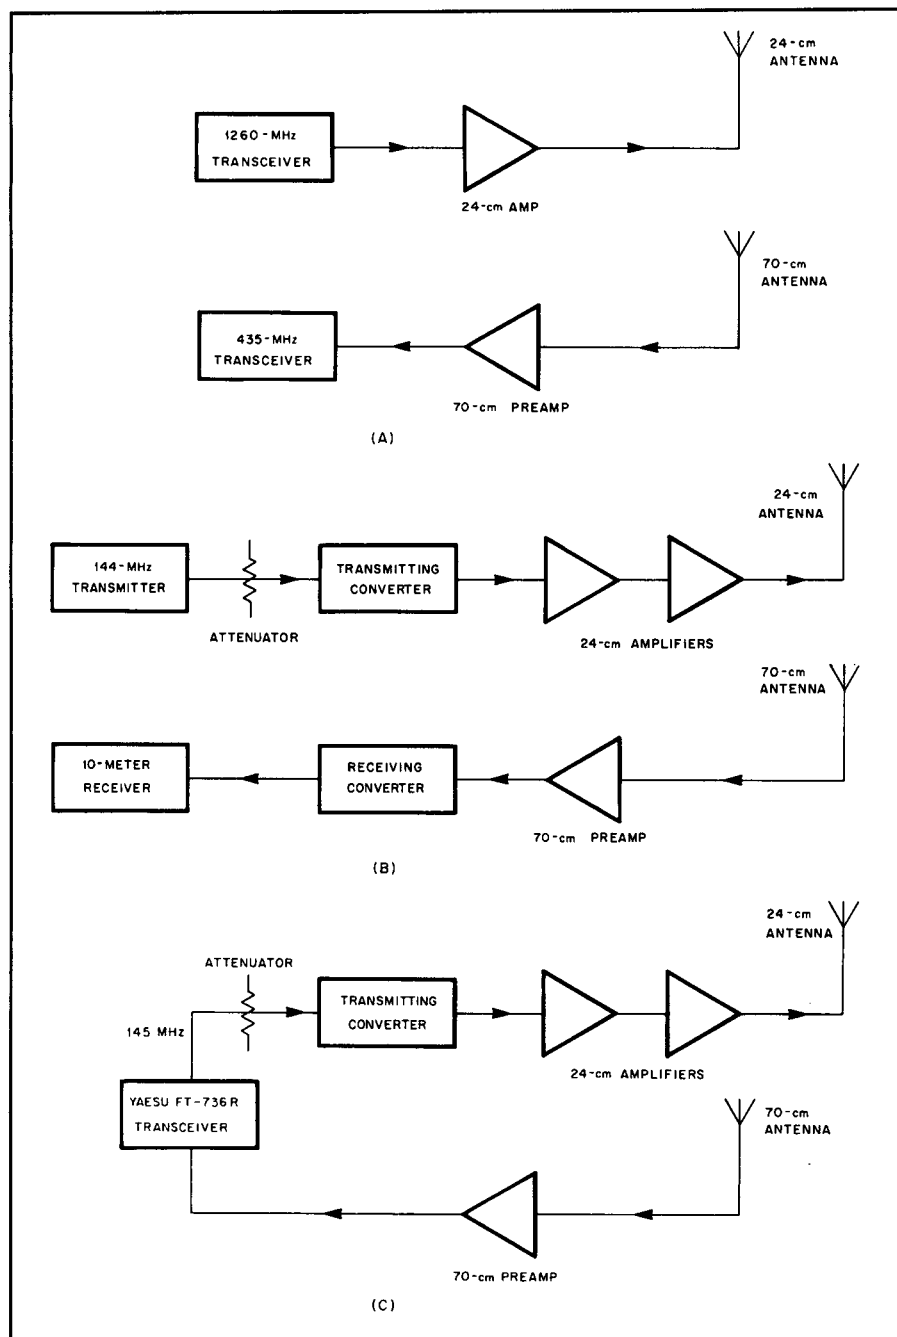

**Fig 23.36 — Several different Mode-J satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, a multimode, multiband transceiver can perform both transmitting and receiving functions, full duplex, in one package.**

Perhaps the biggest difference between terrestrial and satellite communications is that the latter is full-duplex operation. This means that you transmit and receive simultaneously. When communicating through an analog transponder, you can hear your own downlink signal while transmitting, as well as that of the station being worked. Full duplex provides the opportunity for a fully interactive conversation, as if the other station is in the very same room.

Successful satellite operation demands that you can locate and hear your own signal from the spacecraft. Choose equipment with this goal in mind. Equipping a station for full-duplex operation is not too difficult because the transmitter is on a different band than the receiver. Ground-station configurations for high-altitude satellites vary according to the communications "mode" being used. **Figs 23.35, 36, 37 and 38** show several different configurations suitable for Modes B, J, L and S. An example of an entry-level receive-only station can be seen in **Fig 23.39**.

### Computer System

The main reason for mentioning computer equipment in this section is that in many cases some other part of the station will be used in conjunction with a computer. For example, automatic antenna positioning may be done using a computer and appropriate rotator control interface.

**Fig 23.37 — Several different Mode-L satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, a multimode, multiband transceiver can be used for full duplex receiving and transmitting (with the addition of a 2-m to 24-cm transmitting converter).**

One of the most common uses for a computer in the amateur satellite station is determining when and where a particular satellite will be visible. When considering this aspect of satellite operations, think carefully about what you really need and what "would be nice." If you are an entry-level operator and using omnidirectional antennas, a simple listing of AOS, LOS and position at 1-minute intervals is sufficient. Many different orbital prediction programs are available; they range in complexity from those that produce simple time, heading and position printed output (see Fig 23.40) to those that produce graphical displays in real time (see Figs 23.15 and 16).

When considering a program for tracking purposes, be sure and note the hardware capabilities that are required. For example, if you have an original IBM PC, you may not be able to use a program that produces a graphical display. Another point to consider, especially if other station functions such as tracking will be computer controlled, is that you may be better off with one computer dedicated to satellite-related functions rather than trying to do orbit prediction, antenna pointing, radio frequency control and your word processing and financial records all on the same machine. There is nothing more annoying than stopping in the middle of some other important work to get the right programs going for the next

Fig 23.38 — Several different Mode-S satellite-station configurations are shown here.

Fig 23.39 — An entry-level receiving station using 2 m and 70-cm converters and a general coverage communications receiver.

satellite contact. With every new generation of microprocessor, systems using the preceding technologies become more plentiful at reasonable prices. As your interest in amateur satellite operations solidifies, keep your eye open for a good computer buy at the next hamfest.

### Other Microprocessor-Based Equipment

If, after monitoring satellites such as DO-17, you develop a serious interest in the digital satellites, you will want to consider a DSP-based TNC. Since digital amateur satellites tend to use different modulation techniques than terrestrial packet radio, TNCs will usually require an additional external or internal modem. Although choosing a DSP-based TNC will result in a higher initial cost, the modem then becomes a matter of software rather than additional hardware. Consequently, as new modulation techniques require new modems, only software has to be changed, either by downloading from a PC or changing ROM chips in the TNC.

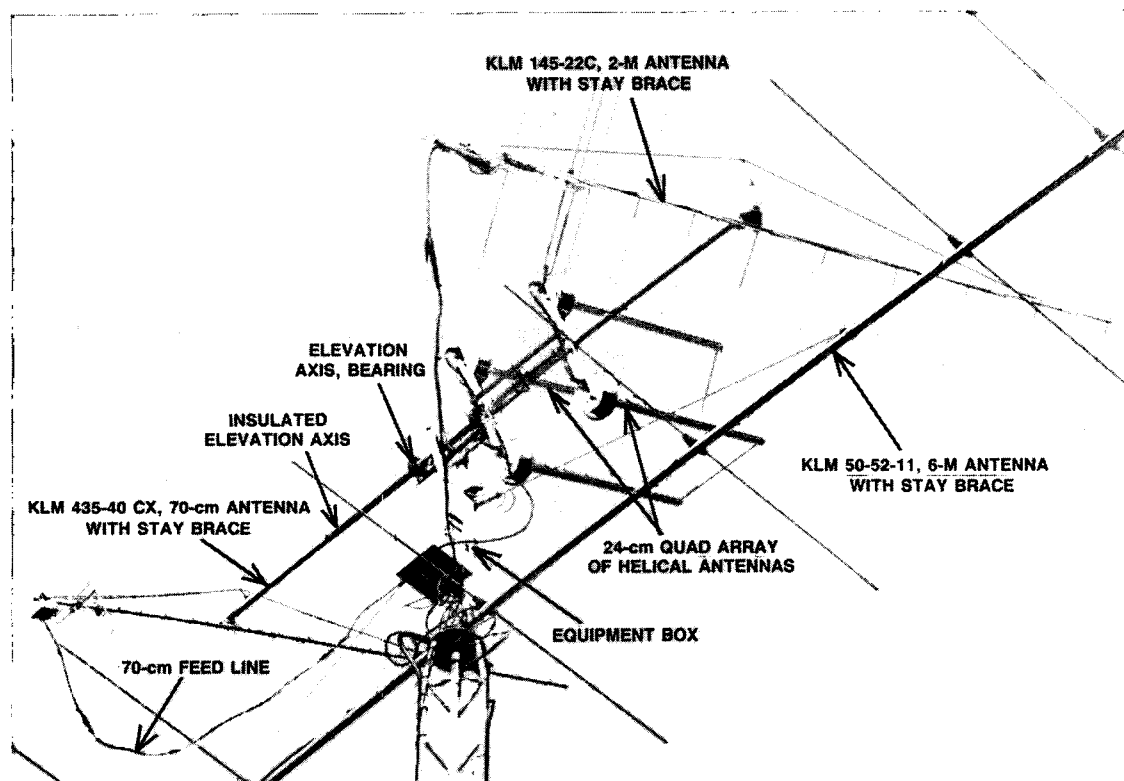

### Antennas

Antennas for receive-only and entry-level stations will usually be simple fixed-position types such as ground plane, turnstile over reflector, dipole and wire loop. High-orbit satellites such as AO-10 and AO-13 require high-gain antennas that are movable in both azimuth and elevation. In between these two extremes are the antenna requirements for the typical LEO satellite station that has evolved beyond the entry level. In this case the gain requirements are not as high as for AO-10 and AO-13 but for serious, dependable, day-to-day operation, automated azimuth and elevation positioning will become most desirable.

Fig 23.40 — Tabular output from an orbit prediction program showing time and position information for AO-16.

**Fig 23.41 — A popular commercially manufactured antenna array for AO-10 and AO-13, Modes B and J, is a pair of KLM crossed Yagis. Shown also are Mode-L helical antennas. The large box on the mast contains a 2-m and 70-cm preamplifier, coaxial relays, a 24-cm transverter and power amplifier, and power-supply regulators.**

The best antennas for use in the amateur satellite service are circularly polarized (CP). The present trend in satellite arrays for 145 and 435 MHz is to use two complete Yagis mounted perpendicular to each other on the same boom. One set of elements is mounted  $\frac{1}{4}$  wavelength ahead of the other. The antennas are fed in phase and are switchable from RHCP to LHCP. This is in contrast to using helical antennas. Circularly polarized Yagi antenna arrays are manufactured by KLM, Cushcraft, Telex/HyGain, M<sup>2</sup> and others. A typical set of crossed-Yagi antennas is shown in Fig 23.41.

Satellite antennas should be mounted as close to the station as possible. Height above ground makes no difference for satellite work, except that the antennas must be mounted high enough that trees and other obstructions do not block the view of the satellite at low elevations. A low mount allows use of shorter feed lines (lower losses) and often reduces noise pickup by the antennas. Many operators are able to set up their antennas on a 10 to 15-ft mast right next to the shack and have only 20 ft of feed line. Plan to use good-quality, low-loss coaxial cable from the start, such as Belden 9913. Even better are runs of Hardline coaxial cable, available from a number of manufacturers.

Mode L transmitting antennas and Mode S receiving antennas have taken numerous forms, mostly based on the technology

**Fig 23.42 — A boom brace may be desirable for long Yagis. This arrangement is made from non-conductive material to prevent undesirable effects on the antenna pattern.**

needed for EME communications. Loop Yagis, such as those presented in the **Antennas and Projects** chapter, are popular, but you must stack at least two in an array

to achieve the 20+ dBi gain necessary for AO-13, Mode L. Also popular are the large parabolic reflector antennas seen in EME and TVRO services. For AO-13 Mode L

**Fig 23.43 — KLM 2M-22C antenna CP switching relay with relocated balun and protective cover.**

some of these higher gain antennas get good results, but are overkill. While higher gain means lower transmitter power, the narrow beamwidths require the operator to reposition the antenna more often.

Although a practical CP Yagi for 24 cm has not yet been demonstrated, such an approach may be feasible. As AO-13 Mode L is only operated near the satellite apogee, essentially on the satellite antenna pattern main lobe, RHCP operation is the only CP sense needed. This makes the use of a helical antenna attractive. A home-built Mode L helical antenna array is shown in Fig 23.41. Active Mode L operators have also found that a small parabolic dish (6 ft in diameter, or larger) with a circularly polarized feed can make a fine Mode L antenna. A number of reasonably priced TVRO dishes are available; they require only the addition of a suitable feed for Mode L service. For TVRO dishes of 12 ft diameter, a dual-band (70 cm and 24 cm) feed for Mode L is a possibility, as the gain at 70 cm is sufficient for excellent reception, and the gain is very substantial for QRP 24-cm transmissions.

For AO-13 Mode S reception, the most commonly used antennas are a small helix (16 turns) or a small parabolic dish (less than 3 ft).

### Antenna Accessories

Long-boom Yagis, such as the KLM antennas shown in Fig 23.41, can suffer from boom sag that might cause pattern distortion and pointing errors. In addition, a boom support is desirable in areas where

high winds or ice are a problem. To avoid possible interference with the antenna pattern, the boom brace must be made from nonconductive material such as Phillystran HPTG2100 guy cable. Details for the brace are shown in Fig 23.42.

The vertical boom-brace support member is nonconductive and made from a fiberglass fishing rod blank. A short piece of threaded stainless-steel rod inserted in the top of the tube is used to adjust tension on the boom brace. A 2-inch piece of  $5/16$ -inch copper tubing brazed across the threaded rod in a "T" fashion holds the Phillystran cable in place. Jam nuts secure the threaded rod once the boom is straight.

Experience with the exposed relays on the polarity switchers used on some commercial antennas has shown that they are prone to failure caused by an elusive mechanism known as "diurnal pumping." The relay is covered with a plastic case, and the seam between the case and PC board is sealed with a silicone sealant. It is not hermetically sealed, however. As a result, the day/night temperature swings pump air and moisture in and out of the relay case. Under the right conditions of temperature and moisture content, moisture from the air will condense inside the relay case when the air cools. Water builds up inside the case, promoting extensive corrosion and unwanted electrical conduction, seriously degrading relay performance in a short time.

If you have antennas with sealed plastic relays, such as the KLM CX series, you can avoid problems by making the modi-

fications shown in Fig 23.43. Relocate the 4:1 balun as shown and place a clear polystyrene plastic refrigerator container over the relay. Notch the container edges for the driven element and the boom so the container will sit down over the relay, sheltering it from the elements. Bond the container in place with a few dabs of RTV adhesive sealant.

Position the antenna in an “X” orientation, so neither set of elements is parallel to the ground. The switcher board should now be canted at an angle, and one side of the relay case should be lower than the other. Carefully drill, by hand, a pair of  $\frac{3}{32}$ -inch holes through the low side to vent the relay case. The added cover keeps rain water off the relay, and the holes will prevent any build-up of condensation inside the relay case. Relays so treated have remained clean and operational over periods of years without any problems.

### Antenna Rotators

Unlike stations located on the surface of the Earth, AO-10 and AO-13 will be found somewhere in the sky above. Operators commonly aim antennas toward another station by changing the pointing angle, or *azimuth* (sometimes called *az*). Aiming antennas toward AO-10 and AO-13 requires the control of antenna *elevation* (el). Satellite antennas must be able to rotate from side to side and up and down simultaneously. While the use of electrically controlled antenna rotators will be discussed here, it might be noted

that Phase 3 satellite motions are slow enough that hand-operated, “armstrong” antenna control is feasible. At times, the antennas may not need repositioning for periods of up to four hours. On the other hand, the fast-moving LEO satellites such as AO-16 and UO-22 will almost certainly require an automatic positioning system.

Azimuth rotators are commonly used for positioning terrestrial HF and VHF antennas. Antennas for low-orbit satellites can be on the smaller and lighter side, so light-duty TV-antenna rotators such as those sold by Alliance, Channel Master, Radio Shack and others could be used for the azimuth rotator. Today’s high-gain satellite arrays are a bit large for these light-duty rotators. Look for something more robust, such as a rotator recommended for turning a small HF beam or VHF array. Various models manufactured by Alliance, Daiwa, Kenpro, Telex and others are advertised in *QST*.

Elevation rotator selection is more limited. Commercially manufactured models such as the Yaesu G-500A and G-5400B are available. The G-500A has been available in the past under different designations such as KLM and Kenpro KR-500 and is designed for elevating small-to medium-size VHF or UHF arrays. The G-5400B is a combined azimuth and elevation rotator. See Fig 23.44. Home-built elevation mounts can also be fabricated from TVRO antenna jack-screw motion controls or other similar muscular devices.

A lower cost alternative is the Alliance

U110 TV-antenna rotator. Rotators of this type have been used successfully by satellite operators for many years. Despite its relatively light construction, the U110 will handle antenna loads weighing up to 40 pounds. The key to success is to achieve a static balance of the antenna mass so the rotator does not have to elevate a “dead” load. A highly attractive feature of the elevation rotators noted above is that the cross boom to be rotated passes completely through the rotator. This allows the mounting of one antenna on each side of center and the adjustment of their respective positions for a side-to-side balanced load.

### Automatic Antenna Positioning

Several products are now available to automatically steer a satellite antenna array under computer control. Automatic antenna pointing is particularly useful when operating the OSCARs in low Earth orbit. Among the products available are the Kansas City Tracker/Tuner sold by L. L. Grace Co and the TrakBox sold by TAPR. There are other sources for similar products but these two represent the two general approaches to automated antenna control. The Kansas City Tracker is installed in an existing station computer while the TrakBox is a standalone controller with its own built-in microprocessor.

The Kansas City Tracker is available either as a tracker only or with the tuner option which sets and corrects the radio frequency throughout a pass. In either case, the tracking and/or tuning functions are carried out by the rotator control card in conjunction with Terminate and Stay Resident (TSR) programs running in the computer. Position and Doppler frequency correction information for the TSRs is supplied by the tracking program. Some rotators, such as the Yaesu G-5400B, already have a connector for the computer interface.

The TrakBox and similar units are specialized microprocessor-based control units. Usually, the position information is downloaded from a PC to the control box. After receiving the position information, the controller operates in a standalone mode. Devices such as the TrakBox have an LCD display that shows the operational status of the controller.

Whether to use a tracker and/or tuner that plug into the PC expansion bus or a standalone unit is a complicated question involving both technical matters and personal preference. If your station computer is using at least an 80386 class processor, the question is largely a matter of preference. In the case of 80286 class or lower processors, it may be a good idea to offload

**The Yaesu 736R is a multimode transceiver for 2 m (144-148 MHz) and 70 cm (430-450 MHz). It can be used for full-duplex receiving and transmitting on AO-10 Mode B and AO-13 Modes B and J. An optional 23-cm module covers 1230-1300 MHz (Mode L). Approximate power output: 20 W on 2 m and 70 cm, and 10 W on 23 cm.**

the work of tracking and/or tuning to an independent unit. Consider the situation of working one of the digital satellites like UO-22. With everything running in a single computer that machine must: update antenna position, set the radio frequency often enough to keep up with the Doppler shift, accept data from the TNC at a rate of 19,200 bps, update files and directories on disk as data is being captured, and update the screen display.

Finally, even though a tracker/tuner construction project has not been included in this section, it is an area where homebrew systems are certainly a possibility. Relay drivers can be built to control the rotators via signals from a parallel port. Analog-to-digital converters can be used to read the position indicating voltage from the meter circuit. Furthermore, most modern transceivers can be controlled by commands from a serial I/O port. Consequently, it is not beyond the capabilities of someone with programming and hardware experience to build an antenna and frequency control system.

### Antenna Cross-Boom Construction

One requirement not commonly discussed is that of using a nonmetallic elevation axis boom for antennas that have their boom-to-mast mounting hardware in the center of the boom. A metal cross boom will seriously distort the beam pattern of a circularly polarized antenna, so it is important to make those portions of the cross boom nearest to the antennas from nonmetallic materials.

From a structural standpoint, the best nonmetallic material for this job is glass-epoxy composite tubing, because its stiffness is excellent. Lengths of this material may be found at an industrial supply house that specializes in plastics. Also, KLM sells lengths of 1½ in. OD fiber-

glass mastings for this purpose, and Telex/HyGain includes fiberglass mastings with their OSCAR antennas. If you have a rotator that will accept a 1½ in. elevation boom, then your best bet is to use a single piece of this tubing. The 1½ in. OD fiberglass tubing also slides into the ID of the 1½ in. pipe used for the heavy-duty elevation axis.

A less expensive alternative is to make the cross boom from a combination of metallic and nonmetallic tubing. For strength and stiffness, use a short length of steel or aluminum tubing through the middle of the rotator. Let the metal tubing extend for about 6 in. on each side of the rotator. Then install nonmetallic mastings, such as common PVC pipe, over the steel stubs.

The elevation boom pictured in Fig 23.41 was constructed with this method. The center piece that fits through the U110 is a 2-ft section of 1.33-in.-OD steel tubing that originally was part of the top support rail of a chain-link fence. Attached to the steel stub on each side of the rotator is a 4-ft length of 1¼ in., schedule-40 PVC pipe. This pipe slipped nicely over the center stub. The fit is perfect — no machining was needed.

Unlike glass-epoxy tubing, PVC pipe is not very stiff. The secret to making PVC pipe capable of supporting satellite Yagis is to insert a wooden dowel into the PVC pipe, along its entire length. The finished dimension of 1⅜ in. wooden clothes-rod dowel (the kind you might hang inside a closet) is just perfect for a slide fit into the pipe. This material is available from most lumber yards. Add a few ¼ in. bolts to each side to secure the pieces, and you have a sturdy, inexpensive, nonmetallic elevation boom.

### Receivers

The old adage “You can’t work ‘em if you can’t hear ‘em” especially applies to satellite operation. Receiving requirements for AO-10 and AO-13 are demanding, but pleasurable results can be achieved with the right kind of equipment. OSCAR operation is a weak-signal mode where contacts can be made with signals that are only 4 dB stronger than the noise. Conversational quality can be assured with signals that are 6 to 9 dB above the noise.

The first step to be taken before attempting to work such high altitude satellites as AO-10 and AO-13 is to assemble the best receiving setup possible. There is no point in getting transmitting capability until the satellite signals can be comfortably heard.

Amateurs active on 2 m with a multimode transceiver already have the basic

building block for receiving Mode B and transmitting on Modes J and L (with an additional transmitting converter). If you currently have no VHF equipment, consider that a multimode, multiband transceiver will also allow you to explore the exciting world of terrestrial 2-m and 70-cm SSB operations. The basic requirements are that the rig includes SSB and CW modes and that it covers the entire 144-MHz band and (most of the) 420-MHz band. A multimode transceiver also makes an excellent replacement for an FM-only 144-MHz rig.

The equipment manufacturers listed in Table 23.10 all make suitable transceivers, either single-band or multiband units. The current crop of base-station rigs includes the Kenwood single-band transceivers TS-711A (2 m) and TS-811 (70 cm), and multiband transceiver TS-471H and IC-475H (70 cm). Yaesu offers their multiband FT-726R and FT-736R transceivers. There are also several compact multimode radios intended for mobile use that will be quite usable. These include the Yaesu single-band FT-290R and FT-790R, Kenwood single-band TR-751A and TR-851A, and the ICOM single-band IC-290H. In addition, there are often good buys on the used market, if you’re interested in an older radio. Gear such as the Kenwood TS-700 series, Yaesu FT-225RD and ICOM IC-251 are still popular. Many of these transceivers have been reviewed in *QST*.

Users of Mode L may want to consider the use of a full transceiver in the station for the 24-cm transmissions, as such a unit will also allow operations on the 23-cm band (1296 MHz). Kenwood and Yaesu offer 23-cm modules for their multiband transceivers for this service. ICOM also offers the single-band IC-271A. Alternatively, there are some 24-cm transmitting converters and transverters offered that employ a 2-m IF.

An excellent solution to receiving Modes B, J and L satellite signals can be found in the form of receiving converters used with a high-quality HF transceiver or receiver. The 2-m and 70-cm receiving converter consists of a mixer and a local oscillator and may contain a preamplifier. The local oscillator frequency is usually chosen so that signals will be converted to the 10-m band. In addition, a number of manufacturers offer transverters that include receiving and transmitting converters in the same package. Receiving converters are available from several suppliers listed in Table 23.10.

There are several advantages to using a receiving converter. Modern HF transceivers and receivers most likely have

excellent frequency stability, a frequency readout in 1 kHz or smaller steps, good SSB and CW crystal filters, an effective noise blanker and high dynamic range. Chances are good that a multimode VHF transceiver will offer some, but not all, of these features. Cost is another factor. If you already own an HF rig, but are not interested in terrestrial VHF/UHF SSB operation (you don't need 2-m transmit capability for Mode B), the cost of building or buying a superior receiving converter will be significantly less than that of even an older multimode transceiver. One commercial example of a Mode-B-only unit is the Ten-Tec 2510B, providing an excellent 2-m receiving converter and a complete 70-cm SSB/CW transmitter, all with coupled VFOs for simultaneous tracking on both bands. While the '2510 is an economical way to get into satellite operation, it is limited to Mode B service only and cannot provide any help for Mode J and L services.

Experience has shown that daytime noise will often raise the practical 2-m receiver noise floor by 10 to 20 dB, thus making Mode B daytime communications difficult, at best. Weak downlink signals are often no match for the noise. In general, noise is not a problem on 70-cm (for Mode J and Mode L reception), but in some areas interference from airport radar can be troublesome. In addition, local FM repeaters may be heard in the satellite passband of the ground-based receiver because the VHF transceiver may offer poor rejection of strong nearby signals. Use of a high-dynamic-range receiving converter with a good HF transceiver has been shown to solve both of these problems. The lesson is that many VHF transceivers have noise blankers that are inadequate for VHF/UHF satellite operation and some VHF transceivers do not work well in areas with many nearby, strong signals. Consequently, in some cases, better results may be achieved with a receiving converter than with a VHF multimode transceiver.

### Receiving Accessories

For those stations using a receiving converter and an HF receiver for downlink reception, an in-line switchable attenuator, installed between the converter output and the antenna jack of the 10-m receiver, may prove useful. Such an attenuator can be used to lower the AGC level and improve the perceived signal-to-noise ratio. In addition, by adjusting the attenuator so that the S meter on the HF rig rests at zero at no signal, more accurate signal reports can be given. An attenuator circuit is shown in the **Test Equipment** chapter. A

useful modified form may include only three steps — 5, 10 and 20 dB. These three settings allow attenuation in 5-dB steps from 0 to 35 dB.

### Preamplifiers

No discussion of satellite receiving systems would be complete without mentioning preamplifiers. Good, low-noise preamplifiers are essential for receiving weak downlink signals. Multimode rigs and most transverters will hear much better with the addition of a GaAsFET preamplifier ahead of the receiver front end, albeit at the expense of a considerable reduction in the third-order intercept point of the receiver. While a preamplifier can be added right at the receiver in the station, it may not do much good there. Considerably better results can be obtained if the preamp is mounted near the antenna. Indeed, antenna mounting of a preamp is essential for UHF and higher operation. Losses in the feed line will seriously degrade the noise figure of even the best preamplifier mounted at the receiver, while an antenna-mounted preamplifier can overcome nearly all of these noise figure problems.

Table 23.10 lists several sources of commercially built preamplifiers. These are available in several configurations. Some models are designed to be mounted in a receive-only line, for use with a receiving converter or transverter. Others, designed with multimode transceivers in mind, have built-in relays and circuitry that automatically switch the preamplifier out of the antenna line during transmit. Still others are housed, with relays, in weatherproof enclosures that mount right at the antenna. For the equipment builder, several suitable designs appear in *The Satellite Experimenter's Handbook*.

### Tower-Mounted Preamplifiers

Mast-mounting of sensitive electronic equipment has been a fact of life for the serious VHF/UHFer for years, although it may seem to be a strange or difficult technology for many HF operators. To get the most out of your satellite station, you'll need to mount a low-noise preamplifier on the tower or mast, near the antenna, so that feed-line losses do not degrade low-noise performance. Feed-line losses ahead of the preamplifier add directly to receiver noise figure. A preamp with a 0.5-dB noise figure will not do you much good if there is 3 dB of feed-line loss between it and the antenna.

In Fig 23.41, note the large white box located below the elevation rotator. Fig 23.45 shows the interior of this box. A close look shows a 2-m preamplifier for

the Mode B downlink and relays to switch it in and out of the line to the antenna. This setup is designed to beat excessive feed-line losses for basic stations. Transmitting equipment for the 70-cm and

**Fig 23.45** — Interior of the tower-mounted equipment rack with the cover removed. The 70-cm equipment is on the left, while power-supply regulators, a 24-cm transmit converter and a 2-m preamp are mounted on the right.

**Kenwood's TS-790A** is a dual-band (144-148 MHz and 430-450 MHz) multimode transceiver. A 23-cm (1240-1300 MHz) module is optional. Power output is 35-45 W on 144 MHz, 30-40 W on 430 MHz and 10 W on 1240 MHz.

**The ICOM IC-820** is a state-of-the-art transceiver designed especially for satellite use.

24-cm bands is also housed in the same enclosure. Normal installations may require only the receiving preamplifier (2 m for Mode B and 70 cm for Mode J and L) to be mounted on the mast. The transmitting equipment is discussed further in the next section.

## Transmitters

The AO-10 and AO-13 Mode B uplinks require a controllable 5 to 50 W of 435-MHz RF power at the antenna. This assumes a good antenna, which will be discussed later. Feed-line losses in a typical 435-MHz installation can easily run 3 dB, so you'll need anywhere between 10 and 100 W output from your transmitter. AO-13, Mode L, has an uplink requirement of 15 to 100 W, depending on antenna gain.

Since there are many combinations of transmitter power and antenna gain that will result in a satisfactory signal through AO-10 and AO-13, satellite users generally talk about their uplink capability in terms of effective radiated power (ERP). ERP takes into account antenna gain, feed-line loss and RF output power. For example, a 10-W signal into a 3-dB-gain antenna will have an ERP of 20 W (3 dB greater than, or twice as strong as, 10 W). This assumes no loss in the feed line and all 10 W from the transmitter reaches the antenna. If the signal is 10 W into a 10-dB-gain antenna, the ERP is 100 W. The same 100-W ERP can be achieved with a 50-W transmitter and a 3-dB-gain antenna.

Stations with an uplink ERP as low as 10 W can be copied through AO-10 and AO-13, Modes B and J, but ERP levels of 100 to 400 W are the norm. No matter what your ERP, your signal on the downlink should never be stronger than the general beacon at 145.81 MHz (Mode B) and 435.65 MHz (Mode J). As a reminder, satellite service ground stations do not have to be as strong as the beacon to provide excellent communications, good operators will adjust their signals to just the level needed for the QSO. You must have a way of adjusting your uplink signal power so that your downlink is no stronger than the beacon. These points are discussed in detail in *The ARRL Operating Manual*.

If the Mode-B satellite ground station has a 10-W transmitter, a short run of low-loss feed line and good antenna gain, an additional amplifier would probably not be needed. If losses and gains do not add up to the required ERP, a 30 to 40-W amplifier may be needed. Some operators have 100-W amplifiers, but with the antennas available today, use of that much power is guaranteed to create an uplink signal that far exceeds the beacon level. This is considered by good operators to be

an antisocial action. Considerate operators with the 100-W amplifiers quickly reduce drive power to lower the ERP to acceptable levels.

Most satellite operators use UHF multimode transceivers to generate Mode B uplink signals. The manufacturers listed in Table 23.10 make 70-cm multimode transceivers that are similar to the 2-m units as described earlier. Although most of these transceivers provide 10-W output, some can deliver 25 W or more.

Earlier satellites in the AMSAT programs created and fostered the need for good multimode 2-m transceivers, as they formed the nucleus of the satellite station. Current and future satellite programs will find the 70-cm transceiver as the focal point of the satellite station, emphasizing the trend to even higher frequencies. Note that the 70-cm transceiver is involved in all of the AO-13 operating Modes.

For Mode L transmitting, there are several transmitting converters, transverters, amplifiers and even a multimode transceiver available from the suppliers listed in Table 23.10. AO-13 Mode L operation can use the power levels offered by a tube-type amplifier, but useful results can be obtained using power levels that can be generated by transistors.

## Transmitting Accessories

The tower-mounted equipment rack shown in Fig 23.45 contains the 70-cm and 24-cm power amplifiers. Tower mounting of a transmitter is probably unnecessary for 70-cm, but becomes much more important for higher frequencies. Feed-line losses at 70 cm are generally twice those of 2 m, while those at 24 cm are about twice those of 70 cm, or four times those of 2 m. For an 80-ft feed line, the losses at 24 cm can easily reach 6 dB for even the best coaxial cable. Consequently, a 100-W amplifier in the shack will only yield 25 W at the antenna. A good alternative is to place the transmitting converter and a 20-W solid-state amplifier in the tower-mounted box near the antennas. The results are nearly the same, and you avoid the time and money needed to generate high power that will just be lost in the feed line anyway.

A coaxial RF sampler is connected to the output of the 70-cm amplifier since it is good amateur practice to monitor the power at the antenna to be sure the transmitter is working properly. Coaxial relays are used for proper switching of the power amplifiers and 70-cm preamp for OSCAR Mode J and L operation as well as for terrestrial communications.

One very important aspect of using

GaAsFET preamps with transmitting equipment is getting everything to switch at the proper time. If transmitters, amplifiers and antenna relays are keyed simultaneously, it's likely that RF will be applied to the feed line before the relays are fully connected to the antenna load. Such hot switching can easily arc the contacts on expensive coaxial relays. In addition, if the TR relay is not fully closed, RF may be applied to the preamplifier. Such bursts of RF energy are guaranteed to destroy the GaAsFET in the preamplifier. Many pieces of transmitting equipment (especially multimode transceivers) emit a short burst of RF power when switched on or off, so there is the risk of transmitting into your preamp even if you are careful to pause before keying.

Ideally, keying of a transmitter should follow a timing sequence that will ensure the safety of the equipment. When you switch into transmit from receive, the coaxial relays change state to remove the preamplifier from the line. Next, the power amplifier is keyed on. The last thing that happens is that the transmitter RF is enabled. When switching back to receive, the sequence is just the opposite. First, the transmitter RF is switched off, the power amplifier is disabled, and then the TR relays change state to place the preamp back in service. Solid-state sequencers to control station TR switching are shown in the **Station Accessories** chapter.

## Specialized Transceivers

Separate transceivers or transmitting and receiving converters are no longer the only way to go. Modern equipment offerings by Kenwood, Yaesu and Ten-Tec, tailored for the satellite user, do it all in one package.

The Kenwood TR-790A and Yaesu FT-726R and FT-736R units start out as 2-m multimode transceivers. They are, however, expandable to work on other bands with the addition of optional modules. The Mode-B satellite operator would most likely be interested in the TR-790A or FT-726R/FT-736R with the stock 144-MHz and 430-MHz modules. These same RF modules will also serve well for Mode J directly and Mode L using an outboard 23-cm transmitting converter. Both manufacturers also offer 23-cm transceive modules, for Mode L, for their multiband units. To tie it all together, these Kenwood and Yaesu transceivers also both offer satellite modules (stock or optional) that allow the amateur to transmit on one band for the uplink while receiving on another

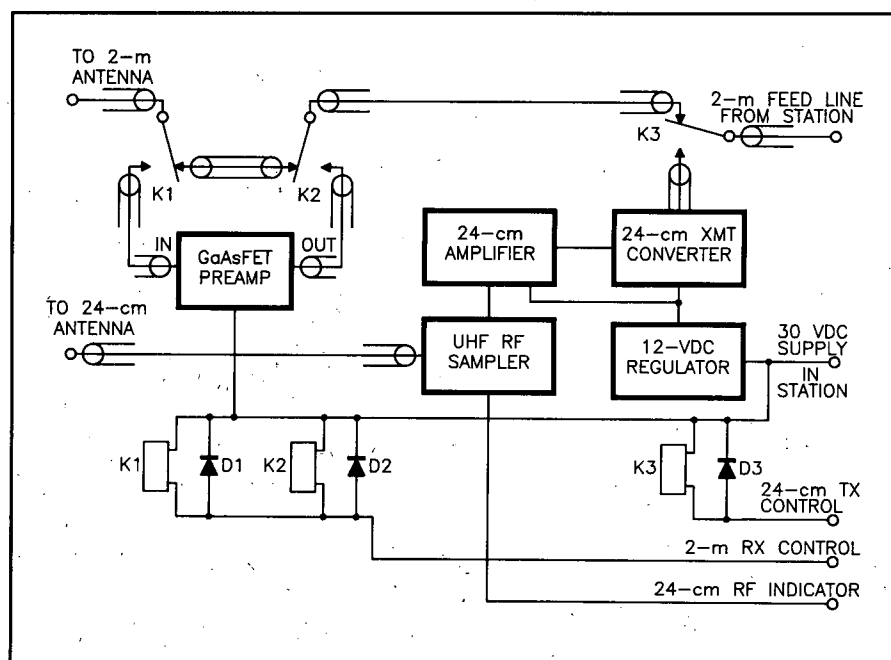

**Fig 23.46 — Protection for tower-mounted equipment need not be elaborate. Be sure to dress the cables as shown so that water drips off the cable jacket before it reaches the enclosure.**

band for the downlink. This is full duplex operation; the effect is the same as having two separate radios in one box.

### Tower-Mounted Equipment Shelters

A great many amateurs seem apprehensive about placing their valuable radio equipment outdoors. Such fears are unfounded if adequate care is taken to protect the equipment from the elements. The equipment shown in the photos has been outdoors for years without any adverse effects.

Fig 23.46 shows the basic scheme for weatherproofing tower-mounted equipment. The fundamental concept is to provide a cover to shelter equipment from rain. A deep drawn aluminum pan can make an excellent shelter. A trip to the housewares section of the local department store will reveal a variety of plastic and aluminum trays and pans that can make suitable rain covers. Polyethylene plastic is not durable in the sunlight. Clear polystyrene refrigerator containers work better than those made of polyethylene, and aluminum is best of all. Choose a cover that is large enough for your equipment; remember to leave room for con-

**Fig 23.47 — Control circuitry for the mast-mounted 2-m preamplifier and 24-cm Model-L transmitter. K1-K3 are surplus coaxial relays.**

necting cables.

The bottom of the rain cover is open to the elements. This is done on purpose and will not cause any problems. Do not try to hermetically seal the enclosure. By leaving the bottom open, adequate ventilation will prevent accumulation of water condensation. Just make sure that water cannot run into the enclosure by way of cables coming from above. Form the cables as shown in Fig 23.46 to provide drip loops. Adding a piece of window screen over the opening should be considered to avoid infestations of nesting insects, such as wasps, and the wire-hungry ravages of squirrels.

The mast-mounted enclosure shown earlier is a welded aluminum box purchased from a surplus dealer. It was used because it was available and the price was right. You don't really need a big box like this if you just want to protect a preamp and relays.

### Station Control

Fig 23.47 is a schematic diagram of the control circuitry for the 2-m side tower-mounted rack. Parts of this diagram will be helpful, even if only the preamp is mounted at the antenna. Note that this circuit is designed around the surplus coaxial relays that were available at the time. Your version will probably be different and will depend on the relays available to you.

This circuitry performs several functions. For starters, it places the preamp in the line only during receiving periods and takes it out of the line during transmitting periods as well as at those times when the

station is not in use. This is needed if the satellite array is used for terrestrial transceive operation as well. The switching arrangement shown also protects the preamp from stray electromagnetic pulses (EMP), such as lightning strokes, when the station is not in use. EMP protection is desirable even if the antenna and preamp are used only for receiving satellite signals.

Fig 23.47 is only a little more complicated than the average mast-mounted preamp setup because it also allows 2-m RF to drive a 24-cm Mode L transmitting converter. An extra relay (K3) is used to switch between 2-m and 24-cm operation. K1, an SPDT transfer relay, switches the antenna between the input of the preamp and a through line to K2. K2, another SPDT relay, switches the feed line, from the shack, between the preamp output and K1. The relays are connected so that they must be energized to place the preamp in line, thus ensuring that the preamp is disconnected when not in use.

Depending on the complexity of your satellite station, you might want to combine most of the switching and control circuitry into a single box so that it provides ready access to all controls. Fig 23.48 shows a Minibox cut to a low profile (beneath the multi-antenna rotator control unit) that contains all of the switches needed to control the station accessories. It houses a TR sequencer circuit board as well. This box controls the following functions: change antenna polarization from RHCP to LHCP on 2 m and 70 cm; switch the 2-m and 70-cm pream-

**Fig 23.48** — The satellite station at WD4FAB, with a home-brew antenna controller mounted above a low-profile station controller. On the right is a Yaesu FT-726R transceiver, with a power meter, clock and 23-cm transverter mounted on top.

plifiers in and out of the circuit; and switch the power amplifier in or out of the line. The box also contains a high performance 2-m receive converter, for use with the station HF transceiver, when the Mode B conditions get to be really difficult. As shown, home-built control unit boxes can be dressed up with the addition of a plotted or printed label on white paper. The label is bonded to the panel with the use of thin double-sided adhesive tape. A covering of clear label tape protects the label from smudges and dirt.

### Station Equipment Summary

Satellite communication, like any other facets of Amateur Radio, requires some specialized station equipment and accessories. Having the best equipment does not necessarily guarantee success. There are a number of “hints-and-kinks” type ideas that can make OSCAR operation far more satisfying. Some of the equipment items that have been discussed here provide capabilities beyond the bare minimum needed for successful satellite operation. They may also be of value in VHF and UHF terrestrial work. Design your station to suit your own needs. Some operators may continually tinker with their station equipment, making frequent improvements, as part of their participation in the Amateur Radio hobby.

### SUPPORTING CONCEPTS AND THEORY

Previous sections have described the satellites and communication modes available as well as various types of equipment needed for successful satellite operations. As is often the case with other specialized communications systems, there are certain concepts and theory peculiar to satellite communication. The purpose of this section is to review some topics that range in

importance from “essential” to “interesting to know.”

Orbital mechanics and tracking will be examined first. The material presented here will be more descriptive than mathematical. For a complete treatment of this subject, the reader is directed to *The Satellite Experimenter's Handbook* published by the ARRL. The need to use circularly polarized antennas was mentioned in the discussion of equipping a station. This section includes a more complete discussion of circular polarization along with a related phenomenon whose effects can be mitigated somewhat by using circularly polarized antennas — spin modulation. The sections on path loss and link budget will help explain why certain combinations of receiving and transmitting equipment and antennas were recommended.

### Tracking and Orbital Mechanics

In order to complete a QSO via an Amateur Radio satellite, the ground station operators must be able to predict when the satellite will be visible at their respective locations. Previous sections have recommended a stepwise approach to the complexities of amateur satellite operation. Expertise in the area of satellite tracking can be gained in a similar manner.

One method of tracking that is adequate for operations using omnidirectional antennas on LEO satellites uses the *Oscarlocator*, published by the ARRL as part of *The Satellite Experimenter's Handbook*. The *Oscarlocator* is a graphical tracking aid that consists of a satellite ground track indicator and a set of range circles overlaid on a polar projection map of the world. Since the ground track is calibrated in minutes, it is only necessary to position the track at the correct equator crossing location and note how many minutes later the satellite will cross inside the range circle.

There are, of course, many computer programs available for satellite tracking. These range in complexity from those that produce text output such as shown in Fig 23.40 to those that produce graphical output in real-time such as seen in Figs 23.15 and 16. It is also possible to obtain real-time tracking programs that will, in conjunction with the proper antenna controller, position your antennas automatically.

All of these programs rely on what is called a reference *Keplerian element set* for their operation. The Keplerian element sets for Amateur Radio satellites are distributed via on-the-air nets, terrestrial and packet radio networks and printed media.

The reference element sets used by the program need to be updated periodically. This is necessary because a future position is being computed based on a known previous position specified by the element set. As the length of time between the reference element set and the future prediction increases, the predictions are prone to inaccuracies due to perturbations of the orbit such as atmospheric drag.

How often the reference elements should be updated is dependent on the satellite. Reference elements for LEO satellites should probably be updated about once per month. Element sets for HEO satellites such as AO-10 and AO-13 need not be updated nearly as often. This is particularly true if the element set in use has been produced by averaging previous element sets over a long period of time. Other special cases such as the US Space Shuttle SAREX missions can require very frequent updates of the elements sets because the orbit geometry can change significantly and frequently depending on the goals of the mission. Reference element sets are distributed by AMSAT every week by many media including HF and VHF packet radio networks, the packet radio satellites such as AO-16 and UO-22, as well as commercial information services such as CompuServe's HamNet.

Satellite tracking software is now available for a wide variety of computers from many different sources. However, if you purchase your tracking program from AMSAT-NA, you can be sure that your contribution will help finance the next Amateur Radio satellite project. No matter where you purchase your program, you should be sure that it has the features you need and will run correctly on your computer system.

### Circular Polarization

In the HF bands, polarization differences between antennas are not really noticeable because of the nonlinearities of ionospheric reflections. On the VHF and

**Table 23.11****Polarization and Gain of AO-10 and AO-13 Antennas**

<b>High Gain Antennas</b>			<b>Omni Antennas</b>	
Frequency (MHz)	Polarization	Gain (dBi)	Polarization	Gain (dBi)
146	RHCP	9.0	Linear	0.0
436	RHCP	9.5	Linear	2.1
1269	RHCP	12.0	RHCP	0.0

UHF bands, however, there is little ionospheric reflection. Cross-polarized stations (one using a vertical antenna, the other a horizontal antenna) often find considerable difficulty, with upwards of 20-dB loss. Such linearly polarized antennas are “horizontal” or “vertical” in terms of the antenna’s position relative to the surface of the Earth, a reference that loses its meaning in space.

The need to use circularly polarized (CP) antennas for space communications is well established. If spacecraft antennas used linear polarization, ground stations would not be able to maintain polarization alignment with the spacecraft because of changing orientation. Ground stations using CP antennas are not as sensitive to the polarization motions of the spacecraft antenna, and therefore will maintain a better communications link.

All AO-10 and AO-13 gain antennas (for 2 m, 70 cm, 24 cm and 13 cm) are configured for RHCP operation along their maximum gain direction. See **Table 23.11** and **Fig 23.49**. Since this direction is also the main antenna lobe along the spacecraft +Z axis, the best communications with AO-10 and AO-13 will also be along that direction. Since the AO-10 and AO-13 radiations are RHCP, ground stations should also be RHCP for optimum communications.

There are times, however, when LHCP provides a better satellite link. AO-13 is designed so that the main antenna lobe is oriented toward the center of the Earth when the satellite is at apogee. AO-10 is not under active orientation control due to a failure of the flight computer memory. Thus, the AO-10 main-lobe orientation is a matter of chance. However, AO-13 is only oriented toward the Earth center for up to a few hours either side of apogee. As the satellite moves away from apogee, the orientation changes and the RHCP main lobe is not centered on Earth. At other times, ground command stations have to orient the spacecraft to odd angles to maintain proper sunlight on the solar cells that are used for prime power. Again, at such times the satellite antenna’s main lobe is not pointed directly at Earth. During the periods when the main lobe is directed away from Earth, communications are still possible through the use of AO-13’s antenna side lobes. CP

antenna patterns, however, exhibit side lobes that can be polarized in the opposite sense to the main lobe. At times when only LHCP side lobes are available, ground stations must be able to switch to LHCP to maintain optimum communications.

Independently switchable RHCP/LHCP antenna circularity is necessary, especially for 70 cm. It is not required for 24 cm operation on AO-13 as Mode L operations are only conducted on the main lobe. Switchable RHCP/LHCP on 2 m is very convenient and useful for Mode B operations.

### Spin Modulation

A characteristic of the AO-10 and AO-13 designs is that the 2-m and 70-cm high-gain array patterns have three side lobes located along the spin axis that are only about 3 dB weaker than the primary axial lobe. The effective radiation pattern intended for this antenna is shown in **Fig 23.49**. Lobes in the off-axis antenna patterns produce amplitude modulation of signal strength as the spacecraft spins about its axis. Off-axis operations of AO-10 and AO-13 are an established fact of life, creating spin modulation frequencies of about 0.5 Hz from a 10 r/min spin rate.

Stations using CP antennas are much less prone to be affected by spin modulation than those using linearly polarized antennas. Good signals are maintainable even far off-axis from the main lobe, if the ground station is using switchable CP.

In free space, a station located at a dis-

**Fig 23.49** — This diagram shows the far-field radiation pattern (undeformed) for the 2-m high-gain antenna on AO-10 and AO-13. (Adapted from *The AMSAT-Phase III Satellite Operations Manual*, prepared by AMSAT and Project OSCAR.)

tance from an RF source will receive an average power flow from that source that is inversely proportional to the square of the distance. Doubling the range will reduce the signal by 6 dB. Since Phase 3 satellites have substantially elliptical orbits, the changes in path length (slant range) and path loss is correspondingly sizable. **Fig 23.50** illustrates the changes in path length of AO-10/13 signals for all conditions from apogee to perigee and for direct overhead passes (subsattellite point location) to the far-limb viewing at AOS or LOS.

Other physical processes introduce additional losses in signals traveling to and from AO-13 through the troposphere and

SNR	Avg Signal-to-Noise Ratio	14.8 dB	13.4 dB

Link computations are based on the following parameters:

- 11.7 hour elliptical orbit
- Eccentricity = 0.6
- Slant range = 41,395 km at AOS/LOS
- 2.4 kHz SSB Signal
- 6 dB peak (PEP) to average signal ratio

Ground Station Receiving Noise Characteristics

- at 2 m: T = 505 K, NF = 4.4 dB
- at 70 cm: T = 65 K, NF = 0.9 dB

(Adapted from *The AMSAT Phase III Satellite Operations Manual*, prepared by AMSAT and Project OSCAR)

ionosphere. While many of these effects are frequency dependent, the additional path losses for AO-13 signals are small compared to the slant range path losses. **Table 23.12** summarizes the path losses for each band used on AO-13.

**Link Budget**

Link budget computations can be deceiving to the unwary observer. The problems arise from the application of wide-bandwidth spacecraft transponders to handle a wide variety of complex, time-averaged, narrow-bandwidth QSOs. The analysis presented in **Table 23.13** employs a somewhat lower signal-to-noise ratio than the source information. Actual on-the-air experience has shown these lower values to be workable. The computation is also performed on the basis of averaged RF power levels. The conversion to PEP is done at the end, assuming a 6-dB relationship between PEP and average.

In the link computations, no allowances have been made for ground station transmission line attenuation. Information for attenuation of a variety of popular feed lines is shown in the **Transmission Lines** chapter. If you measure RF power near the antenna and have a tower-mounted, low-noise preamp, the link computations can be used as presented. The computation is based on two possible worst-case conditions: with the maximum slant range values at AOS/LOS, and with the spacecraft at apogee. An important assumption is that the spacecraft antenna pattern is on-axis to the communications path, a highly unusual spacecraft orientation condition. Of course, an infinite number of cases could be presented in such a tabular assessment.

Another highly variable parameter that must be taken into account is pointing and polarization loss. With the wide variety of AO-10 and AO-13 offset pointing situations that are seen in typical operation, the pointing and polarization losses can easily achieve values of 10 dB or more. Nevertheless, the presentation of Table 23.12 is in the ballpark for Mode B operations for those power levels and received signal conditions seen in practice.

Consistent AO-13 Mode L performance, with the spacecraft near apogee, can be attained with uplink power in the range of 3 to 5-kW EIRP, preferably circularly polarized. Also required is a good receiving setup, with 70-cm downlink antenna gain about 18 dBic and a low-noise GaAsFET preamp at (or very near) the antenna.

## THE 4 × 3 × 5 MHz FILTER FOR MODE J

If your 435-MHz receive system is sensitive enough to experience desense from your 2-m uplink, the filter shown in Fig 23.51 should solve the problem. Most Mode J OSCAR users have experienced some difficulty getting satisfactory results on this mode. Being able to receive well is the secret. Adding this filter should narrow the passband enough to allow rejection of unwanted noise and birdies. Insert it before any preamp or converter in the antenna feed line. If the third-harmonic level is high, it may be necessary to use a similar filter built for the 144-MHz band after your uplink 144-MHz rig.

Most plumbing-supply outlets can supply you with the material for the 3/4- and

3-inch copper pipe. The only other item of cost is the type of coax receptacle you want to use. Make it adaptable to your system, without sacrificing loss. The filter should cost less than \$10.

Be careful when you solder double-sided PC board. Direct the heat of your torch at the pipe and enough heat will transfer to the board to allow the solder to flow. It is not necessary to use PC board, as copper or brass that is thick enough to support the unit will do. If copper or brass is not available, a soup can you can solder to works well. The more stable the structure, the better.

The filter has a narrow passband, but with a good high-gain, low-noise system you should be able to peak up the noise

with no signal. A low-power 145.050-MHz signal into a dummy load should give you a test signal to peak the filter.

The insertion loss measured in the ARRL Lab was around 0.4 to 0.5 dB. If you want to improve this figure, use silver braze and silver plating. This filter was fashioned after a design by Joe Reisert, W1JR, and was built by Jay Rusgrove, W1VD.

A similar filter is available as a kit from the Microwave Filter Co, Inc (see the **References** chapter). MFC developed their model 9397 filter specially as a kit for amateur Mode-J satellite operators. Dick Jansson, WD4FAB, describes the kit fully in September 1992 *QEX*.

### Parts List

#### Piece No.

- |   |  |
|---|--|
| 1 Pipe, copper<br>3" diam, 5" long              | Cut ends square. Drill or punch for connectors 3 3/4" from bottom.   |
| 2 Pipe, copper<br>3/4" diam, 4" long            | AgSn (plumbing alloy) solder to center of 10.  |
| 3 Disk, copper<br>3/4" diam<br>1/16"-1/8" thick | Drill through center. Solder solid hook-up wire between disk and connector to space disk 3/16" from piece 2.                     |
| 4 Disk, copper<br>3/4" diam<br>1/16"-1/8" thick | Drill through center. Solder solid hook-up wire between disk and connector to space disk 3/16" from piece 2.                     |
| 5 Connector, coax                               | BNC, SMA or N type. Solder to prevent turning. For large connector, use chassis punch.   |
| 6 Same as 5                                     |  |
| 7 Nut, brass<br>1/4"-20 hex                     |  |
| 8 Nut, brass<br>1/4"-20 hex                     |  |
| 9 PC board, double-sided. Top 4" × 4".          | Drill hole in center to clear 1/4-20 bolt. Solder 7 and 8 each side of hole. (Use bolt 11 to hold nuts in place when soldering.) |
| 10 PC board, double-sided. Bottom 4" × 4".      | Solder 2 in center.  |
| 11 Bolt, brass<br>1/4-20 × 3"                   | Insert through 12, then through 7 and 8  |
| 12 Locking nut, brass, 1/4-20 hex               | To hold piece 11 after resonance adjustment.   |

Fig 23.51—Parts list for the 4 × 3 × 5 MHz filter.

## PARABOLIC REFLECTOR AND HELICAL ANTENNAS FOR AO-13 MODE S

The Mode S transponder on AO-13 has become very popular for a variety of reasons. Among the reasons are: good performance can be realized with a physically small downlink antenna and good quality downconverters and preamps are available at reasonable prices. Increased operation on Mode S has long been advocated by a number of people including Bill McCaa, KØRZ, who led the team that designed and built the Mode S transponder<sup>14</sup> and James Miller, G3RUH, who operates one of the AO-13 command stations.<sup>15</sup> Ed Krome, KA9LNV, and James Miller have published many articles detailing the construction of preamps, downconverters, and antennas for Mode S.<sup>16-19,20-22</sup> The following is a condensation of several articles written by G3RUH describing two types of antennas that can be easily built and used for reception of the AO-13 Mode S downlink.

### Parabolic Reflector

There are three parts to the dish antenna — the parabolic reflector, the boom, and the feed. There are as many ways to accomplish the construction as there are constructors. It is not necessary to slavishly replicate every nuance of the design. The only critical dimensions occur in the feed system. When the construction is complete, you will have a 60-cm diameter

S-band dish antenna with a gain of about 20 dBi with RHCP and a 3 dB beamwidth of 18°. Coupled with the proper downconverter, performance will be more than adequate for AO-13 Mode S.

The parabolic reflector used for the original antenna was intended to be a lampshade. Several of these aluminum reflectors were located in department store surplus. The dish is 585 mm in diameter and 110 mm deep corresponding to an  $f/d$  ratio of  $585/110/16 = 0.33$  and a focal length of  $0.33 \times 585 = 194$  mm. The  $f/d$  of 0.33 is a bit too concave for a simple feed to give optimal performance but the price was right, and the under-illumination keeps ground noise pickup to a minimum. The reflector already had a 40-mm hole in the center with three 4-mm holes around it in a 1-inch radius circle.

The boom passes through the center of the reflector and is made from 12.5 mm square aluminum tube. The boom must be long enough to provide for mounting to the rotator boom on the back side of the dish. The part of the boom extending through to the front of the dish must be long enough to mount the feed at the focus. If you choose to mount the downconverter or a preamp near the feed, some additional length will be necessary. Carefully check the requirements for your particular equipment.

A 3 mm thick piece of aluminum, 65 mm in diameter is used to support the boom at the center of the reflector. Once the center mounting plate is installed, the center boom is attached using four small angle brackets — two on each side of the reflector. See Fig 23.52 for details of reflector and boom assembly.

A small helix is used for the S-band antenna feed. The reflector for the helix is made from a 125 mm square piece of 1.6 mm thick aluminum. The center of the reflector has a 13-mm hole to accommodate the square center boom described above. The type N connector is mounted to the reflector about 21.25 mm from the middle. This distance from the middle is, of course, the radius of a helical antenna for S band. Mount the N connector with spacers so that the back of the connector is flush with the reflector surface. The helix feed assembly is shown in Fig 23.53.

Copper wire about 3.3 mm in diameter is used to wind the helix. Wind four turns around a 40-mm diameter form. The turns are wound counterclockwise. This is because the polarization sense is reversed from RHCP when reflected from the dish surface. The wire helix will spring out slightly when winding is complete.

Once the helix is wound, carefully stretch it so that the turns are spaced 28 mm ( $\pm 1$  mm). Make sure the finished spacing of the turns is nice and even. Cut off the first half turn. Carefully bend the first quarter turn about 10° so it will be parallel to the reflector surface once the helix is attached to the N connector. This

Fig 23.52 — Detail of 60-cm Mode-S dish and feed.

Fig 23.53 — Helix side of 60-cm Mode-S dish feed. The N-type connector is fixed with three screws, and is mounted on a 1.6-mm spacer to bring the PTFE molding flush with the reflector. Dimensions are in mm; 1 in. = 25.4 mm.

Fig 23.54 — 16-turn helix antenna for AO-13 Mode S.

quarter turn will form part of the matching section.

Cut a strip of brass 0.2 mm thick and 6 mm wide matching the curvature of the first quarter turn of the helix by using a paper pattern. Be careful to get this pattern and subsequent brass cutting done exactly right. Using a large soldering iron and working on a heat-proof surface, solder the brass strip to the first  $\frac{1}{4}$  turn of the helix. Unless you are experienced at this type of soldering, getting the strip attached just right will require some practice. If it doesn't turn out right, just dismantle, wipe clean and try again.

After tack soldering the end of the helix to the type N connector, the first  $\frac{1}{4}$  turn, with its brass strip in place, should be 1.2 mm above the reflector at its start (at the

N connector) and 3.0 mm at its end. Be sure to line up the helix so its axis is perpendicular to the reflector. Cut off any extra turns to make the finished helix have  $2\frac{1}{4}$  turns total. Once you are satisfied, apply a generous amount of solder at the point the helix attaches to the N connector. Remember this is all that supports the helix.

Once the feed assembly is completed, pass the boom through the middle hole and complete the mounting by any suitable method. The middle of the helix should be at the geometric focus of the dish. In the figures shown here, the feed is connected directly to the downconverter and then the downconverter is attached to the boom. You may require a slightly different configuration depending on whether you are attaching a downconverter, preamp, or just

a cable with connector. Angle brackets may be used to secure the feed to the boom in a manner similar to the boom-to-reflector mounting. Be sure to use some method of waterproofing if needed for your preamp and/or downconverter.

### 16-Turn Helix

The 16-turn helix described in this section was designed to be as physically small as possible and still allow reception of AO-13 Mode S downlink signals.<sup>21</sup> The results of tests using the antenna while AO-13 was at apogee of 43,000 km can be found in Reference 22. When coupled with an adequate preamp/downconverter system, the 15.5 dBic gain of the 16-turn helix is adequate for CW operation, and under good conditions, may be adequate for SSB operation as well.

The 16-turn helix is shown in Fig 23.54. The helix and reflector plate are constructed as described for the parabolic dish above, except that the helix is wound right handed (clockwise). The matching section spacing from the reflector is 2 mm at the start and 8 mm at the end. The helix is supported at every fifth turn, starting with turn  $\frac{3}{4}$ , using PTFE (Teflon) spacers screwed to the boom.

For additional information on constructing antennas for use at microwave frequencies, see *The ARRL UHF/Microwave Experimenter's Manual*.

## MODE-S RECEIVE CONVERTER

This project, designed by Zack Lau, KH6CP/1, in the ARRL Lab, was first published in July 1994 *QEX*, pp 25-30. Its goal is a simple yet high-performance 13-cm receive converter optimized for 2401-MHz OSCAR Mode-S reception. The design takes advantage of recent advances in PHEMT technology to simplify the circuitry while also improving performance. See Fig 23.55. A template package is available.<sup>23</sup> The finished unit checks out with a 0.33-dB NF and 31 dB of conversion gain, according to the ARRL Lab's HP 346A/8970 noise-figure meter. This low noise figure, combined with a 15-turn helix antenna, achieves a gain-to-noise-temperature ratio of around 1. The converter also is small enough to be mounted at the focus of a dish with minimal blockage.

The biggest design simplification comes from the use of Hewlett-Packard PHEMT GaAs MGA-86576 MMICs, which are almost ideal in this application.

The MGA-86576 has a relatively low noise figure of 1.5 dB, just the right output power of +7 dBm, a low current draw of 16 mA, and a gain of 23 dB that peaks in-band. The major disadvantage of the device is that it requires very good grounding for stability. Hewlett-Packard suggests four plated-through holes under each lead. Since this design is for amateurs to duplicate, rather than for commercial manufacturers, very thin circuit board, 15-mil 5880 Rogers Duroid, was used. Microwave Components of Michigan has been selling this material for many years. Excellent stability can be obtained with this thin board by bending the leads sharply and running them through the board. Unlike those of some surface-mount devices, the leads of these MMICs are long enough to go through and bend back against the board for a good mechanical attachment.

An advantage to PHEMT MMICs is

their significant power efficiency. The 564 to 2256-MHz multiplier draws only 23 mA, even when an inefficient LM317L linear regulator is used. See Table 23.14.

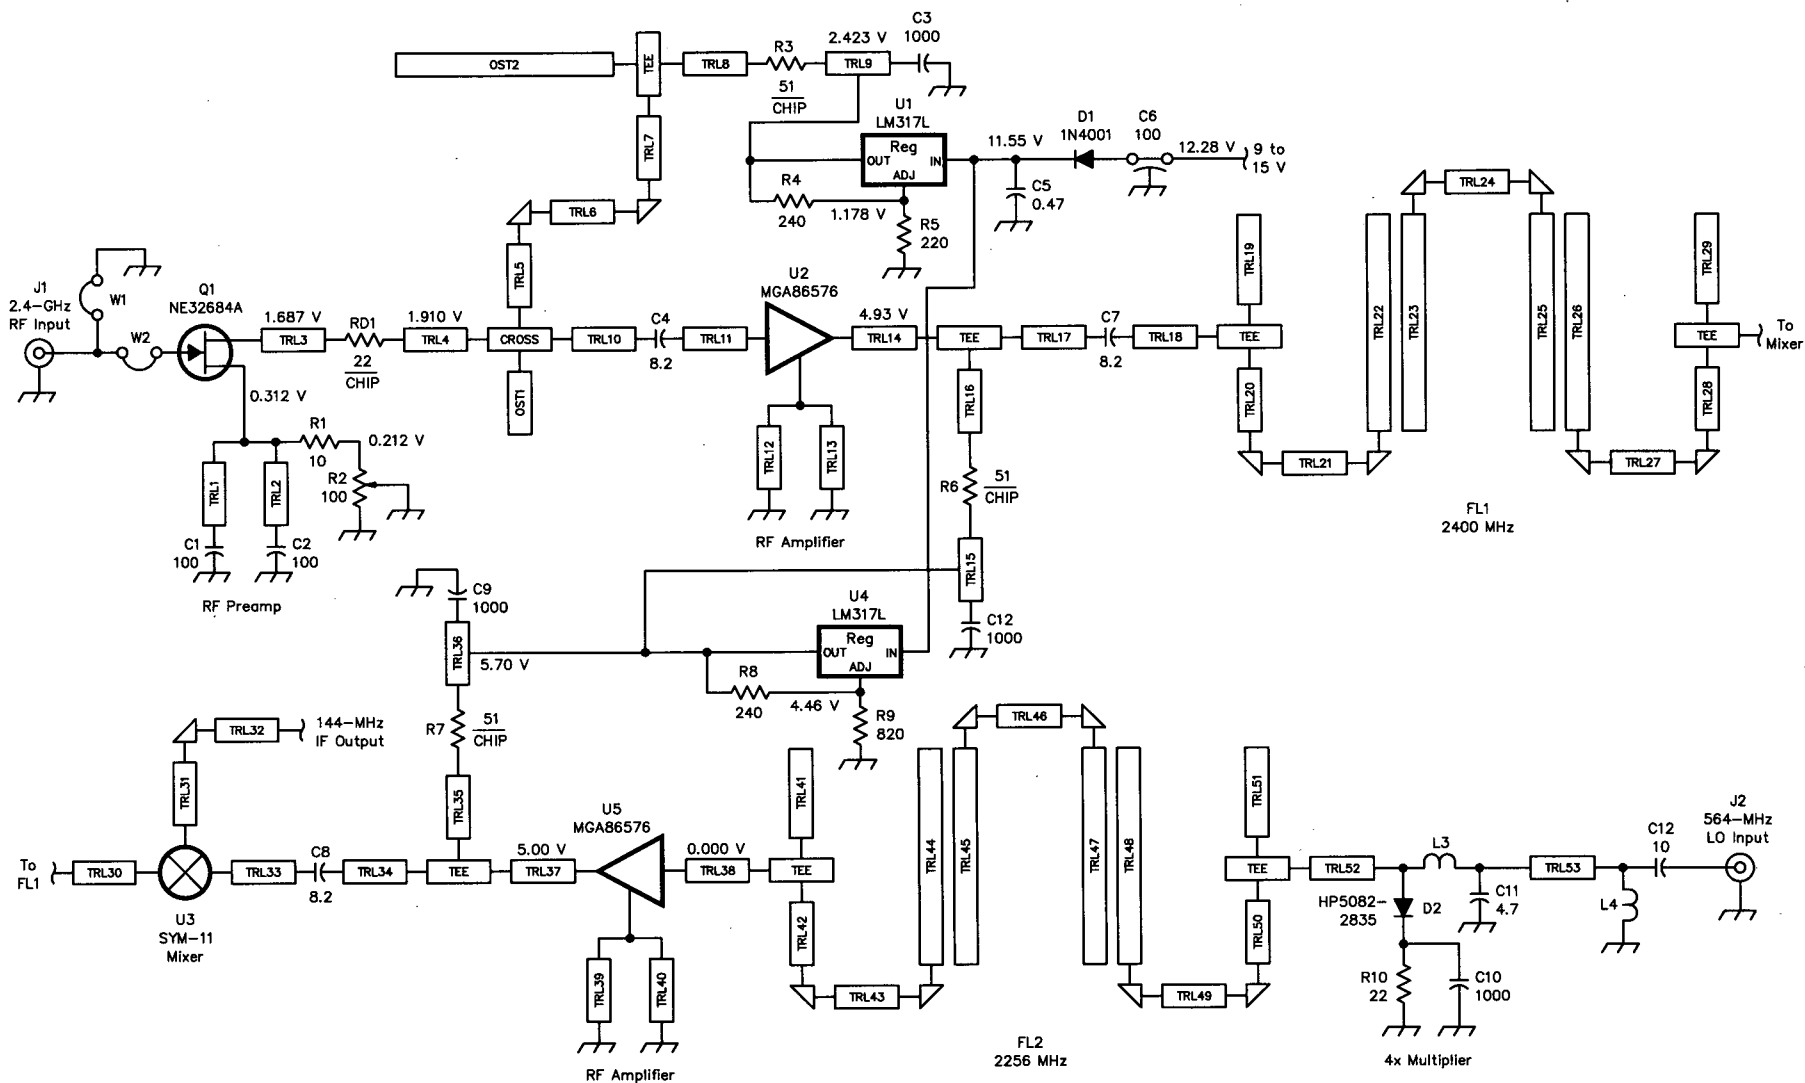

The mixer is a Mini-Circuits SYM-11, a surface mount device with a reasonable RF port impedance. Its 50- $\Omega$  input SWR is roughly 2:1.

Since the two MMICs and PHEMT draw only about 50 mA, the local oscillator

Table 23.14

### Measured Performance of the 564 to 2256-MHz Multiplier

Input (dBm)	Output (dBm)
7.0	3.3
7.9	5.0
8.8	6.0
10.0	6.8
10.7	7.0
13.0	7.3

board was redesigned. See Fig 23.56. Size and current consumption were both cut in half. A major part of the size reduction was obtained by using smaller filters. This was done by capacitively loading the hair-pin loops of the filter with 4.7-pF chip capacitors. This adds an interesting variable to no-tune designs. A disadvantage is that capacitor tolerances can skew the center frequency of the filter, perhaps unacceptably. On the other hand, it also can compensate for variations in board material. Thus, a bad batch of boards might well be salvaged merely by changing the value of the chip capacitors. This circuit might also be used for a 561.6 or 568-MHz LO. Multiply the former frequency by 10 for a 5616-MHz, 6-cm LO and the latter by 18 for a 10,224-MHz, 3-cm LO.

A major variable in dealing with G-10 or FR-4 glass-epoxy board is the board thickness. Variations can be as large as 14%—significant in determining the resonant frequency of a microstrip filter. Rogers advertises an available thickness tolerance of  $\pm 1.5\%$ .

The local oscillator is the circuit used in the no-tune transverters.<sup>24</sup> This circuit is not recommended if you wish to set the oscillator to a precise frequency, however. Like many overtone circuits, this one may be difficult to get running properly, since there are at least three things that can go wrong. The most insidious is a parallel resonance in the tank bypass circuit at around 100 MHz. This may prevent the circuit from oscillating properly. This problem can be prevented by changing the value of the bypass capacitors or by changing the spacing between them so the stray inductance changes. The next possibility is that the tank circuit may not resonate at the desired frequency. The easiest solution is to install a 47- $\Omega$  resistor in place of the crystal and resonating inductor to see

what the tuning range of the tank circuit is. Be sure to verify that the oscillator is operating at 94 MHz. It is entirely possible that the output is near 564 MHz but the oscillator is operating at some other frequency, such as 80.6 MHz. Finally, the parallel resonating inductor must resonate near the desired overtone. Since the shunt capacitance across the crystal seems to vary, the inductance value also must vary. This shunt capacitance can be measured with a 1-kHz capacitance meter that reads a few picofarads accurately.

With a temperature compensating capacitor for C5, a home-built 561-MHz local oscillator drifted 368 Hz over a temperature variation of 41° (0 to 41°C). Unfortunately, temperature compensating capacitors of specific values are not readily available in small quantities, although they can be found in "bargain assortments" at Radio Shack.

## CONSTRUCTION

After etching the Teflon board, cut slots in the board for ground foils and transistor source leads. These are marked with thin pads. Use a no. 10 X-acto knife with a sharp blade. The slot should just touch the outside of the pad, so the transistor will cover the copper pads. In addition to the four slots for the transistors, there are seven slots to ground pads with thin copper foil (roughly 1 mil thick). Next, cut the "U" for the RF preamplifier. This allows a piece of unetched circuit board to be soldered in place for the ground plane. Finally, three holes are needed for the IF and dc power connections. Coax can be run between the IF connection and a panel-mount connector. Copper can be cleared away from the holes with a hand-held drill bit. This takes a bit of practice with such thin board material.

A disadvantage of 15-mil board is poor

mechanical rigidity. Thus, the board should be mounted in a brass frame. 0.025×1-inch brass strip can be used. Attach the connectors to the brass strips with screws, then solder the strips to the circuit board. The strips without connectors are then soldered to the circuit board. An extra brass strip was added at the center of the enclosure near the mixer for extra stiffness.

The preamplifier construction is almost identical to the design published in Nov. 1993 *QEX*.<sup>25</sup> Instead of an SMA connector, however, a nonstandard N connector was used—one with a panel-mount flange similar in size to a BNC connector.

R2 is set so the voltage across R1 is 0.10 V, making the bias current of Q1 10 mA. W1 and W2 may have to be tweaked for best noise figure. It is easy to damage Q1 via electrostatic discharge while doing this, so take proper precautions.

## OPERATING HINTS

If this converter will be used with a typical transceiver, the mixer must be protected from the transmitter. When turned off, many modern transceivers transmit momentarily. Installation of a postamplifier and attenuator is recommended if you wish to connect this converter to the antenna port of a transceiver. This unit was really meant to be hooked up at the antenna, much like a mast-mounted preamplifier. There is little benefit to using an expensive GaAs FET preamplifier if it is fed with many feet of lossy coax. However, you can separate the preamp/MMIC amplifier and the rest of the converter, mounting the RF amplifiers at the antenna and having the converter in the station. Doing the calculations to determine the noise figure of the new system is recommended.

Fig 23.55—Schematic of the S-band converter.

C1, C2—100-pF ATC 100A chip capacitors (substitution not recommended).  
C3, C9, C10—1000-pF chip capacitors.  
C4, C7, C8—8.2-pF, 50-mil chip capacitors.  
C5—0.1- $\mu$ F or larger capacitor.  
C6—100-pF feedthrough capacitor (any value from 10 pF to 0.1  $\mu$ F should work fine).  
C11—4.7-pF chip capacitor.  
C12—10-pF chip capacitor.  
D1—1N4001 rectifier diode.

D2—Hewlett-Packard 5082-2835 Schottky diode (or another Schottky switching diode).  
L3, L4—4 turns #28 enameled wire, 1/16-inch ID.  
RD1—22- $\Omega$ , 1/10-W chip resistor, 50×80 mils.  
R3, R6, R7—51- $\Omega$ , 1/10-W chip resistor.  
U1, U4—LM317L adjustable voltage regulator.  
U2, U5—Hewlett-Packard MGA 86576 PHEMT MMIC.  
U3—Mini-Circuits SYM-11 mixer.

W1—#32 silver-plated wire taken from 20-gauge Teflon stranded wire (8-mil diameter). This is a loop whose ends are 200 mils apart using 250 mils of wire (plus more for the connections). One end is 55 mils above ground; the other end is grounded.  
W2—#32 silver-plated wire. This loop is between the center pin of the coax and the transistor gate. The gate lead is 20 mils long. Not counting connections, the length is 310 mils. The ends of the loop are 182 mils apart.

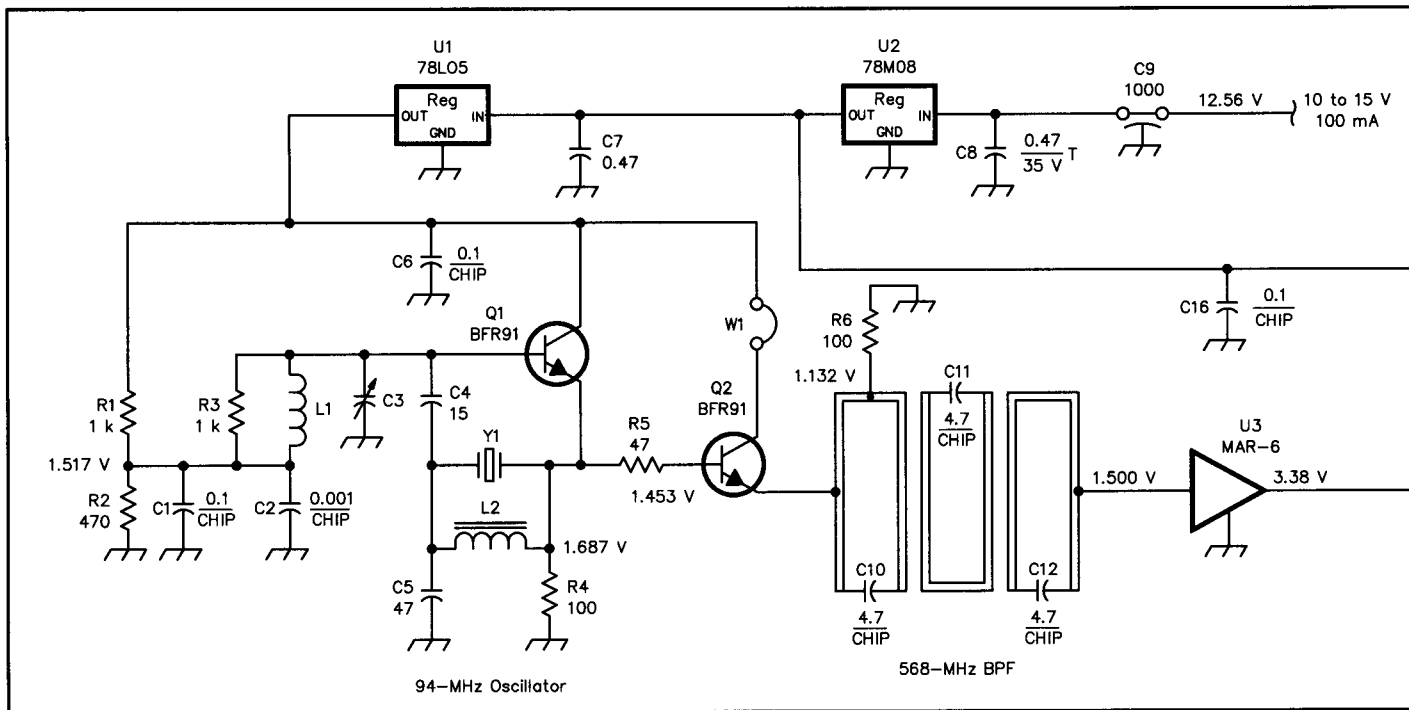

Fig 23.56—Schematic of the 564-MHz local oscillator.

C3—2 to 10-pF trimmer capacitor.  
 C4—15-pF NP0 capacitor.  
 C5—47-pF N1500 capacitor. A commonly available NP0 could be used, but the temperature compensation improves stability. (See text.)  
 C8—0.33-µF or larger capacitor to prevent U2 from oscillating.  
 C9—1000-pF feedthrough capacitor. Any value from 100 pF to 0.1 µF should work well.  
 J1—SMA panel jack. At 564 MHz connectors are optional.

L1—7 turns #28 enameled wire, 0.1-inch diameter, closewound. 8 turns may work if C3 tunes low enough.  
 L2—14 turns #26 enameled wire on a T-25-10 core. As many as 17 turns may be needed on a T-25-6 core, though 10 turns are usually specified. It depends on the crystal's shunt capacitance.  
 R7—270-Ω resistor. Replace with a 470-Ω resistor to run the MMIC from +12 V (no 8-V regulator).  
 R8—82-Ω resistor. Replace with a 220-Ω, 1/2-W resistor to run the MMIC from +12 V.

RFC1—8 turns #26 enameled wire, 0.10-inch ID, closewound.  
 U1—78L05 5-V regulator.  
 U2—78M08 8-V regulator.  
 U3—MAR-6, MSA-0685 MMIC.  
 U4—MAR-3, MSA-0385 MMIC.  
 W1—Wire jumper.  
 Y1—94-MHz crystal. International Crystal Manufacturing part number 473390. For better temperature stability, mount the crystal on the ground-plane side of the board and cover it with antistatic foam.

## A SIMPLE JUNKBOX SATELLITE RECEIVER

This project, by John Reed, W6IOJ, appeared first in April 1994 *QEX*. Single-conversion receivers—including direct-conversion designs—have received a good deal of attention, primarily because of the article by Rick Campbell, KK7B, in August 1992 *QST*. The receiver described here has been configured for monitoring the 70-cm polar-orbiting PACSATs, and has demonstrated very good performance in spite of the limitations of single-conversion designs. In addition, it has retained the simplicity, compactness and versatility of single conversion. The receiver can operate in any part of the 70-cm band. The output is an IF signal having a 250-Hz to 2-MHz passband.

Fig 23.57 is a block diagram of the receiver. This diagram shows one particular

PACSAT configuration—the receiver is being used with a 50-kHz IF filter/amplifier/FM discriminator, a 9600-baud modem and a TNC/computer.

### GENERAL DESCRIPTION

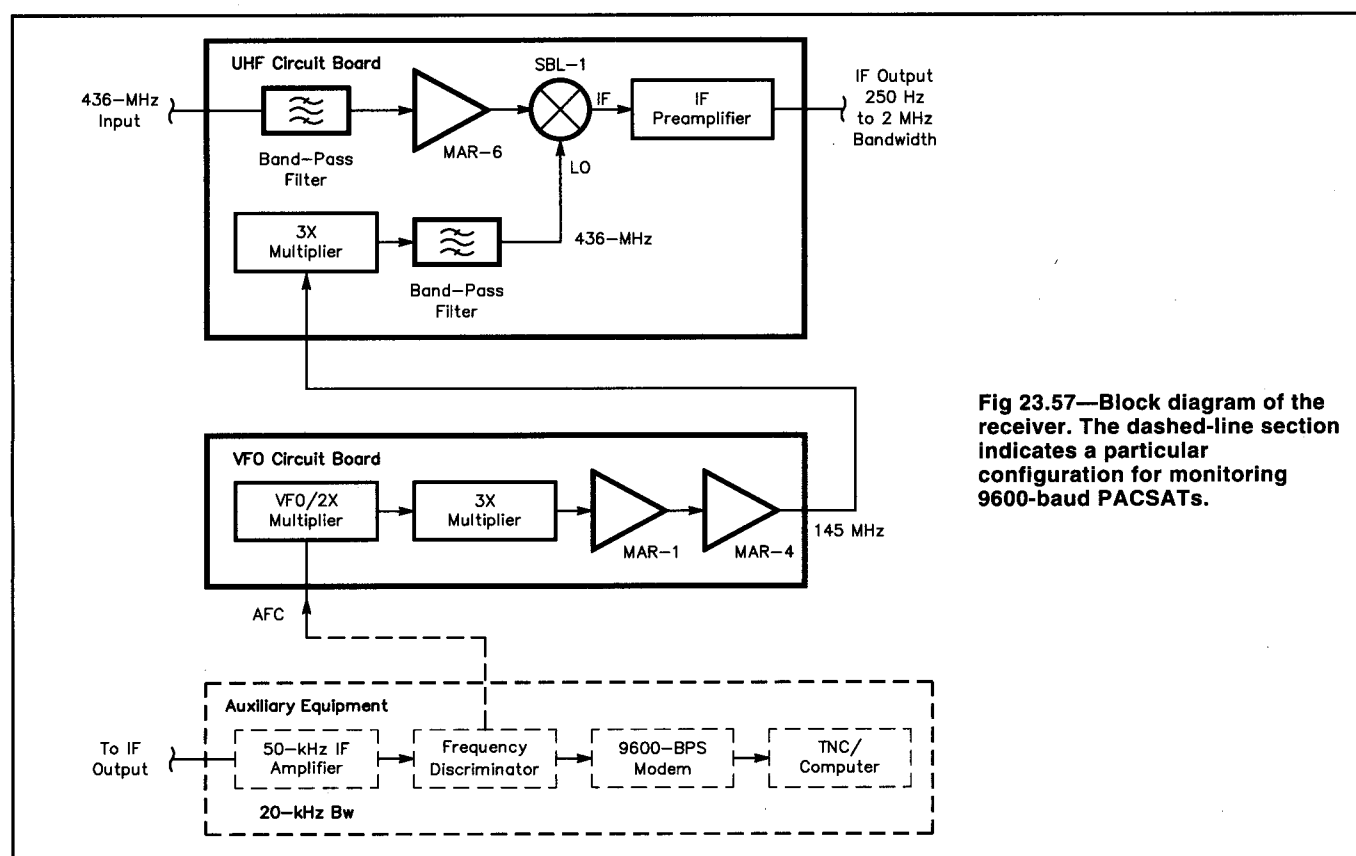

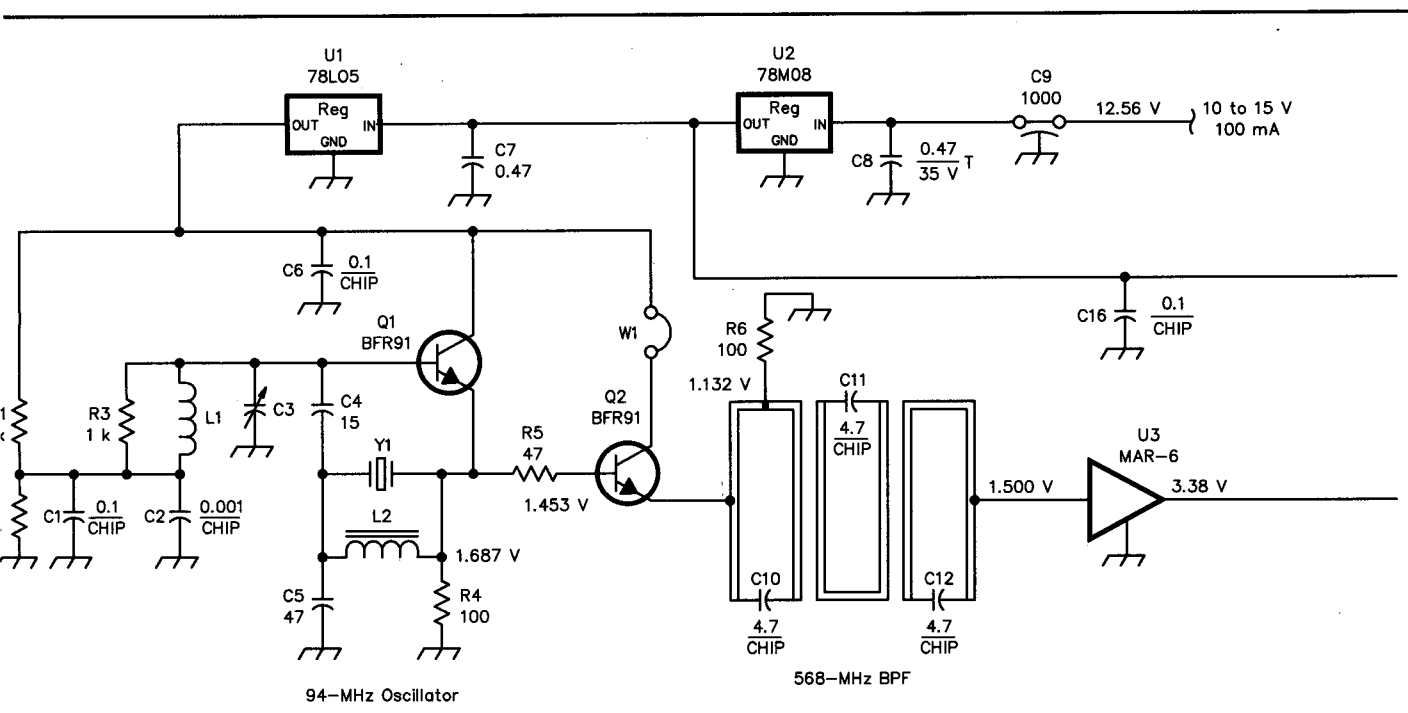

The receiver's 3×5 1/4×5 7/8-inch metal cabinet contains two 4 3/4×5-inch circuit boards. One is the UHF circuit board that has a 70-cm input filter, low-noise monolithic preamplifier, double-balanced mixer and IF preamplifier. See Fig 23.58. There is also an LO driver consisting of a tripler/filter arrangement operating from a 145-MHz, 6-mW source. The VFO circuit board has a 24-MHz varactor-tuned VFO and a 145-MHz frequency multiplier followed by a two-stage monolithic amplifier. This amplifier output is the LO

driver input. The VFO circuit board includes a 10-V regulator operating from a 12 to 20-V external source.

On the front panel there is a 12-position band selector switch covering 3.6 MHz of the 70-cm band in 300-kHz steps. Fine tuning within these steps is accomplished with a potentiometer covering a 500-kHz spread. The selector range can be placed in any part of the 70-cm band by trimmer adjustments located on the circuit boards. The back panel contains a BNC connector for the 70-cm input and jacks for the receiver output and the AFC input.

### LIMITATIONS

Single-conversion receivers lack discrimination of the unused sideband. For example, in a PACSAT application with a

**Fig 23.57—Block diagram of the receiver. The dashed-line section indicates a particular configuration for monitoring 9600-baud PACSATs.**

50-kHz IF there will be an image frequency 100 kHz from the received signal. In actual operation, there has been no interference from a signal at this image frequency while monitoring PACSATs. In the rare case where there may be interference, you can tune to the opposite sideband, placing the image at a different frequency.

Probably of more importance is that unattenuated noise at the image frequency causes a 3-dB S/N degradation. Although this is clearly not optimal, typical signal variations of polar-orbiting satellites are so large that this loss does not represent a major compromise. A second possible limitation is  $1/f$  noise originating from the diode mixer. But practically all  $1/f$  noise is below 10 kHz. Therefore, PACSAT application, with its 50-kHz IF, is not affected. Even in applications requiring the use of lower frequencies, the receiver's RF amplifier will largely override the  $1/f$  noise.

The IF preamplifier has been left wideband simply as a versatility feature. Although the dynamic ranges of both the mixer and IF preamplifier start to roll over at about the same input levels, a filter between the mixer and preamplifier will help avoid possible overloading effects of unwanted signals that pass through the input filter but are outside the useful passband. For example, a 50-kHz filter (20-kHz bandwidth) will improve the performance of the PACSAT configuration during some interference conditions.

Frequency stability is a major consideration of simple 70-cm local-oscillator design. One influencing factor in this case is that polar-orbiting satellites have total Doppler shifts of up to 20 kHz. This alone requires automatic frequency control—unless you are willing to keep one hand on the tuner! Of course, if AFC can compensate for Doppler, it can also compensate for some drift in the local oscillator.

## CIRCUIT BOARDS

The circuit boards are assembled using a glue-down stripline technique that holds the components and acts as conducting RF links. Using this method, the printed-circuit board foil remains a solid ground-plane, making it appropriate to use a single-sided board. A second feature is that the glued-down pads can be easily removed to accommodate layout changes. The component striplines are about  $1/8$ -inch wide, and the lengths are determined by how many connections are desirable in a single line. The connecting pads are separated by foil notches made with a hacksaw, about  $3/16$ -inch apart or longer, depending upon layout convenience.

The 50- $\Omega$  RF conducting lines are made  $3/32$ -inch wide, assuming the use of standard glass-epoxy 0.059-inch material. The width is different from conventional etched striplines due to the raised glue-down stripline edge effect. In this particular application, the critical RF lines are so short that the type of PC board material is of little consequence. Elmer's Clear Household Cement can be used for fastening the striplines. The cement sets up enough to use the pad in a few minutes. Removal of a pad becomes difficult after setting-up for several weeks or more.

## UHF CIRCUIT BOARD

The possibility of overloading of the preamplifier by off-frequency interference is minimized by first passing the input signals through a three-section stripline filter. It has an insertion loss of 0.7 dB. As shown in Fig 23.59, the filter is easy to build from readily available materials. Although the diagram specifies a Sprague capacitor, which is available from many sources (Digi-Key, for example), there are inexpensive surplus miniature ceramic trimmers that will work fine as long as the minimum capacitance is 2.5 pF or less.

The MAR-6 preamplifier MMIC has a typical gain of 18 dB with a noise figure of 3.0 dB. The critical operating characteristic is the 3.5-V bias voltage (measured at the MMIC output terminal). A 10-V  $V_{CC}$ , together with 430-D series resistors, sets the proper bias to allow the MMIC to operate near its nominal 16-mA current specification. Although chip coupling capacitors are recommended, standard disc ceramics offer little performance compromise. People with poor eyesight will find disc ceramics much easier to use. Two capacitors in parallel reduce possible compromising inductance. The two MMIC ground leads are raised above the board surface using strips of  $1/16$ -inch thick brass to make them level with the input and output leads, which connect to the glue-down striplines.

The SBL 1 mixer is mounted in the conventional manner. Use of a drill to slightly ream each of the eight pin holes to avoid pin contact with the foil allows proper connection to the glue-down striplines. Grounded pins are soldered to the PC board with a small piece of soldering braid over the pin. This permits a relatively easy desoldering procedure if for some reason it becomes necessary to remove the mixer. The LO level into the mixer is monitored by a diode peak-reading detector. The nominal level is 5 mW, or about 0.8 V at TP3.

The LO driver filter is like the input fil-

ter except the input stripline is made shorter and used with a larger value capacitor. This optimizes loading of Q4, the MRF 901 tripler. The LO driver has a maximum output of 20 mW. The output is reduced to the desired level by the drive control, R1, located on the VFO circuit board.

The IF preamplifier is similar to the one described in Campbell's *QST* article. The grounded-base stage, Q5, provides a 50- $\Omega$  load to the mixer and approximately 40 dB of gain. It is followed by an emitter follower to supply a low output impedance.

## VFO CIRCUIT BOARD

See Fig 23.60. The VFO, Q1, is a 24-MHz JFET Colpitts oscillator. It is tuned by a 12-V Zener diode connected to operate like a varactor. It produces approximately a 10-pF capacitance change that provides the desired 436-MHz LO shift of 4 MHz (222-kHz shift at the VFO). The output is taken from the FET drain with a 48-MHz tuned circuit. This doubles the frequency while providing reasonable isolation from the VFO.

Fig 23.61 shows the results of tests made of various VFO components. Fig 23.61 also describes two acceptable component combinations. The dominant temperature-sensitive components are the inductor (L1) and the tuned circuit capacitors (C2, 3, 4). The band-set trimmers (both the capacitors and the variable ferrite), and the varactor are less sensitive. The two recommended combinations have an initial turn-on frequency shift of about 10 kHz during the first 15 minutes of operation. After that the shift is less than 10 kHz. An uncompensated configuration using all mica capacitors together with a Plexiglas coil form has a frequency shift of about 15 kHz per degree change of ambient temperature.

A resistive divider network, shown in Fig 23.62, provides the varactor tuning voltage and an input for the AFC or scanner function. A 12-position switch selects voltage divider resistors having values that compensate for the varactor nonlinearity, resulting in a 300-kHz frequency shift for each position. The voltage for the varactor will vary from 3.7 to 6.6 V or 3.4 to 6.0 V depending on the position of the fine-tuning potentiometer. The AFC/scanner input is nominally biased to 5 V. The frequency can be shifted up to 200 kHz either plus or minus by forcing the bias to 0 or 10 V. The bias resistance is 5 k $\Omega$ .

Two 10-turn potentiometers, one for bandset and the other for fine tuning, are an alternative method. Frequency calibra-

C1—40-pF FILMTRIM (Sprague-Goodman #GYC40000).  
 C2—100-pF silver mica.  
 C3—100-pF polypropylene (Panasonic #ECQ-P1H101JZ).  
 C4—330-pF silver mica.  
 D1—1N4742, 12-V Zener diode (used as a varactor).  
 L2—10 turns #26 wire wound on a 1/4-inch diam form (wood dowel).  
 L3—10 turns #26 wire wound on a 1/4-inch diam form with a 2-turn link coupling coil made from #30 wire-wrapping wire. The twisted pair is about 2 inches long.

L4—5 turns #18 wire, 1/4-inch ID, 5/16-inch long with a 1-turn link coupling coil made from #22 hookup wire. The twisted pair is about 1 inch long.  
 L5—7 turns #18 wire, 1/4 inch ID, 3/8 inch long with a 1-turn link coupling coil made from #22 hookup wire. The twisted pair is about 1.5 inches long.  
 RFC—20 turns #26 wire, 1/16 inch ID. Output coupling to the tripler—about 1 ft of miniature microphone cable (RS 278-510).  
 A—3/8 inch diam Plexiglas rod.

B—7 turns coil #26 gauge wire.  
 C—4 turns coil #26 gauge wire.  
 D—.010-inch diam carpet thread wound with the coil for uniform turn spacing.  
 E—3/16 inch diam holes to hold the coil.  
 F—#4-40 coil mounting stud. It is cemented or threaded into the Plexiglas form.  
 G—Place several lines of clear cement along the coil length (Elmer's Clear Household Cement).

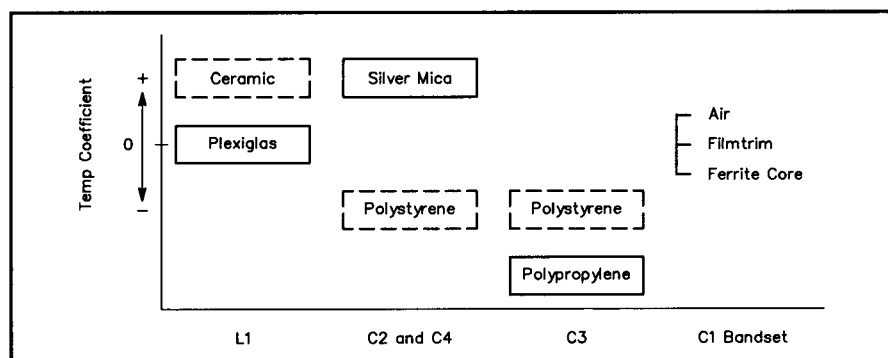

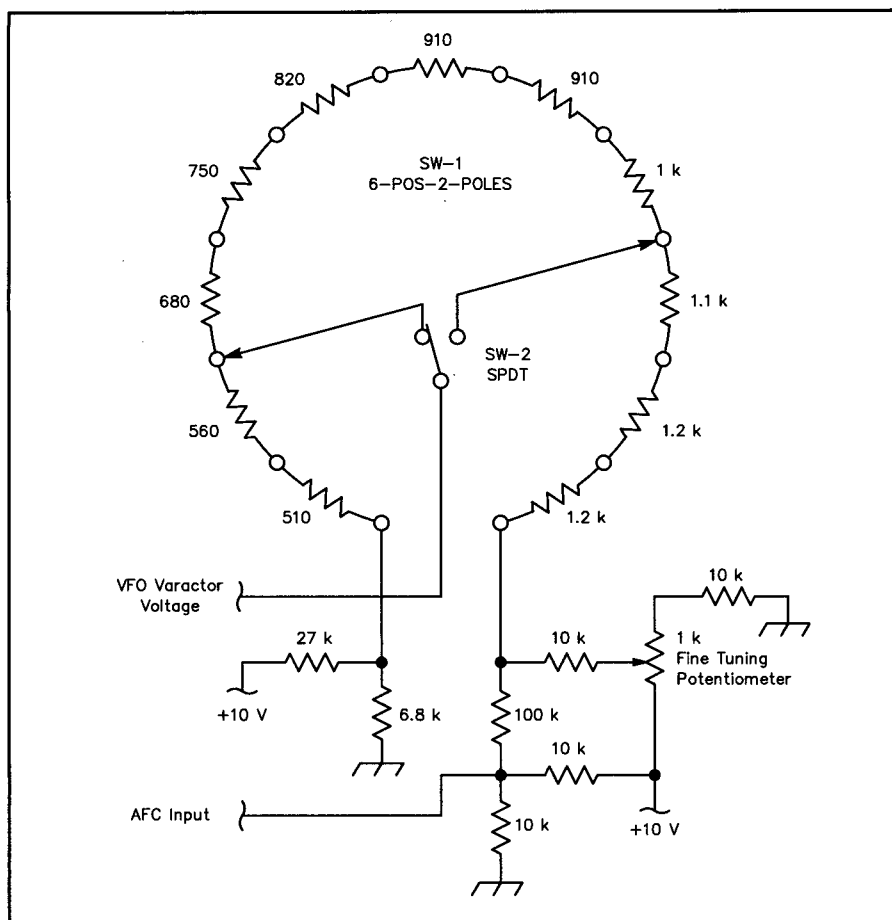

Fig 23.61—Relative temperature coefficients of the VFO components as observed during circuit operation. The solid lines indicate a configuration using a solid Plexiglas coil form and the dashed lines a thin-wall ceramic form. Both configurations will operate continuously for six hours together with a 10° F ambient temperature change with less than a 20-kHz shift in frequency. There is little performance difference between the three types of band-set methods as a function of temperature change.

**Fig 23.62—Schematic of the varactor voltage controller.** There is a 300-kHz frequency shift between each SW-1 position. The fine tuning frequency shift is 500 kHz. The total tuning range is 4 MHz. The AFC input can shift the frequency up to  $\pm 200$  kHz. It is biased to +5 V by a 5-k $\Omega$  resistive divider. Maximum shift occurs when it is forced to 0 or +10 V.

tion is performed simply by monitoring the varactor input voltage with a meter. This method worked very well. It didn't compensate for the nonlinear varactor, but the tuning was fine enough to make that unimportant.

The VFO is followed by an FET tripler and a two-stage MMIC amplifier. The 145-MHz tripler has a maximum output of about 0.5 mW. This level is controlled by varying the FET drain voltage with the potentiometer R1, and monitored by a diode peak detector (TP1). The first MMIC MAR1 stage has a gain of about 18 dB and an output capability of +7 dBm in the VHF region. Its nominal operating current is 17 mA with a bias of 5 V. Although this output is probably enough to drive the LO tripler, the MAR4 was added as a safety factor to allow for circuit performance variations. It has a gain of about 8 dB with an output of +13 dBm. Its nominal operating current is 50 mA with a bias voltage of 6 V. The bias resistors, 300 and 100  $\Omega$ , together with the 10-V source, operate the MMICs close to their nominal values.

There is a relatively high-Q tuned circuit used in the interstage coupling between the two MMICs for filtering out unwanted VFO responses. There are three tuned circuits for this purpose, L4/C6, L5/C7 and L6/C8, to ensure a reasonably pure waveform for driving the LO tripler. Output of the VFO amplifier is monitored by a peak voltmeter at TP2. It is also used to initially align L6/C8. At resonance, TP2 will read a minimum value due to lowering of the load impedance. About one foot of miniature microphone cable is used to connect the amplifier RF output to the UHF circuit board. There is a bit of loss in using this cable, but there is power to spare and cable flexibility is an important consideration.

## ALIGNMENT

The receiver can be aligned using nothing more than a multimeter and a 2-m transceiver. The 2-m receiver permits initial frequency set of the VFO, and the third harmonic of the 2-m transmitter provides a signal for initial test and alignment of the input filter and RF amplifier. The re-

**Table 23.15**

## Procedures for Final Alignment

1. Adjust all capacitors to minimum capacitance except C1, C5 and C8. Set these three at maximum capacitance. Set R1 for maximum VFO output.
  2. Turn the tuner controls for midband response. SW1: pos 6, SW2: low pos. Fine tuning potentiometer: midway point.
  3. Set the 2-m transceiver to 145.33 MHz and arrange conditions such that a rubber duck, or some other pick-up device, can be placed near L1.
  4. Tune the VFO to 24 MHz by decreasing C1 until the VFO is heard on the receiver.
  5. Tune L3/C5 to 48 MHz by decreasing C5 while peaking the 2-m receiver response.
  6. Peak the 146-MHz multiplier response by decreasing C6 while monitoring TP1; it should read about 0.3 V.
  7. Peak the VFO amp response by increasing C7 while monitoring TP2; it should read greater than 1 V.
  8. Peak L6/C8 to 146 MHz by increasing C8 while monitoring TP2; it will null to about 0.8 V.
  9. Peak the LO filter by decreasing C9 while monitoring TP3, then trim the remaining two 5-pF capacitors. TP3 should read about 1.2 V.
  10. Correct the LO mixer input by adjusting R1 on the VFO circuit board for 0.8 V at TP3.
  11. Normalize the IF preamp operation by adjusting R2 to make the dc voltage at TP4 2 V.
  12. Peak the three input filter 5-pF capacitors for maximum response to the 2-m transmitter's third harmonic.
  13. Optimize the S/N by tuning to a marginal input signal that is about +10 dB S/N (transmitter harmonic, noise, etc) and peaking the three filter 5-pF capacitors. S/N alignment requires the receiver input be terminated with a 50- $\Omega$  load.
- Parts Suppliers**
- MMICs—Down East Microwave.  
SBL1—Oak Hills Research.  
Panasonic P-Series Polypropylene capacitors and Sprague-Goodman FILMTRIMs—Digi-Key Corp.  
Silver mica capacitors and ceramic trimmers—All Electronics.  
Plexiglas—Check the Yellow Pages under Plastics.  
Brass—Hobby shops usually stock small sheets of brass in various thicknesses.

quired alignment steps are detailed in **Table 23.15**.

Performance of the compact stripline filter is far from outstanding. However, it does allow me to monitor PACSATs while transmitting into the adjacent 2-m uplink

antenna without interfering with the received signal (for the PACSAT full-duplex mode). The author has concluded that a more complex internal filter would not substantially improve the receiver's performance.

The receiver has been used to copy FM 9600-baud packet from UO-22 and KO-23, and 1200-baud PSK from AO-16. It is a simple assembly that is a pleasure to use.

## Earth-Moon-Earth (EME)

EME communication, also known as "moonbounce," has become a popular form of space communication. The concept is simple: The moon is used as a passive reflector for VHF and UHF signals. With a total path length of nearly 500,000 miles, EME is the ultimate DX. EME is a natural and passive propagation phenomenon, and EME QSOs count toward the WAS, DXCC and VUCC awards. EME opens up the VHF and UHF bands to a new universe of worldwide DX.

The first demonstration of EME capability was done by the US Army Signal Corps just after WW II. In the 1950s, using 400 MW of effective radiated power, the US Navy established a moon relay link between Washington, DC, and Hawaii that could handle four multiplexed Teletype (RTTY) channels. The first successful amateur reception of EME signals occurred in 1953 by W4AO and W3GKP.

It took until 1960 for two-way amateur communications to take place. Using surplus parabolic dish antennas and high-power klystron amplifiers, the Eimac Radio Club, W6HB, and the Rhododendron Swamp VHF Society, W1BU, accomplished this milestone in July 1960 on 1296 MHz. In the 1960s, the first wave of amateur EME enthusiasts established amateur-to-amateur contacts on 144 MHz and 432 MHz. In April 1964, W6DNG and OH1NL made the first 144-MHz EME QSO. 432-MHz EME experimentation was delayed by the 50-W power limit (removed January 2, 1963). Only one month after the first 144-MHz QSO was made, the 1000-ft-diameter dish at Arecibo, Puerto Rico,

was used to demonstrate the viability of 432-MHz EME, when a contact was made between KB4BPZ and W1BU. The first amateur-to-amateur 432-MHz EME QSO occurred in July 1964 between W1BU and KH6UK.

The widespread availability of reliable low-noise semiconductor devices along with significant improvements in Yagi arrays ushered in the second wave of amateur activity in the 1970s. Contacts between stations entirely built by amateurs became the norm instead of the exception. In 1970, the first 220- and 2304-MHz EME QSOs were made, followed by the first 50-MHz EME QSO in 1972. 1970s activity was still concentrated on 144 and 432 MHz, although 1296-MHz activity grew.

As the 1980s approached, another quantum leap in receive performance occurred with the use of GaAsFET preamplifiers. This, and improvements in Yagi performance (led by DL6WU's log-taper design work), and the new US amateur power output limit of 1500 W have put EME in the grasp of most serious VHF and UHF operators. The 1980s saw 144- and 432-MHz WAS and WAC become a reality for a great number of operators. The 1980s also witnessed the first EME QSOs on 3456 MHz and 5760 MHz (1987), followed by EME QSOs on 902 MHz and 10 GHz (1988).

EME is still primarily a CW mode. As stations have improved, SSB is now more popular. Regardless of the transmission

Tommy Henderson, WD5AGO, pursues 144-MHz EME from his Tulsa, Oklahoma, QTH with this array. Local electronics students helped with construction.

**Fig 23.63 — Variations in EME path loss can be determined from this graph. SD refers to semi-diameter of the moon, which is indicated for each day of the year in *The Nautical Almanac*.**

mode, successful EME operating requires:

- 1) As close to the legal power output as possible.
- 2) A fairly large array (compared to OSCAR antennas).
- 3) Accurate azimuth and elevation rotation.
- 4) Minimal transmission-line losses.
- 5) A low system noise figure, preferably with the preamplifier mounted at the array.

### Choosing an EME Band

Making EME QSOs is a natural progression for many weak-signal terrestrial operators. Looking at EME path loss vs frequency (Fig 23.63), it may seem as if the lowest frequency is best, because of reduced path loss. This is not entirely true. The path-loss graph does not account for the effects of cosmic and man-made noise, nor does it relate the effects of ionospheric scattering and absorption. Both short- and long-term fading effects also must be overcome.

50-MHz EME is quite a challenge, as the required arrays are very large. In addition, sky noise limits receiver sensitivity at this frequency. Because of power and licensing restrictions, it is not likely that many foreign countries will be able to get on 50-MHz EME.

144 MHz is probably the easiest EME band to start on. It supports the largest number of EME operators. Commercial equipment is widely available; a 144-MHz EME station can almost be completely assembled from off-the-shelf equipment. 222 MHz is a good frequency for EME, but there are only a handful of active stations, and 222 MHz is available only

in ITU Region 2.

432 MHz is the most active EME band after 144 MHz. Libration fading (see Fig 23.118) is more of a problem than at 144 MHz, but sky noise is more than an order of magnitude less than on 144 MHz. The improved receive signal-to-noise ratio may more than make up for the more rapid fading. However, 432-MHz activity is most concentrated into the one or two weekends a month when conditions are expected to be best.

902 MHz and above should be considered if you primarily enjoy experimenting and building equipment. If you plan to operate at these frequencies, an unobstructed moon window is a must. The antenna used is almost certain to be a dish. 902 MHz has the same problem that 222 MHz has — it's not an international band. Equipment and activity are expected to be limited for many years.

1296 MHz currently has a good amount of activity from all over the world. Recent equipment improvements indicate 1296 MHz should experience a significant growth in activity over the next few years. 2300 MHz has received renewed interest. It suffers from nonaligned international band assignments and restrictions in different parts of the world.

### Antenna Requirements

The tremendous path loss incurred over the EME circuit requires a high-power transmitter, a low-noise receiver and a high-performance antenna array. Although single-Yagi QSOs are possible, most new EME operators will rapidly become frustrated unless they are able to

work many different stations on a regular basis. Because of libration fading and the nature of weak signals, a 1- or 2-dB increase in array gain will often be perceived as being much greater. An important antenna parameter in EME communications is the antenna noise temperature. This refers to the amount of noise received by the array. The noise comes from cosmic noise (noise generated by stars other than the sun), Earth noise (thermal noise radiated by the Earth), and noise generated by man-made sources such as power-line leaks and other broadband RF sources.

Yagi antennas are almost universally used on 144 MHz. Although dish antennas as small as 24 ft in diameter have been successfully used, they offer poor gain-to-size trade-offs at 144 MHz. The minimum array gain for reliable operation is about 18 dBd (20.1 dBi). The minimum array gain should also allow a station to hear its own echoes on a regular basis. This is possible by using four 2.2-λ Yagis. The 12-element 2.5-λ Yagi described in the **Antennas and Projects** chapter is an excellent choice. When considering a Yagi design, you should avoid old-technology Yagis, that is, designs that use either constant-width spacings, constant-length directors or a combination of both. These old-design Yagis will have significantly poorer side lobes, a narrower gain bandwidth and a sharper SWR bandwidth than modern log-taper designs. Modern wide-band designs will behave much more predictably when stacked in arrays, and, unlike many of the older designs, will deliver close to 3 dB of stacking gain.

222-MHz requirements are similar to those of 144 MHz.

Although dish antennas are somewhat more practical, Yagis still predominate. The 16-element 3.8-λ Yagi described in the **Antennas and Projects** chapter is a good building block for 222-MHz EME. Four of these Yagis are adequate for a minimal 222-MHz EME station, but six or eight will provide a much more substantial signal.

At 432 MHz, parabolic-dish antennas become viable. The minimum gain for reliable 432-MHz EME operation is 24 dBi.

Yagis are also used on 432 MHz. The 22-element Yagi described in the **Antennas and Projects** chapter is an ideal 432-MHz design. Four of the 22-element Yagis meet the 24-dBi-gain criteria, and have been used successfully on EME. If you are going to use a fixed polarization Yagi array, you should plan on building an array with substantially more than 24-dBi gain if you desire reliable contacts with small stations. This extra gain is needed to overcome polarization misalignment.

At 902 MHz and above, the only antenna worthy of consideration is a parabolic dish. While it has been proven that Yagi antennas are capable of making EME QSOs at 1296 MHz, Yagi antennas, whether they use rod or loop elements, are simply not practical.

EME QSOs have been made at 1296 MHz with dishes as small as 6 ft in diameter. For reliable EME operation with similarly equipped stations, a 12-ft diameter dish (31 dBi gain at 1296 MHz) is a practical minimum. TVRO dishes, which are designed to operate at 3 GHz make excellent antennas, provided they have an accurate surface area. The one drawback of TVRO dishes is that they usually have an undesirable F/d ratio. More information on dish construction and feeds can be found in *The ARRL Antenna Book* and *The ARRL UHF/Microwave Experimenter's Manual*.

### Polarization Effects

All of the close attention paid to operating at the best time, such as nighttime perigee, with high moon declination and low sky temperatures is of little use if signals are not aligned in polarization between the two stations attempting to make contact. There are two basic polarization effects. The first is called spatial polarization. Simply stated, two stations (using az-el mounts and fixed linear polarization) that are located far apart, will usually not have their arrays aligned in polarization as seen by the moon. Spatial polarization can easily be predicted, given the location of both stations and the position of the moon.

The second effect is Faraday rotation. This is an actual rotation of the radio waves in space, and is caused by the charge level of the Earth's ionosphere. At 1296 MHz and above, Faraday rotation is virtually nonexistent. At 432 MHz, it is believed that up to a 360° rotation is common. At 144 MHz, it is believed that the wavefront can actually rotate seven or more complete 360° revolutions. When Faraday rotation is combined with spatial polarization, there are four possible results:

- 1) Both stations hear each other and can QSO.
- 2) Station A hears station B, station B does not hear station A.
- 3) Station B hears station A, station A does not hear station B.
- 4) Neither station A nor station B hear each other.

At 144 MHz, there are so many revolutions of the signal, and the amount of Faraday rotation changes so fast that, generally, hour-long schedules are arranged. At

432 MHz, Faraday rotation can take hours to change. Because of this, half-hour schedules are used. During the daytime, you can count on 90 to 180° of rotation. If both stations are operating during hours of darkness, there will be little Faraday rotation, and the amount of spatial polarization determines if a schedule should be attempted.

At 1296 MHz and above, circular polarization is standard.

The predominant array is a parabolic reflector, which makes circular polarization easy to obtain. Although the use of circular polarization would make one expect signals to be constant, except for the effect of the moon's distance, long-term fading of 6 to 9 dB is frequently observed.

With improved long-Yagi designs, for years the solution to overcoming polarization misalignment has been to make the array larger. Making your station's system gain 5 or 6 dB greater than required for minimal EME QSOs will allow you to work more stations, simply by moving you farther down the polarization loss curve. After about 60° of misalignment, however, making your station large enough to overcome the added losses quickly becomes a lifetime project! See Fig 23.64.

At 432 MHz and lower, Yagis are widely used, making the linear polarization standard. Although circular polarization may seem like a simple solution to polarization problems, when signals are reflected off the moon, the polarization sense of circularly polarized radio wave is reversed, requiring two arrays of opposite polarization sense be used. Initially, crossed Yagis with switchable polarization may also look attractive. Unfortunately, 432-MHz Yagis are physically small enough that the extra feed lines and switching devices become

complicated, and usually adversely affect array performance. Keep in mind that even at 144 MHz, Yagis cannot tolerate metal mounting masts and frames in line with the Yagi elements.

When starting out on EME, keep in mind that it is best to use a simple system. You will still be able to work many of the larger fixed-polarization stations and those who have polarization adjustment (only one station needs to have polarization control). Once you gain understanding and confidence in your simple array, a more complex array such as one with polarization rotation can be attempted.

### Receiver Requirements

A low-noise receiving setup is essential for successful EME work. Many EME signals are barely, but not always, out of the noise. To determine actual receiver performance, any phasing line and feed line losses, along with the noise generated in the receiver, must be added to the array noise reception. When all losses are considered, a system noise figure of 0.5 dB (35 K) will deliver about all the performance that can be used at 144 MHz, even when low-loss phasing lines and a quiet array are used.

The sky noise at 432 MHz and above is low enough (cold sky is <15 K (kelvins) at 432 MHz, and 5 K at 1296 MHz) so the lowest possible noise figure is desired. Current high-performance arrays will have array temperatures near 30 K when unwanted noise pickup is added in. Phasing line losses must also be included, along with any relay losses. Even at 432 MHz, it is impossible to make receiver noise insignificant without the use of a liquid-cooled preamplifier. Current technology gives a minimum obtainable GaAsFET preampli-

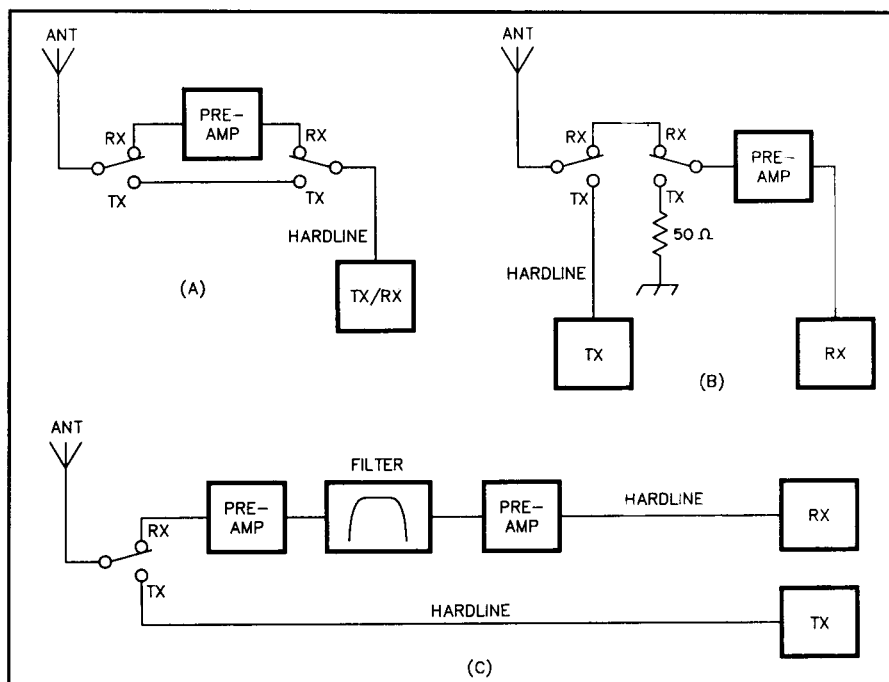

Fig 23.64 — The graph shows how quickly loss because of polarization misalignment increases after 45°. The curve repeats through 360°, showing no loss at 0° and maximum loss at 90° and 270°.

**Fig 23.65 — Two systems for switching a preamplifier in and out of the receive line. At A, a single length of cable is used for both the transmit and receive line. At B is a slightly more sophisticated system that uses two separate transmission lines. At C, a high-isolation relay is used for TR switching. The energized position is normally used on receive.**

fier noise figure, at room temperature, of about 0.35 dB (24 K). See Fig 23.65.

GaAsFET preamps have also been standard on 1296 MHz and above for several years. Noise figures range from about 0.4 dB at 1296 MHz (30 K) to about 2 dB (170 K at 10 GHz). HEMT devices are now available to amateurs, but are of little use below 902 MHz because of  $1/f$  noise. At higher frequencies, HEMT devices have already shown impressively low noise figures. Current HEMT devices are capable of noise figures close to 1.2 dB at 10 GHz (93 K) without liquid cooling.

At 1296 MHz, a new noise-limiting factor appears. The physical temperature of the moon is 210 K. This means that just like the Earth, it is a black-body radiator. The additional noise source is the reflection of sun noise off the moon. Just as a full moon reflects sunlight to Earth, the rest of the electromagnetic spectrum is also reflected. On 144 and 432 MHz, the beamwidth of a typical array is wide enough ( $15^\circ$  is typical for 144 MHz,  $7^\circ$  for 432 MHz) that the moon, which subtends a  $0.5^\circ$  area is small enough to be insignificant in the array's pattern. At 1296 MHz, beamwidths approach  $2^\circ$ , and moon-noise figures of up to 5 dB are typical at full moon. Stations operating at 2300 MHz and above have such narrow array patterns that many operators actually use moon noise

to assure that their arrays are pointed at the moon!

A new weak-signal operator is encouraged to experiment with receivers and filters. A radio with passband tuning or IF-shift capability is desired. These features are used to center the passband and the pitch of the CW signal to the frequency at which the operator's ears perform best. Some operators also use audio filtering. Audio filtering is effective in eliminating high-frequency noise generated in the radio's audio or IF stages. This noise can be very fatiguing during extended weak signal operation. The switched-capacitor audio filter has become popular with many operators.

### Transmitter Requirements

Although the maximum legal power (1500 W out) is desirable, the actual power required can be considerably less, depending on the frequency of operation and size of the array. Given the minimum array gain requirements previously discussed, the power levels recommended for reasonable success are shown in Table 23.16.

The amplifier and power supply should be constructed with adequate cooling and safety margins to allow extended slow-speed CW operation without failure. The transmitter must also be free from drift and chirp. The CW note must be pure and properly shaped. Signals that drift and chirp

**Table 23.16**

### Transmitter Power Required for EME Success

*Power at the array*

50 MHz	1500 W
144 MHz	1000 W
222 MHz	750 W
432 MHz	500 W
902 MHz	200 W
1296 MHz	200 W
2300 MHz and above	100 W

are harder to copy. They are especially annoying to operators who use narrow CW filters. A stable, clean signal will improve your EME success rate.

### Calculating EME Capabilities

Once all station parameters are known, the expected strength of the moon echoes can be calculated given the path loss for the band in use (see Fig 23.61). The formula for the received signal-to-noise ratio is:

$$S/N = P_o - L_t + G_t - P_l + G_r - P_n \quad (1)$$

where

$P_o$  = transmitter output power (dBW)

$L_t$  = transmitter feed-line loss (dB)

$G_t$  = transmitting antenna gain (dBi)

$P_l$  = total path loss (dB)

$G_r$  = receiving antenna gain (dBi)

$P_n$  = receiver noise power (dBW).

Receiver noise power,  $P_n$ , is determined by the following:

$$P_n = 10 \log_{10} KBT_s \quad (2)$$

where

$K = 1.38 \times 10^{-23}$  (Boltzmann's constant)

$B$  = bandwidth (Hz)

$T_s$  = receiving system noise temperature (K).

Receiving system noise temperature,  $T_s$ , can be found from:

$$T_s = T_a + (L_r - 1) T_l + L_r T_r \quad (3)$$

where

$T_a$  = antenna temperature (K)

$L_r$  = receiving feed-line loss (ratio)

$T_l$  = physical temperature of feed line (normally 290 K)

$T_r$  = receiver noise temperature (K).

An example calculation for a typical 432-MHz EME link is:

$P_o = +30$  dBW (1000 W)

$L_t = 1.0$  dB

$G_t = 26.4$  dBi ( $8 \times 6.1\text{-}\lambda$  22-el Yagis)

$P_l = 262$  dB

$G_r = 23.5$  dBi (15 ft parabolic)

$T_a = 60$  K

$L_r = 1.02$  (0.1-dB preamp at antenna)

$T_l = 290$  K

$T_r = 35.4$  K (NT = 0.5 dB)

**Fig 23.66 — Parabolic-antenna gain vs size, frequency and surface errors. All curves assumed 60% aperture efficiency and 10-dB power taper. Reference: J. Ruze, British IEEE.**

$T_s = 101.9 \text{ K}$   
 $P_n = -188.5 \text{ dB}$   
 $S/N = +5.4 \text{ dB}$

It is obvious that EME is no place for a compromise station. Even relatively sophisticated equipment provides less-than optimum results.

Fig 23.66 gives parabolic dish gain for a perfect dish. The best Yagi antennas will not exceed the gain curve shown in the **Antennas and Projects** chapter. If you are using modern, log-taper Yagis, properly spaced, figure about 2.8 to 2.9 dB of stacking gain. For old-technology Yagis, 2.5 dB may be closer to reality. Any phasing line and power divider losses must also be subtracted from the array gain.

### Locating the Moon

The moon orbits the Earth once in approximately 28 days, a lunar month. Because the plane of the moon's orbit is tilted from the Earth's equatorial plane by approximately  $23.5^\circ$ , the moon swings in a sine-wave pattern both north and south of the equator. The angle of departure of the moon's position at a given time from the equatorial plane is termed declination (abbreviated decl). Declination angles of the moon, which are continually changing (a few degrees a day), indicate the latitude on the Earth's surface where the moon will be at zenith. For this presentation, positive declination angles are used when the moon is north of the equator, and negative angles when south.

The longitude on the Earth's surface where the moon will be at zenith is related to the moon's Greenwich Hour Angle, abbreviated G.H.A. or GHA. "Hour angle" is defined as the angle in degrees to the west of the meridian. If the GHA of the moon were  $0^\circ$ , it would be directly over the Greenwich meridian. If the moon's GHA were  $15^\circ$ , the

moon would be directly over the meridian designated as  $15^\circ \text{ W}$  longitude on a globe. As one can readily understand, the GHA of the moon is continually changing, too, because of both the orbital velocity of the moon and the Earth's rotation inside the moon's orbit. The moon's GHA changes at the rate of approximately  $347^\circ$  per day.

GHA and declination are terms that may be applied to any celestial body. *The Astronomical Almanac* (available from the Superintendent of Documents, US Government Printing Office) and other publications list the GHA and decl of the sun and moon (as well as for other celestial bodies that may be used for navigation) for every hour of the year. This information may be used to point an antenna when the moon is not visible. *Almanac* tables for the sun may be useful for calibrating remote-readout systems.

### Using the Almanac

*The Astronomical Almanac* and other almanacs show the GHA and declination of the sun or moon at hourly intervals for every day of the period covered by the book. Instructions are included in such books for interpolating the positions of the sun or moon for any time on a given date. The orbital velocity of the moon is not constant, and therefore precise interpolations are not linear.

Fortunately, linear interpolations from one hour to the next, or even from one day to the next, will result in data that is entirely adequate for Amateur Radio purposes. If linear interpolations are made from 0000 UTC on one day to 0000 UTC on the next, worse-case conditions exist when apogee or perigee occurs near midday on the next date in question. Under such conditions, the total angular error in the position of the moon may be as much

as a sixth of a degree. Because it takes a full year for the Earth to orbit the sun, the similar error for determining the position of the sun will be no more than a few hundredths of a degree.

If a polar mount (a system having one axis parallel to the Earth's axis) is used, information from the *Almanac* may be used directly to point the antenna array. The local hour angle (LHA) is simply the GHA plus or minus the observer's longitude (plus if east longitude, minus if west). The LHA is the angle west of the observer's meridian at which the celestial body is located. LHA and declination information may be translated to an EME window by taking local obstructions and any other constraints into account.

### Azimuth and Elevation

An antenna system that is positioned in azimuth (compass direction) and elevation (angle above the horizon) is called an *az-el* system. For such a system, some additional work will be necessary to convert the almanac data into useful information. The GHA and decl information may be converted into azimuth and elevation angles with the mathematical equations that follow. A calculator or computer that treats trigonometric functions may be used. **CAUTION:** Most almanacs list data in degrees, minutes, and either decimal minutes or seconds. Computer programs generally require this information in degrees and decimal fractions, so a conversion may be necessary before the almanac data is entered.

Determining az-el data from equations follows a procedure similar to calculating great-circle bearings and distances for two points on the Earth's surface. There is one additional factor, however. Visualize two observers on opposite sides of the Earth who are pointing their antennas at the moon. Imaginary lines representing the boresights of the two antennas will converge at the moon at an angle of approximately  $2^\circ$ . Now assume both observers aim their antennas at some distant star. The boresight lines now may be considered to be parallel, each observer having raised his antenna in elevation by approximately  $1^\circ$ . The reason for the necessary change in elevation is that the Earth's diameter in comparison to its distance from the moon is significant. The same is not true for distant stars, or for the sun.

Equations for az-el calculations are:

$$\sin E = \sin L \sin D + \cos L \cos D \cos \text{LHA} \quad (4)$$

$$\tan F = \frac{\sin E - K}{\cos E} \quad (5)$$

$$\cos C = \frac{\sin D - \sin E \sin L}{\cos E \cos L} \quad (6)$$

where

E = elevation angle for the sun

L = your latitude (negative if south)

D = declination of the celestial body

LHA = local hour angle = GHA plus or minus your longitude (plus if east longitude, minus if west longitude)

F = elevation angle for the moon

K = 0.01657, a constant (see text that follows)

C = true azimuth from north if sin LHA is negative; if sin LHA is positive, then the azimuth = 360 - C.

Assume our location is 50° N latitude, 100° W longitude. Further assume that the GHA of the moon is 140° and its declination is 10°. To determine the az-el information we first find the LHA, which is 140 minus 100 or 40°. Then we solve equation 4:

$$\sin E = \sin 50 \sin 10 + \cos 50 \cos 10 \cos 40$$

$$\sin E = 0.61795 \text{ and } E = 38.2^\circ$$

Solving equation 5 for F, we proceed. (The value for sin E has already been determined in equation 4.)

$$\tan F = \frac{0.61795 - 0.06175}{\cos 38.2}$$

$$= 0.76489$$

From this, F, the moon's elevation angle, is 37.4°.

We continue by solving equation 6 for C. (The value of sin E has already been determined.)

$$\cos C = \frac{\sin 10 - 0.61795 \sin 50}{\cos 38.2 \cos 50}$$

$$= 0.59308$$

C therefore equals 126.4°. To determine if C is the actual azimuth, we find the polarity for sin LHA, which is sin 40° and has a positive value. The actual azimuth then is 360 - C = 233.6°.

If az-el data is being determined for the sun, omit equation 5; equation 5 takes into account the nearness of the moon. The solar elevation angle may be determined from equation 4 alone. In the above example, this angle is 38.2°.

The mathematical procedure is the same for any location on the Earth's surface. Remember to use negative values for southerly latitudes. If solving equation 4 or 5 yields a negative value for E or F, this indicates the celestial body below the horizon.

These equations may also be used to determine az-el data for man-made satel-

lites, but a different value for the constant, K, must be used. K is defined as the ratio of the Earth's radius to the distance from the Earth's center to the satellite.

The value for K as given above, 0.01657 is based on an average Earth-moon distance of 239,000 miles. The actual Earth-moon distance varies from approximately 225,000 to 253,000 mi. When this change in distance is taken into account, it yields a change in elevation angle of approximately 0.1° when the moon is near the horizon. For greater precision in determining the correct elevation angle for the moon, the moon's distance from the Earth may be taken as:

$$D = -15,074.5 \times SD + 474,332$$

where

D = moon's distance in miles

SD = moon's semi-diameter, from the almanac.

### Computer Programs

As has been mentioned, a computer may be used in solving the equations for azimuth and elevation. For EME work, it is convenient to calculate az-el data at 30-minute intervals or so, and to keep the results of all calculations handy during the EME window. Necessary antenna-position corrections can then be made periodically.

A BASIC language program for the IBM PC is available from the ARRL Technical Secretary. Request the '95 *Handbook* EME template. This program provides azimuth and elevation information for half-hour intervals during a UTC day when the celestial body is above the horizon. The program makes a linear interpolation of GHA and declination values (discussed earlier) during the period of the UTC day.

Commercial, shareware and public-domain tracking programs are also available. See the **References** chapter for a list of some available programs. *RealTrak* prints out antenna azimuth and elevation headings for nearly any celestial object. It can be used with the Kansas City Tracker program described in the satellite section to track celestial objects automatically. *VHF PAK* provides real-time moon and celestial object position information. Two other real-time tracking programs are *EME Tracker* and the *VK3UM EME Planner*.

### Libration Fading of EME Signals

One of the most troublesome aspects of receiving a moonbounce signal, besides the enormous path loss and Faraday rotation fading, is libration fading. This section will deal with libration (pronounced *lie-brayshun*) fading, its cause and effects,

and possible measures to minimize it.

Libration fading of an EME signal is characterized in general as fluttery, rapid, irregular fading not unlike that observed in tropospheric scatter propagation. Fading can be very deep, 20 dB or more, and the maximum fading will depend on the operating frequency. At 1296 MHz the maximum fading rate is about 10 Hz, and, scales directly with frequency.

On a weak CW EME signal, libration fading gives the impression of a randomly keyed signal. In fact on very slow CW telegraphy the effect is as though the keying is being done at a much faster speed. On very weak signals only the peaks of libration fading are heard in the form of occasional short bursts or "pings."

Fig 23.67 shows samples of a typical EME echo signal at 1296 MHz. These recordings, made at W2NFA, show the wild fading characteristics with sufficient S/N ratio to record the deep fades. Circular polarization was used to eliminate Faraday fading; thus these recordings are of libration fading only. The recording bandwidth was limited to about 40 Hz to minimize the higher sideband-frequency components of libration fading that exist but are much smaller in amplitude. For those who would like a better statistical description, libration fading is Raleigh distributed. In the recordings shown in Fig 23.63, the average signal-return level computed from path loss and mean reflection coefficient of the moon is at about the +15 dB S/N level.

It is clear that enhancement of echoes far in excess of this average level is observed. This point should be kept clearly in mind when attempting to obtain echoes or receive EME signals with marginal equipment. The probability of hearing an occasional peak is quite good since random enhancement as much as 10 dB is possible. Under these conditions, however, the amount of useful information that can be copied will be near zero. Enthusiastic newcomers to EME communications will be stymied by this effect since they know they can hear the signal strong enough on peaks to copy but can't make any sense out of what they try to copy.

What causes libration fading? Very simply, multipath scattering of the radio waves from the very large (2000-mile diameter) and rough moon surface combined with the relative motion between Earth and moon called librations.

To understand these effects, assume first that the Earth and moon are stationary (no libration) and that a plane wave front arrives at the moon from your Earthbound station as shown in Fig 23.68A.

The reflected wave shown in Fig 23.68B

Fig 23.67 — Chart recording of moon echoes received at W2FNA on July 26, 1973, at 1630 UTC. Antenna gain 44 dBi, transmitting power 400 W and system temperature 400 K.

Fig 23.68 — How the rough surface of the moon reflects a plane wave as one having many field vectors.

Fig 23.69 — The moon appears to "wander" in its orbit about the Earth. Thus a fixed marker on the moon's surface will appear to move about in a circular area.

consists of many scattered contributions from the rough moon surface. It is perhaps easier to visualize the process as if the scattering were from many small individual flat mirrors on the moon that reflect small portions (amplitudes) of the incident wave energy in different directions (paths) and with different path lengths (phase). Those paths directed toward the moon arrive at your antenna as a collection of small wave fronts (field vectors) of various amplitudes and phases. The vector summation of all these coherent (same frequency) returned waves (and there is a near-infi-

nite array of them) takes place at the feed-point of your antenna (the collecting point in your antenna system). The level of the final summation as measured by a receiver can, of course, have any value from zero to some maximum. Remember that we assumed the Earth and moon were stationary, which means that the final summation of these multipath signal returns from the moon will be one fixed value. The condition of zero relative motion between Earth and moon is a rare event that will be discussed later in this section.

Consider now that the Earth and moon are moving relative to each other (as they are in nature), so the incident radio wave "sees" a slightly different surface of the moon from moment to moment. Since the lunar surface is very irregular, the reflected wave will be equally irregular, changing in amplitude and phase from moment to moment. The resultant continuous summation of the varying multipath signals at your antenna feed-point produces the effect called libration fading of the moon-reflected signal.

The term *libration* is used to describe small perturbations in the movement of celestial bodies. Each libration consists mainly of its diurnal rotation; moon libration consists mainly of its 28-day rotation which appears as a very slight rocking motion with respect to an observer on Earth. This rocking motion can be visualized as follows: Place a marker on the surface of the moon at the center of the moon disc, which is the point closest to the observer, as shown in Fig 23.69. Over time, we will observe that this marker wanders around within a small area. This means the surface of the moon as seen from the Earth

is not quite fixed but changes slightly as different areas of the periphery are exposed because of this rocking motion. Moon libration is very slow (on the order of  $10^{-7}$  radians per second) and can be determined with some difficulty from published moon ephemeris tables.

Although the libration motions are very small and slow, the larger surface area of the moon has nearly an infinite number of scattering points (small area). This means that even slight geometric movements can alter the total summation of the returned multipath echo by a significant amount. Since the librations of the Earth and moon are calculable, it is only logical to ask if there ever occurs a time when the total libration is zero or near zero. The answer is yes, and it has been observed and verified experimentally on radar echoes that minimum fading rate (not depth of fade) is coincident with minimum total libration. Calculation of minimum total libration is at best tedious and can only be done successfully by means of a computer. It is a problem in extrapolation of rates of change in coordinate motion and in small differences of large numbers.

## EME OPERATING TECHNIQUES

Many EME signals are near the threshold of readability, a condition caused by a combination of path loss, Faraday rotation and libration fading. This weakness and unpredictability of the signals has led to the development of techniques for the exchange of EME information that differ from those used for normal terrestrial work. The fading of EME signals chops dashes into pieces and renders strings of dots incomplete. This led to the use of the

**Table 23.17****Signal Reports Used on 144-MHz EME**

SK	— End of contact

"T M O R" reporting system. Different, but similar, systems are used on the low bands (50 and 144 MHz) and the high bands (432 MHz and above). **Tables 23.17** and **23.18** summarize the differences between the two systems.

As equipment and techniques have improved, the use of normal RST signal reports has become more common. It is now quite common for two stations working for the first time to go straight to RST reports if signals are strong enough. These normal reports let stations compare signals from one night to the next. EME QSOs are often made during the ARRL VHF contests. These contacts require the exchange of 4-digit grid locators. On 432 MHz and above, the sending of GGGG has come to mean "Please send me your grid square," or conversely, "I am now going to send my grid square."

The length of transmit and receive periods is also different between the bands. On 50 and 144 MHz, 2-minute sequences are used. That is, stations transmit for two full minutes, and then receive for two full minutes. One-hour schedules are used, with the eastern-most station (referenced to the international date line) transmitting first. **Table 23.19** gives the 2-minute sequence procedure. On 222 MHz, both the

144 and 432-MHz systems are used.

On 432 MHz and above, 2½-minute sequences are standard.

The longer period is used to let stations with variable polarization have adequate time to peak the signal. The last 30 seconds is reserved for signal reports only.

**Table 23.20** provides more information on the 432-MHz EME QSO sequence. The western-most station usually transmits first. However, if one of the stations has variable polarization, it may elect to transmit second, to take the opportunity to use the first sequence to peak the signal. If both stations have variable polarization, the station that transmits first should leave its polarization fixed on transmit, to avoid "polarization chasing."

CW sending speed is usually in the 10 to 13-wpm range. It is often best to use greater-than-normal spacing between individual dits and dahs, as well as between complete letters. This helps to overcome libration fading effects. The libration fading rate will be different from one band to another. This makes the optimum CW speed for one band different from another. Keep in mind that characters sent too slowly will be chopped up by typical EME fading. Morse code sent too fast will simply be jumbled. Pay attention to the sending practices of the more successful stations, and try to emulate them.

Doppler shift must also be understood. As the moon rises or sets it is moving toward or away from objects on Earth. This leads to a frequency shift in the moon echoes. The amount of Doppler shift is directly proportional to frequency. At 144 MHz, about 500 Hz is the maximum shift. On 432 MHz, the maximum shift is 1.5 kHz. The shift is upward on moonrise and downward on moonset. When the moon is due south, your own echoes will have no Doppler shift, but stations located far away will still be affected. For scheduling, the accepted practice is to transmit zero beat on the schedule frequency, and tune to compensate for the Doppler shift. Be careful—most transmitters and transceivers have a built-in CW offset. Some radios read this offset when transmitting, and others don't. Find out how your transmitter operates and compensate as required.

Random operation has become popular in recent years. In the ARRL EME contest, many of the big guns will not even accept schedules during the contest periods, because they can slow down the pace of their contest contacts.

**EME Operating Times**

Obviously, the first requirement for EME operation is to have the moon visible by both EME stations. This requirement not only consists of times when the moon is above the horizon, but when it is actually clear of obstructions such as trees and buildings. It helps to know your exact EME operating window, specified in the form of beginning and ending GHAs (Greenwich Hour Angle) for different moon declinations. This information allows two different stations to quickly determine if they can simultaneously see the moon.

Once your moon window is determined, the next step is to decide on the best times during that window to schedule or operate. Operating at perigee is preferable because of the reduced path loss. Fig 23.61 shows that not all perigees are equal. There is about a 0.6-dB difference between the closest and farthest perigee points. The next concern is operating when the moon is in a quiet spot of the sky. Usually, northern declinations are preferred, as the sky is quietest at high declinations. If the moon is too close to the sun, your array will pick up sun noise and reduce the sensitivity off your receiver. Finally, choosing days with minimal libration fading is also desirable.

Perigee and apogee days can be determined from the *Astronomical Almanac* by inspecting the tables headed "S.D." (semi-diameter of the moon in minutes of arc). These semi-diameter numbers can be compared to Fig 23.63 to obtain the approximate moon distance. Many computer programs for locating the moon now give the moon's distance. The expected best weekends to operate on 432 MHz and the higher bands are normally printed well in advance in various EME newsletters.

When the moon passes through the galactic plane, sky temperature is at its maximum. Even on the higher bands this is one

**Table 23.19****144-MHz Procedure — 2-Minute Sequence**

Period	1½ minutes	30 seconds
1	Calls (W6XXX DE W1XXX)	
2	W1XXX DE W6XXX	TTTT

of the least desirable times to operate. The areas of the sky to avoid are the constellations of Orion and Gemini (during northern declinations), and Sagittarius and Scorpius (during southern declinations). The position of the moon relative to these constellations can be checked with information supplied in the *Astronomical Almanac* or *Sky and Telescope* magazine.

### Frequencies and Scheduling

According to the ARRL-sponsored band plan, the lower edge of most bands is reserved for EME operation. On 144 MHz, EME frequencies are primarily between 144.000 and 144.080 MHz for CW, and 144.100 and 144.120 MHz for SSB. Random CW activity is usually between 144.000 and 144.020 MHz. In the US, 144.000 to 144.100 MHz is a CW subband, so SSB QSOs often take place by QSYing up 100 kHz after a CW contact has been established. Because of the large number of active 144-MHz stations, coordinating schedules in the small EME window is not simple. The more active stations usually have assigned fre-

quencies for their schedules.

On 432 MHz, the international EME CW calling frequency is 432.010 MHz. Random SSB calling is done on 432.015 MHz. Random activity primarily takes place between 432.000 and 432.020 MHz. The greater Doppler shift on 432 MHz requires greater separation between schedule frequencies than on 144 MHz. Normally 432.000 MHz, 432.020 MHz and each 5-kHz increment up to 432.070 MHz are used for schedules.

Activity on 1296 MHz is centered between 1296.000 and 1296.040 MHz. The random calling frequency is 1296.010 MHz. Operation on the other bands requires more specific coordination. Activity on 33 cm is split between 902 and 903 MHz. Activity on 2300 MHz has to accommodate split-band procedures because of the different band assignments around the world.

### EME Net Information

An EME net meets on 14.345 MHz on weekends for the purpose of arranging

schedules and exchanging EME information. The net meets at 1600 UTC. OSCAR satellites are becoming more popular for EME information exchange. When Mode B is available, a downlink frequency of 145.950 MHz is where the EME group gathers. On Mode L and Mode JL, the downlink frequency is 435.975 MHz.

### Other Modes

Most EME contacts are still made on CW, although SSB has gained in popularity and it is now common to hear SSB QSOs on any activity weekend. The ability to work SSB can easily be calculated from Eq 1. The proper receiver bandwidth (2.3 kHz) is substituted. SSB usually requires a +3-dB signal-to-noise ratio, whereas slow-speed CW contacts can be made with a 0-dB signal-to-noise ratio. Slow-scan television and packet communication has been attempted between some of the larger stations. Success has been limited because of the greater signal-to-noise ratios required for these modes, and severe signal distortion from libration fading.

## Radio Direction Finding

Far more than simply finding the direction of an incoming radio signal, radio direction finding (RDF) encompasses a variety of techniques for determining the exact location of a signal source. The process involves both art and science. RDF adds fun to ham radio, but has serious purposes, too.

This section was written by Joe Moell, K0OV.

RDF is almost as old as radio communication. It gained prominence when the British Navy used it to track the movement of enemy ships in World War I. Since then, governments and the military have developed sophisticated and complex RDF systems. Fortunately, simple equipment, purchased or built at home, is quite effective in Amateur Radio RDF.

In European and Asian countries, direction finding contests are foot races. The object is to be first to find four or five transmitters in a large wooded park. Young athletes have the best chance of capturing the prizes. This sport is known as *foxhunting* (after the British hill-and-dale horseback events) or *ARDF* (Amateur Radio direction finding).

In North America and England, most RDF contests involve mobiles—cars, trucks, vans, even motorcycles. It may be possible to drive all the way to the transmitter, or there may be a short hike at the

end, called a *sniff*. These competitions are also called foxhunting by some, while others use *bunny hunting*, *T-hunting* or the classic term *hidden transmitter hunting*.

In the 1950s, 3.5 and 28 MHz were the most popular bands for hidden transmitter hunts. Today, most competitive hunts worldwide are for 144-MHz FM signals, though other VHF bands are also used. Some international foxhunts include 3.5-MHz events.

Even without participating in RDF contests, you will find a knowledge of the techniques useful. They simplify the search for a neighborhood source of power-line interference or TV cable leakage. RDF must be used to track down emergency radio beacons, which signal the location of pilots and boaters in distress. Amateur Radio enthusiasts skilled in transmitter hunting are in demand by agencies such as the Civil Air Patrol and the US Coast Guard Auxiliary for search and rescue support.

The FCC's Field Operations Bureau has created an Amateur Auxiliary, administered by the ARRL Section Managers, to deal with interference matters. In many areas of the country, there are standing agreements between Local Interference Committees and district FCC offices, permitting volunteers to provide evidence leading to prosecution in serious cases of

malicious amateur-to-amateur interference. RDF is an important part of the evidence-gathering process.

The most basic RDF system consists of a directional antenna and a method of detecting and measuring the level of the radio signal, such as a receiver with signal strength indicator. RDF antennas range from a simple tuned loop of wire to an acre of antenna elements with an electronic beam-forming network. Other sophisticated techniques for RDF use the Doppler effect, or measure the time of arrival difference of the signal at multiple antennas.

All of these methods have been used from 2 to 500 MHz and above. However, RDF practices vary greatly between the HF and VHF/UHF portions of the spectrum. For practical reasons, high gain beams, Dopplers and switched dual antennas find favor on VHF/UHF, while loops and phased arrays are the most popular choices on 6 m and below. Signal propagation differences between HF and VHF also affect RDF practices. But many basic transmitter hunting techniques, discussed later in this chapter, apply to all bands and all types of portable RDF equipment.

### RDF ANTENNAS FOR HF BANDS

Below 50 MHz, gain antennas such as Yagis and quads are of limited value for RDF. The typical installation of a

tribander on a 70-ft tower yields only a general direction of the incoming signal, due to ground effects and the antenna's broad forward lobe. Long monoband beams at greater heights work better, but still cannot achieve the bearing accuracy and repeatability of simpler antennas designed specifically for RDF.

## RDF Loops

An effective directional HF antenna can be as uncomplicated as a small loop of wire or tubing, tuned to resonance with a capacitor. When immersed in an electromagnetic field, the loop acts much the same as the secondary winding of a transformer. The voltage at the output is proportional to the amount of flux passing through it and the number of turns. If the loop is oriented such that the greatest amount of area is presented to the magnetic field, the induced voltage will be the highest. If it is rotated so that little or no area is cut by the field lines, the voltage induced in the loop is zero and a null occurs.

To achieve this transformer effect, the loop must be small compared with the signal wavelength. In a single-turn loop, the conductor should be less than  $0.08\lambda$  long. For example, a 28-MHz loop should be less than 34 inches in circumference, giving a diameter of approximately 10 inches. The loop may be smaller, but that will reduce its voltage output. Maximum output from a small loop antenna is in directions corresponding to the plane of the loop; these lobes are very broad. Sharp nulls, obtained at right angles to that plane, are more useful for RDF.

For a perfect bidirectional pattern, the loop must be balanced electrostatically with respect to ground. Otherwise, it will exhibit

two modes of operation, the mode of a perfect loop and that of a nondirectional vertical antenna of small dimensions. This dual-mode condition results in mild to severe inaccuracy, depending on the degree of imbalance, because the outputs of the two modes are not in phase.

The theoretical true loop pattern is illustrated in Fig 23.70A. When properly balanced, there are two nulls exactly  $180^\circ$  apart. When the unwanted antenna effect is appreciable and the loop is tuned to resonance, the loop may exhibit little directivity, as shown in Fig 23.70B. By detuning the loop to shift the phasing, you may obtain a useful pattern similar to Fig 23.70C. While not symmetrical, and not necessarily at right angles to the plane of the loop, this pattern does exhibit a pair of nulls.

By careful detuning and amplitude balancing, you can approach the unidirectional pattern of Fig 23.70D. Even though there may not be a complete null in the pattern, it resolves the  $180^\circ$  ambiguity of Fig 23.70A. Korean War era military loop antennas, sometimes available on today's surplus market, use this controlled-antenna-effect principle.

An easy way to achieve good electrostatic balance is to shield the loop, as shown in Fig 23.71. The shield, represented by the dashed lines in the drawing, eliminates the antenna effect. The response of a well-constructed shielded loop is quite close to the ideal pattern of Fig 23.70A.

For 160 through 30 m, single-turn loops that are small enough for portability are usually unsatisfactory for RDF work. Multiturn loops are generally used instead. They are easier to resonate with practical capacitor values and give higher output voltages. This type of loop may also be

shielded. If the total conductor length remains below  $0.08\lambda$ , the directional pattern is that of Fig 23.70A.

## Ferrite Rod Antennas

Another way to get higher loop output is to increase the permeability of the medium in the vicinity of the loop. By winding a coil of wire around a form made of high-permeability material, such as ferrite rod, much greater flux is obtained in the coil without increasing the cross-sectional area.

Modern magnetic core materials make compact directional receiving antennas practical. Most portable AM broadcast receivers use this type of antenna, commonly called a *loopstick*. The loopstick is the most popular RDF antenna for portable/mobile work on 160 and 80 m.

As does the shielded loop discussed earlier, the loopstick responds to the magnetic field of the incoming radio wave, and not to the electrical field. For a given size of loop, the output voltage increases with increasing flux density, which is obtained by choosing a ferrite core of high permeability and low loss at the frequency of interest. For increased output, the turns may be wound over two rods taped together. A practical loopstick antenna is described later in this chapter.

A loop on a ferrite core has maximum signal response in the plane of the turns, just as an air core loop. This means that maximum response of a loopstick is broadside to the axis of the rod, as shown in Fig 23.72. The loopstick may be shielded to

**Fig 23.70 — Small loop field patterns with varying amounts of antenna effect — the undesired response of a loop acting merely as a mass of metal connected to the receiver antenna terminals. The horizontal lines show the plane of the loop turns.**

**Fig 23.71 — Electrostatically shielded loop for RDF. To prevent shielding of the loop from magnetic fields, leave the shield unconnected at one end.**

**Fig 23.72 — Field pattern for a ferrite rod antenna. The dark bar represents the rod on which the loop turns are wound.**

eliminate the antenna effect; a U-shaped or C-shaped channel of aluminum or other form of "trough" is best. The shield must not be closed, and its length should equal or slightly exceed the length of the rod.

### Sense Antennas

Because there are two nulls  $180^\circ$  apart in the directional pattern of a small loop or loopstick, there is ambiguity as to which null indicates the true direction of the target station. For example, if the line of bearing runs east and west from your position, you have no way of knowing from this single bearing whether the transmitter is east of you or west of you.

If bearings can be taken from two or more positions at suitable direction and distance from the transmitter, the ambiguity can be resolved and distance can be estimated by triangulation, as discussed later in this chapter. However, it is almost always desirable to be able to resolve the ambiguity immediately by having a unidirectional antenna pattern available.

You can modify a loop or loopstick antenna pattern to have a single null by adding a second antenna element. This element is called a sense antenna, because it senses the phase of the signal wavefront for comparison with the phase of the loop output signal. The sense element must be omnidirectional, such as a short vertical. When signals from the loop and the sense antenna are combined with  $90^\circ$  phase shift between the two, a heart-shaped (cardioid) pattern results, as shown in Fig 23.73A.

Fig 23.73B shows a circuit for adding a sense antenna to a loop or loopstick. For the best null in the composite pattern, signals from the loop and sense antennas must be of equal amplitude. R1 adjusts the level of the signal from the sense antenna.

In a practical system, the cardioid pattern null is not as sharp as the bidirectional null of the loop alone. The usual procedure when transmitter hunting is to use the loop alone to obtain a precise line of bearing, then switch in the sense antenna and take another reading to resolve the ambiguity.

### Phased Arrays and Adcocks

Two-element phased arrays are popular for amateur HF RDF base station installations. Many directional patterns are possible, depending on the spacing and phasing of the elements. A useful example is two  $\frac{1}{2}\lambda$  elements spaced  $\frac{1}{4}\lambda$  apart and fed  $90^\circ$  out of phase. The resultant pattern is a cardioid, with a null off one end of the axis of the two antennas and a broad peak in the opposite direction. The directional frequency range of this antenna is limited to one band, because of the critical length

of the phasing lines.

The best-known phased array for RDF is the Adcock, named after the man who invented it in 1919. It consists of two vertical elements fed  $180^\circ$  apart, mounted so the array may be rotated. Element spacing is not critical, and may be in the range from  $\frac{1}{10}$  to  $\frac{3}{4}\lambda$ . The two elements must be of identical lengths, but need not be self-resonant; shorter elements are commonly used. Because neither the element spacing nor length is critical in terms of wavelengths, an Adcock array may operate over more than one amateur band.

Fig 23.74 is a schematic of a typical Adcock configuration, called the H-Adcock because of its shape. Response to a vertically polarized wave is very similar to a conventional loop. The passing wave induces currents  $I_1$  and  $I_2$  into the vertical members. The output current in the transmission line is equal to their difference. Consequently, the directional pattern has two broad peaks and two sharp nulls, like the loop. The magnitude of the difference current is proportional to the spacing ( $d$ ) and length ( $l$ ) of the elements. You will get somewhat higher gain with larger dimen-

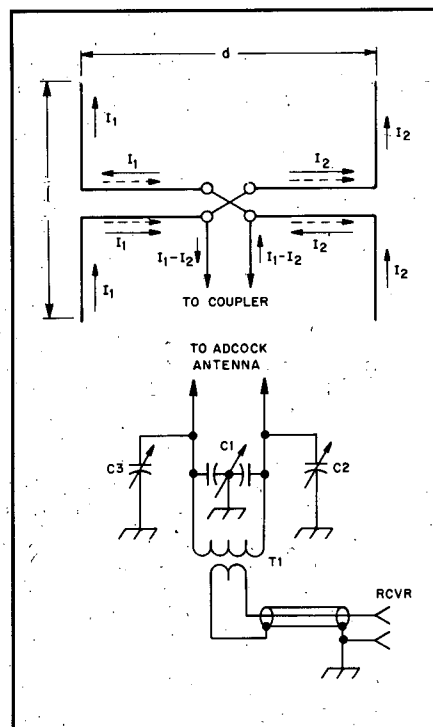

Fig 23.74 — A simple Adcock antenna and its coupler.

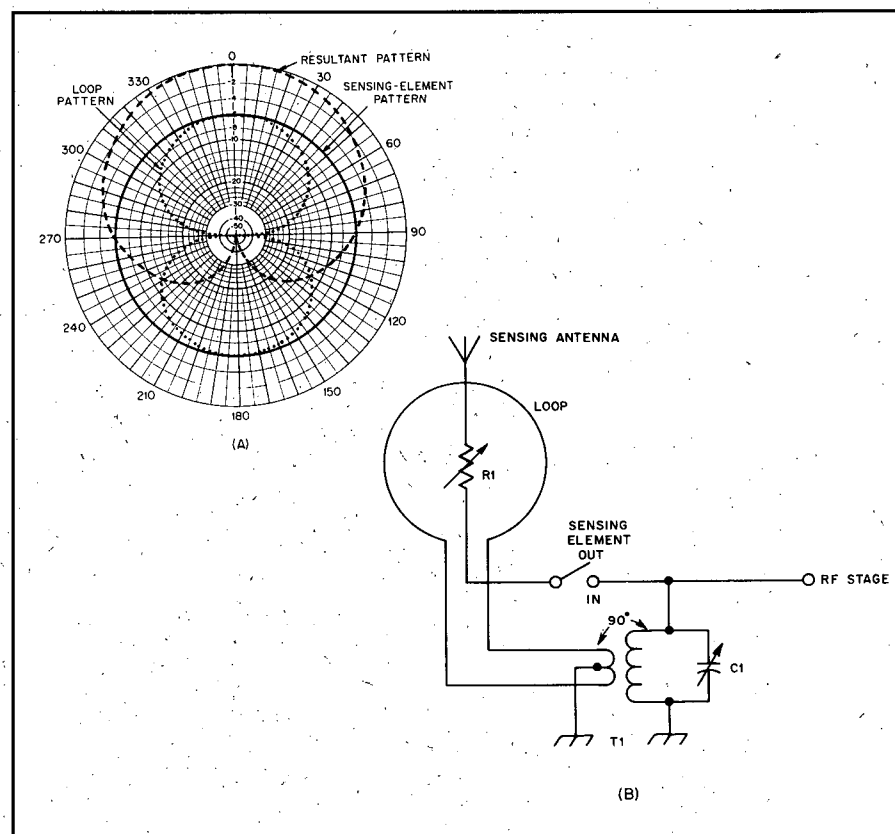

Fig 23.73 — At A, the directivity pattern of a loop antenna with sensing element. At B is a circuit for combining the signals from the two elements. Adjust C1 for resonance with T1 at the operating frequency.

sions. The Adcock of **Fig 23.75**, designed for 40 m, has element lengths of 12 ft and spacing of 21 ft (approximately  $0.15 \lambda$ ).

**Fig 23.76** shows the radiation pattern of the Adcock. The nulls are broadside to the axis of the array, becoming sharper with increased element spacings. When element spacing exceeds  $\frac{3}{4} \lambda$ , however, the antenna begins to take on additional unwanted nulls off the ends of the array axis.

The Adcock is a vertically polarized antenna. The vertical elements do not respond to horizontally polarized waves, and the currents induced in the horizontal members by a horizontally polarized wave (dotted arrows in **Fig 23.74**) tend to balance out regardless of the orientation of the antenna.

**Fig 23.75** — An experimental Adcock antenna on a wooden frame.

**Fig 23.76** — The pattern of an Adcock array with element spacing of  $\frac{1}{2}$  wavelength. The elements are aligned with the vertical axis.

Since the Adcock uses a balanced feed system, a coupler is required to match the unbalanced input of the receiver. T1 is an air-wound coil with a two-turn link wrapped around the middle. The combination is resonated with C1 to the operating frequency. C2 and C3 are null-clearing capacitors. Adjust them by placing a low-power signal source some distance from the antenna and exactly broadside to it. Adjust C2 and C3 until the deepest null is obtained.

While you can use a metal support for the mast and boom, wood is preferable because of its nonconducting properties. Similarly, a mast of thick-wall PVC pipe gives less distortion of the antenna pattern than a metallic mast. Place the coupler on the ground below the wiring harness junction on the boom and connect it with a short length of 300- $\Omega$  twin-lead feed line.

### Loops vs Phased Arrays

Loops are much smaller than phased arrays for the same frequency, and are thus the obvious choice for portable/mobile HF RDF. For base stations in a triangulation network, where the  $180^\circ$  ambiguity is not a problem, Adcocks are preferred. In general, they give sharper nulls than loops, but this is in part a function of the care used in constructing and feeding the individual antennas, as well as of the spacing of the elements. The primary construction considerations are the shielding and balancing of the feed line against unwanted signal pickup and the balancing of the antenna for a symmetrical pattern. Users report that Adcocks are somewhat less sensitive to proximity effects, probably because their larger aperture offers some space diversity.

### Skywave Considerations

Until now we have considered the directional characteristics of the RDF loop only in the two-dimensional azimuthal plane. In three-dimensional space, the response of a vertically oriented small loop is doughnut-shaped. The bidirectional null (analogous to a line through the doughnut hole) is in the line of bearing in the azimuthal plane and toward the horizon in the vertical plane. Therefore, maximum null depth is achieved only on signals arriving at  $0^\circ$  elevation angle.

Skywave signals usually arrive at non-zero wave angles. As the elevation angle increases, the null in a vertically oriented loop pattern becomes more shallow. It is possible to tilt the loop to seek the null in elevation as well as azimuth. Some amateur RDF enthusiasts report success at estimating distance to the target by measurement of the elevation angle with a tilted loop and computations based on estimated

height of the propagating ionospheric layer. This method seldom provides high accuracy with simple loops, however.

Most users prefer Adcocks to loops for skywave work, because the Adcock null is present at all elevation angles. Note, however, that an Adcock has a null in all directions from signals arriving from overhead. Thus for very high angles, such as under-250-mile skip on 80 and 40 m, neither loops nor Adcocks will perform well.

### Electronic Antenna Rotation

State-of-the-art fixed RDF stations for government and military work use antenna arrays of stationary elements, rather than mechanically rotatable arrays. The best known type is the Wullenweber antenna. It has a large number of elements arranged in a circle, usually outside of a circular reflecting screen. Depending on the installation, the circle may be anywhere from a few hundred feet to more than a quarter of a mile in diameter. Although the Wullenweber is not practical for most amateurs, some of the techniques it uses may be applied to amateur RDF.

The device which permits rotating the antenna beam without moving the elements has the classic name *radiogoniometer*, or simply *goniometer*. Early goniometers were RF transformers with fixed coils connected to the array elements and a moving pickup coil connected to the receiver input. Both amplitude and phase of the signal coupled into the pickup winding are altered with coil rotation in a way that corresponded to actually rotating the array itself. With sufficient elements and a goniometer, accurate RDF measurements can be taken in all compass directions.

### Beam Forming Networks

By properly sampling and combining signals from individual elements in a large array, an antenna beam is electronically rotated or steered. With an appropriate number and arrangement of elements in the system, it is possible to form almost any desired antenna pattern by summing the sampled signals in appropriate amplitude and phase relationships. Delay networks and/or attenuation are added in line with selected elements before summation to create these relationships.

To understand electronic beam forming, first consider just two elements, shown as A and B in **Fig 23.77**. Also shown is the wavefront of a radio signal arriving from a distant transmitter. The wavefront strikes element A first, then travels somewhat farther before it strikes element B. Thus, there is an interval between the times that the wavefront reaches elements A and B.

We can measure the differences in ar-

**Fig 23.77** — One technique used in electronic beam forming. By delaying the signal from element A by an amount equal to the propagation delay, two signals are summed precisely in phase, even though the signal is not in the broadside direction.

rival times by delaying the signal received at element A before summing it with that from element B. If two signals are combined directly, the amplitude of the sum will be maximum when the delay for element A exactly equals the propagation delay, giving an in-phase condition at the summation point. On the other hand, if one of the signals is inverted and the two are added, the signals will combine in a 180° out-of-phase relationship when the element A delay equals the propagation delay, creating a null. Either way, once the time delay is determined by the amount of delay required for a peak or null, we can convert it to distance. Then trigonometry calculations provide the direction from which the wave is arriving.

Altering the delay in small increments steers the peak (or null) of the antenna. The system is not frequency sensitive, other than the frequency range limitations of the array elements. Lumped-constant networks are suitable for delay elements if the system is used only for receiving. Delay lines at installations used for transmitting and receiving employ rolls of coaxial cable of various lengths, chosen for the time delay they provide at all frequencies, rather than as simple phasing lines designed for a single frequency.

Combining signals from additional elements narrows the broad beamwidth of the pattern from the two elements and suppress unwanted sidelobes. Electronically switching the delays and attenuations to the various elements causes the formed beam to rotate around the compass. The package of electronics that does this, including delay lines and electronically switched attenuators, is the beam forming network.

## METHODS FOR VHF/UHF RDF

Three distinct methods of mobile RDF are commonly in use by amateurs on VHF/UHF bands: directional antennas, switched dual antennas and Dopplers.

Each has advantages over the others in certain situations. Many RDF enthusiasts employ more than one method when transmitter hunting.

## Directional Antennas

Ordinary mobile transceivers and handhelds work well for foxhunting on the popular VHF bands. If you have a lightweight beam and your receiver has an easy-to-read S-meter, you are nearly ready to start. All you need is an RF attenuator and some way to mount the setup in your vehicle.

Amateurs seldom use fractional wavelength loops for RDF above 60 MHz because they have bidirectional characteristics and low sensitivity, compared to other practical VHF antennas. Sense circuits for loops are difficult to implement at VHF, and signal reflections tend to fill in the nulls. Typically VHF loops are used only for close-in sniffing where their compactness and sharp nulls are assets, and low gain is of no consequence.

## Phased Arrays

The small size and simplicity of 2-element driven arrays make them a common choice of newcomers at VHF RDF. Antennas such as phased ground planes and ZL Specials have modest gain in one direction and a null in the opposite direction. The gain is helpful when the signal is weak, but the broad response peak makes it difficult to take a precise bearing.

As the signal gets stronger, it becomes possible to use the null for a sharper S-meter indication. However, combinations of direct and reflected signals (called *multipath*) will distort the null or perhaps obscure it completely. For best results with this type of antenna, always find clear locations from which to take bearings.

## Parasitic Arrays

Parasitic arrays are the most common RDF antennas used by transmitter hunters in high competition areas such as Southern California. Antennas with significant gain are a necessity due to the weak signals often encountered on weekend-long T-hunts, where the transmitter may be over 200 miles distant. Typical 144-MHz installations feature Yagis or quads of three to six elements, sometimes more. Quads are typically home-built, using data from *The ARRL Antenna Book* and *Transmitter Hunting* (see Bibliography).

Two types of mechanical construction are popular for mobile VHF quads. The model of Fig 23.78 uses thin gauge wire (solid or stranded), suspended on wood dowel or fiberglass rod spreaders. It is lightweight and easy to turn rapidly by

hand while the vehicle moves. Many hunters prefer to use larger gauge solid wire (such as AWG 10) on a PVC plastic pipe frame (Fig 23.79). This quad is more rugged and has somewhat wider frequency

**Fig 23.78** — The mobile RDF installation of WB6ADC features a thin wire quad for 144 MHz and a mechanical linkage that permits either the driver or front passenger to rotate the mast by hand.
